70. What's Wrong with cos? Observation of the oscillation of a mass on the end of a spring reveals that the detailed structure of the position as a function of time is fit very well by a function of the form

$$x(t) = X \cos(\omega t + \phi_0).$$

Yet subsequent observations give convincing evidence that this cannot be a good representation of the motion for long time periods. Explain what observation leads to this conclusion and resolve the apparent contradiction.

71. Where Is the Energy? A block of mass m is attached to a spring of spring constant k that is attached to a wall as shown in Fig. 16-49. (a) If the block starts at time $t = 0$ with the spring being at its rest length but the block having a velocity v_1 , find a solution for the mass's position at all subsequent times. Make any assumptions you like in order to have a plausible but solvable model, but state your assumptions explicitly. (b) Are the energies at the times

FIGURE 16-49 ■ Problem 71.

$$t = 0, \quad t = \frac{\pi}{2} \sqrt{\frac{m}{k}}, \quad t = 2\pi \sqrt{\frac{m}{k}}$$

kinetic, potential, or a mixture of the two? (This is *not* a short-answer question. Show how you know.)

72. Damped Oscillator A class looked at the oscillation of a mass on a spring. They observed for 10 seconds and found its oscillation was well fit by assuming that the mass's motion was governed by Newton's Second Law with the spring force $F_x^{\text{spring}} = -k\Delta x$, where Δx represents the stretch or squeeze of the spring and k is the spring constant. However, it was also clear that this was not an adequate representation for times on the order of 10 minutes, since by that time the mass had stopped oscillating. (a) Suppose the mass was started at an initial position x_1 with a velocity 0. Write down the solution, $x(t)$ and $v_x(t)$, for the equations of motion of the mass using only the spring force. What is the total energy of the oscillating mass? (b) Assume that there is also a velocity-dependent force (the *damping* force) that the spring exerts on an object when it is moving. Let's make the simplest assumption that the dynamic-spring force is linear in the velocity, $F_x^{\text{spring-dyn}} = -\gamma v_x$. Assume further that over one period of oscillation the velocity-dependent piece is small. Therefore, take $x(t)$ and $v_x(t)$ to be given by the oscillation without

damping. Calculate the work done by the damping force over one period in terms of the parameters k , m , and γ and the fraction of the energy lost in one period. (c) The mass used was 1 kg. From the description of the experiment, estimate the spring constant and the number of periods it took to lose half the energy. Use this and your result from (a) to estimate the approximate size of the damping constant γ .

73. Catching a Pellet and Oscillating

The following problem is a standard problem found in this text (and in many others). A block of mass M is at rest on a horizontal frictionless table.

It is attached to a rigid support by a spring of constant k . A clay pellet having mass m and velocity v strikes the block as shown in the figure and sticks to it.

FIGURE 16-50 ■

Problem 73.

(a) Determine the velocity of the block immediately after the collision. (b) Determine the amplitude of the resulting simple harmonic motion. In order to solve this problem you must make a number of simplifying assumption; some are stated in the problem and some are not. First, solve the problem as stated. (c) Discuss the approximations you had to make in order to solve the problem. (There are at least five.)

74. Bungee Jump As part of an open house, a physics department sets up a bungee jump from the top of a crane. See Fig. 16-51. Assume that one end of an elastic band will be firmly attached to the top of the crane and the other to the waist of a courageous participant. The participant will step off the edge of the crane house to be slowed and brought back up by the elastic band before hitting the

ground. Assume the elastic band behaves like a Hooke's law spring. Estimate the length and spring constant of the elastic you would recommend be used.

17

Transverse Mechanical Waves

When a beetle moves along the sand within a few tens of centimeters of this sand scorpion, the scorpion immediately turns toward the beetle and dashes to it (for lunch). The scorpion can do this without seeing (it is nocturnal) or hearing the beetle.

How can the scorpion so precisely locate its prey?

The answer is in this chapter.

17-1 Waves and Particles

Two ways to get in touch with a friend in a distant city are to write a letter and to use the telephone.

The first choice (the letter) involves the concept of “particles”: A material object moves from one point to another, carrying information with it. Most of the preceding chapters deal with particles or with systems of particles.

The second choice (the telephone) involves the concept of “waves,” the subject of this chapter and the next. In your telephone call, a sound wave carries your message from your vocal cords to the telephone. There, an electromagnetic wave takes over, passing along a copper wire or an optical fiber or through the atmosphere, possibly by way of a communications satellite. At the receiving end there is another sound wave, from a telephone to your friend’s ear. Although the message is passed, nothing that you have touched reaches your friend. For example, if you have the flu, she can’t catch it by talking to you on the phone since no matter (and therefore no virus) is passed between the two of you. In a wave, momentum and energy move from one point to another but no material object makes that journey.

Leonardo da Vinci understood waves when he wrote of water waves: “It often happens that the wave flees the place of its creation, while the water does not; like the waves made in a field of grain by the wind, where we see the waves running across the field while the grain remains in place.”

Particles and *waves* are the two important entities described in classical physics. Both entities have positions and velocities associated with them. But there are ways in which these two entities are very different. The word *particle* suggests a tiny concentration of matter capable of transmitting energy and momentum through its movement from one place to another. For example, a baseball is a particle that can transmit the energy and momentum imparted to it by a pitcher to the catcher by moving from one to the other. Alternatively the energy and momentum associated with a *wave* is spread out in space and is transmitted without any matter moving from one place to another. For example, when the pitcher shouts at a catcher, she can disturb the air particles in her vicinity, but the sound wave that transmits her voice depends on a chain of temporary disturbances of the air and not on molecules moving from the pitcher to the catcher.

In this chapter and the next we will put particles aside for a while and learn about mechanical waves and how they travel. Then in Chapters 34, 36, and 37, we will explore the behavior of electromagnetic waves including radio and light waves.

17-2 Types of Waves

Waves are of three main types:

1. **Mechanical waves.** These waves are most familiar because we encounter them almost constantly; common examples include water waves, sound waves, and seismic waves. All these waves have certain central features: They are governed by Newton’s laws, and they can only move through a material medium, such as water, air, and rock.
2. **Electromagnetic waves.** These waves are less familiar, but you use them constantly; common examples include visible and ultraviolet light, radio and television waves, microwaves, x-rays, and radar waves. These waves can transmit energy and momentum without a material medium. Light waves from stars, for example, travel through the vacuum of space to reach us. Electromagnetic waves are treated in Chapters 32, 34, 36 and 37.

3. **Matter waves.** Although these waves are commonly used in modern technology, they are probably very unfamiliar to you. These waves are associated with electrons, protons, and other fundamental particles, and even atoms and molecules. Because we commonly think of these things as constituting matter, such waves are called matter waves. Their behavior is described by the laws of quantum mechanics.

Much of what we discuss in this chapter applies to waves of all kinds. However, for specific examples we shall refer to mechanical waves because they are the simplest and most familiar. In this chapter we consider how to best describe ideal mechanical waves mathematically. An **ideal** mechanical wave does not lose mechanical energy or change its shape as it travels through a medium.

17-3 Pulses and Waves

Consider Figure 17-1, which shows a “Slinky wave demonstrator” consisting of a very long Slinky that hangs from long, evenly spaced strings. If we give a quick pull outward (to the left) on the left end of the Slinky and then give it a quick push back inward (to the right), a compression-expansion disturbance like that shown in Fig. 17-1 will propagate along the length of the Slinky. (You need to look carefully at Fig. 17-1, rather than Fig. 17-2, to see the effect). Since the back-and-forth oscillations of the Slinky coils are parallel to the direction in which the disturbance travels, the motion is said to be **longitudinal**.

FIGURE 17-1 ■ A large Slinky demonstrator hanging from long, evenly spaced strings. Note the compression disturbance moving from left to right near the second and third strings with an expansion just behind it.

On the other hand, if we give the end of the Slinky a quick jerk back and forth (into and out of the page) at right angles to the line of the Slinky, a disturbance like that shown in Fig. 17-2 results and moves down the length of the Slinky. In this case, the displacement of the coils in the Slinky is *perpendicular* to the direction in which the disturbance travels (i.e., along the length of the Slinky). Such a disturbance is called **transverse**.

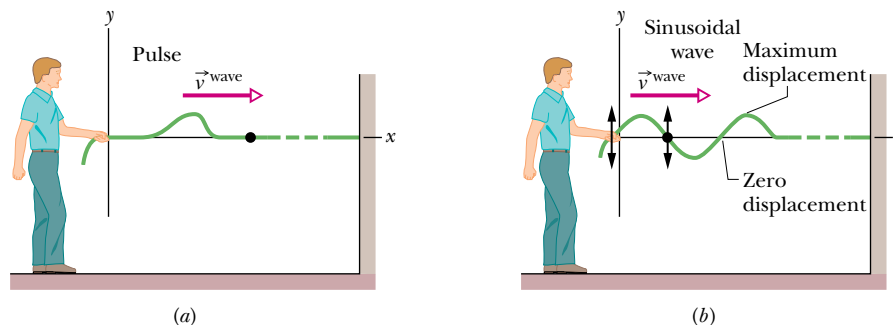

FIGURE 17-2 ■ A transverse or sideways disturbance or pulse moving from left to right along a Slinky wave demonstrator. In this case the viewer is lying on the floor underneath the Slinky looking up at time $t = t_1$.

In both cases discussed above, the singular disturbance is referred to as a **wave pulse** or **short wave**. If we repeat the motion that causes the disturbance (either the back-forth jerk or the push-pull motion) at regular time intervals, the result is a traveling and repeating disturbance that is referred to as a **continuous wave**. Just as with single pulses, waves can be longitudinal or transverse.

For example, if you give one end of a stretched string a single up-and-down jerk, a single *pulse* travels along the string as in Fig. 17-3a. This pulse and its motion can occur because the string is under tension. During the upward part of the jerk, when you pull your end of the string upward, it begins to pull upward on the

FIGURE 17-3 (a) A single pulse travels along a stretched string. A typical string piece (marked with a dot) moves up and back only once as the pulse passes. Since the string piece's displacement is perpendicular to the wave direction, the pulse is called a *transverse wave*. (b) A continuous sinusoidal displacement at the left end also causes the piece of string to move up and down in a transverse direction except now the wave is continuous.

adjacent section of the string via tension between the two sections. As the adjacent section moves upward, it begins to pull the next section upward, and so on. Meanwhile, suppose that you have now pulled down on your end of the string, completing the up-down stroke. As each section is moving upward in turn, it begins to be pulled back downward by neighboring sections that are already on the way down. The net result is that a distortion in the string's shape (the pulse) moves along the string at some velocity \vec{v}^{wave} . Note that although the disturbance moves down the string to the right, the parts of the string itself just move up and down. This is an extremely important, but subtle, point regarding pulses and waves. The wave or pulse travels, but the particles that make up the medium (string or otherwise) do not.

Sinusoidal Transverse Waves

If, instead of a single up-down stroke, you move your hand up and down repeatedly with simple harmonic motion as in Fig. 17-3b, a continuous *wave* travels along the string with a wave velocity denoted by $\vec{v}^{\text{wave}} = v_x^{\text{wave}} \hat{i}$. The vertical displacement of the string is perpendicular to the direction that the wave propagates (along the string), and so this wave is called a **transverse wave**. The larger the vertical displacement of your hand during the up-down stroke, the higher the peak and the lower the valley of the wave will be. This characteristic, measured as the magnitude of the maximum displacement of a small bit of string from its equilibrium position as the wave passes through it, is called the **amplitude** Y of the wave. This definition of amplitude is very similar to the one developed in the last chapter in regard to oscillations.

If we take a photograph of a transverse wave (perhaps the wave in the string of Fig. 17-3b) at some time $t = t_1$, we can see the wave shape and try to find a mathematical function that describes that shape or **wave form**. For example, if the motion of your hand is a sinusoidal function of time, the wave has a sinusoidal shape at any given instant, as in Fig. 17-3b. That is, the wave has the shape of a continuously repeating sine curve or cosine curve. (We consider here only an “undamped” string, in which no friction-like forces within the string cause the wave to die out as it travels along. In addition, we assume that the string is so long that we need not consider a wave rebounding from the far end and that the wave amplitude is small.)

The wave in Fig. 17-3b travels along a single line, so we call it a one-dimensional wave. For example, sound waves traveling in a pipe can only move in one dimension (but they can travel in two or three dimensions in other circumstances). For the wave in Fig. 17-3b, or any other one-dimensional wave or pulse, the convention is to define the line of travel as the x axis. As we can see from Fig. 17-3b, the vertical displacement of a bit of string at a given time depends on how far down along the string we make the measurement. Hence, we say that the vertical displacement of the string is a function of the horizontal position, x . The distance (in this example the horizontal distance) the wave travels in one cycle (for example, the peak-to-peak or valley-to-valley distance) is defined as the **wavelength** λ .

How a Sand Scorpion Catches Its Prey

The sand scorpion shown in the photograph opening this chapter uses waves of both transverse and longitudinal motion to locate its prey. When a beetle even slightly disturbs the sand, it sends pulses along the sand's surface (Fig. 17-4). One set of pulses is longitudinal, traveling with speed $|\vec{v}^{\text{L-wave}}| = v^{\text{L-wave}} = 150 \text{ m/s}$. A second set is transverse, traveling with speed $|\vec{v}^{\text{T-wave}}| = v^{\text{T-wave}} = 50 \text{ m/s}$.

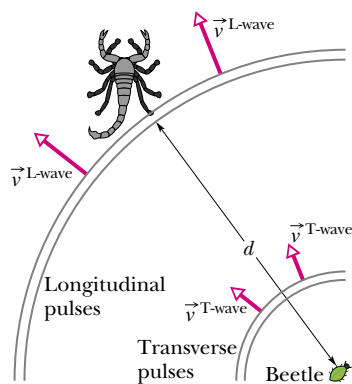

FIGURE 17-4 ■ A beetle's motion sends fast longitudinal pulses and slower transverse pulses along the sand's surface. The sand scorpion first intercepts the longitudinal pulses; here, it is the rear-most right leg that senses the pulses earliest.

The scorpion, with its eight legs spread roughly in a circle about 5 cm in diameter, intercepts the faster longitudinal pulses first and learns the direction of the beetle; it is in the direction of whichever leg is disturbed earliest by the pulses. The scorpion then senses the time interval Δt between that first interception and the interception of the slower transverse waves and uses it to determine the distance d to the beetle. The time interval is given by

$$\Delta t = \frac{d}{v^{\text{T-wave}}} - \frac{d}{v^{\text{L-wave}}}.$$

Solving for the distance gives us

$$d = (75 \text{ m/s}) \Delta t.$$

For example, if $\Delta t = 4.0 \text{ ms}$, then $d = 30 \text{ cm}$, which gives the scorpion a perfect fix on the beetle.

Of course, the scorpion no more does these calculations in its head as it hunts a beetle than you do a conscious recalculation of the location of your center of mass as you decide in what way to throw out your arms when you slip. Instead, instinct and habits based on successful personal experiences rule the scorpion (and you) in such situations. But there is physics behind such “instincts”—they are not arbitrarily successful.

Waves and Oscillations

As we discussed above, if we take a picture of a wave, we can freeze the wave in time and investigate the spatial characteristics of the wave, like the wave's amplitude and its length. Alternatively, we could pick a special place, x_p , along the wave and peek at it through a slit, as in Fig. 17-5. As we peek through the slit, we would see the bits of string or Slinky rise and fall as the wave travels through space. If we made measurements while peeking, we could plot the displacement as a function of time for this location $x = x_p$. Doing so allows us to focus in on the characteristics of the wave that are associated with the passage of time. When we do this, we see several aspects of a wave that remind us of the oscillations we learned about in the last chapter.

FIGURE 17-5 ■ A transverse wave traveling along a hanging Slinky as seen from the perspective of someone looking up through a slit while lying on the floor. The x axis is horizontal and chosen to be along the axis of the Slinky. The y axis is also in the horizontal plane but it lies along the direction of transverse displacement of Slinky coils. The viewer watches displacement y from the Slinky's equilibrium point as a function of time at a fixed position x_p .

FIGURE 17-6 ■ Five “snapshots” of a traveling string wave taken at times 0 , $\frac{1}{4}T$, $\frac{1}{2}T$, $\frac{3}{4}T$, and T , where T is the period of oscillation of a fixed piece of string. A particular bit of string (the piece around $x = 0$) has been boxed so you can see how it moves back and forth as the continuous wave disturbance travels horizontally to the right along the string. The amplitude Y is indicated. A wavelength λ is also indicated. The circle in each snapshot shows the location of the wave crest as it moves from left to right.

For example, let us examine the small piece of string boxed in Fig. 17-6. This figure shows five “snapshots” of a sinusoidal wave traveling in the positive direction of an x axis. The time between snapshots is constant. The movement of the wave is indicated by the rightward progress of the short arrow pointing to a high point of the wave. From snapshot to snapshot, the short arrow moves to the right with the wave shape, but the pieces of the string move *only* parallel to the y axis. Let us follow the motion of the boxed string segment at $x = 0$. In the first snapshot (Fig. 17-6a), it is at displacement $y = 0$. In the next snapshot, it is at its extreme downward displacement because a *valley* (or extreme low point) of the wave is passing through it. It then moves back up through $y = 0$. In the fourth snapshot, it is at its extreme upward displacement because a *peak* (or extreme high point) of the wave is passing through it. In the fifth snapshot, it is again at $y = 0$, having completed one full oscillation. Notice that the wave in Fig. 17-6 moves to the right by $\frac{1}{4}\lambda$ from one snapshot to the next. Thus, by the fifth snapshot, it has moved to the right by 1λ . The time required for the cycle of rising and falling to repeat is called the **period** T of the wave.

READING EXERCISE 17-1: The figure just below shows an asymmetric pulse traveling from left to right along a stretched string. If this snapshot was taken at time $t = 0$ s: (a) which figure represents the graph of the displacement y versus position x at $t = 0$ s? (b) Which figure represents the graph of the displacement y versus time t at $x = x_1$ (as marked with a dot on the snapshot)?

TOUCHSTONE EXAMPLE 17-1: Propagating Pulse

Consider a pulse propagating along a long stretched string in the x direction as shown in Fig. 17-7. Note that the scale in the y direction has been exaggerated for visibility.

FIGURE 17-7 ■ A pulse propagates along a string in the x direction.

(a) Sketch the shape of the string after the wave pulse has traveled a distance of 10 m to the right. Explain why you sketched the shape you did.

SOLUTION ■ The **Key Idea** here is that the crest of the wave, which was at $x = 0$ m, has moved so that it is now at $x = 10$ m, but the wave shape does not change. This is like the continuous sinusoidal wave shown in Fig. 17-6 that is depicted as moving without shape change. Figure 17-8 shows the sketch.

FIGURE 17-8 ■ The pulse after it has moved a distance of 10 m to the right. The original position of the pulse is the dashed line.

(b) If the wave takes 2.0 s to move the 10 m to the right, what are its velocity and wave speed?

SOLUTION ■ The **Key Idea** is that we assume that the wave shape does not change and that it moves at a constant rate determined by the motion of its crest. If the wave moves to the right 10 m in 2 s, then

$$\vec{v}^{\text{wave}} = v_x^{\text{wave}} \hat{i} = \left(\frac{10 \text{ m}}{2 \text{ s}} \right) \hat{i} = (5 \text{ m/s}) \hat{i}$$

(wave velocity L \rightarrow R movement),

and $v^{\text{wave}} = |\vec{v}^{\text{wave}}| = 5 \text{ m/s}$
(wave speed—or velocity magnitude).

(c) Imagine that a small piece of essentially massless tape is placed on the string at $x = 0$ m when $t = 0$ s. Describe the motion of the tape for the next 2 s.

SOLUTION ■ The **Key Idea** here is that as the wave pulse moves along the piece of string with the tape on it, the piece of tape does not move in the horizontal direction. Only its displacement in the y direction changes. At first the tape is at the location of the wave crest and so is at its maximum value of y . It then moves down toward a zero value of y , slowly at first and then more rapidly. In a little more than a second, the tape comes to rest at $y = 0$. The wave pulse has passed and so the tape remains there.

(d) Suppose the pulse shown in Fig. 17-7 is moving to the left instead. Sketch the shape of the string after the wave pulse has traveled a distance of 5 m to the left. Explain why you sketched the shape you did.

SOLUTION ■ The **Key Idea** here is that the crest of the wave which was at $x = 0$ m, has moved without changing shape so that it is now at $x = -5$ m. Figure 17-9 shows the sketch.

FIGURE 17-9 ■ The pulse after it has moved a distance of 5 m to the left. The original position of the pulse is the dashed line.

(e) If the wave takes 1 s to move the 5 m to the left, what are its velocity and wave speed?

SOLUTION ■ Once again we assume that the wave shape does not change and that it moves at a constant rate determined by the motion of its crest. If the wave moves 5 m to the left in 1 s, then

$$\vec{v}^{\text{wave}} = v_x^{\text{wave}} \hat{i} = \left(\frac{-5 \text{ m}}{1 \text{ s}} \right) \hat{i} = (-5 \text{ m/s}) \hat{i}$$

(wave velocity R \rightarrow L movement),

and $v^{\text{wave}} = |\vec{v}^{\text{wave}}| = 5 \text{ m/s}$
(wave speed—or velocity magnitude).

17-4 The Mathematical Expression for a Sinusoidal Wave

We found that the disturbance (whether pulse or wave, transverse or longitudinal) depends on both position x and time t . If we call the displacement y , we can write $y = f(x, t)$ or $y(x, t)$ to represent this functional dependence on time and position. In the example of the transverse pulse traveling along a Slinky as pictured in Fig. 17-2,

$y(x,t)$ represents the transverse (vertical) displacement of the Slinky rings from their equilibrium position at given position x and time t . (Alternatively, in the longitudinal wave on the Slinky shown in Fig. 17-1, $y(x,t)$ could represent the number of Slinky coils per centimeter at a given x and t .)

We can completely describe any wave or pulse that does not change shape over time and travels at a constant velocity using the relation $y = f(x,t)$, in which y is the displacement as a function f of the time t and the position x . In general, a wave can have any shape so long as it is not too sharp. The trick then is to find the correct expression for the function, $f(x,t)$.

Fortunately, it turns out that any shape pulse or wave can be constructed by adding up different sinusoidal oscillations. This makes the description of sinusoidal waves especially useful. So, for the rest of this section we'll discuss the properties and descriptions of continuous waves produced by displacing a stretched string using a sinusoidal motion like that shown in Fig. 17-3b. We will start by using the equation we developed in Chapter 16 to describe for sinusoidal motion at the location of a single piece of string. As we did in looking through the slit in Fig. 17-5, we will only let time vary. Next we can consider how to describe a snapshot that records the displacement of many pieces of the string at a single time. Finally, we can combine our snapshot with the results of peeking through a slit to get a single equation that ought to describe the propagation of a single sinusoidal wave. Basically we are trying to describe the displacement y of every piece of the string from its equilibrium point at every time. We are looking for $y(x,t)$.

Looking Through a Slit: Sinusoidal Wave Displacement at $x = 0$

If we choose a coordinate system so that $x = 0$ m at the left end of the string in Fig. 17-3b, then the motion at the left end of the string can be described using Eq. 16-5 with the string displacement from equilibrium represented by $y(x,t) = y(0,t)$ rather than by simply $y(t)$. To simplify our consideration we assume that the initial phase of the string oscillation at $x = 0$ m and $t = 0$ s is zero. This gives us

$$y(0,t) = Y\cos(\omega t), \quad (\text{Eq. 16-5})$$

where the angular frequency can be related to the period of oscillation by $\omega = 2\pi/T$. Although we use the cosine function in Chapter 16 to describe simple harmonic motion, *it is customary to use the sine function to describe wave motion*. As we mentioned in Chapter 16, when a sine function is shifted to the left by $\pi/2$ it looks like a cosine function. So we can also describe the same string displacement as a function of time at $x = 0$ m as

$$y(0,t) = Y\cos(\omega t) = Y\sin(\omega t + \pi/2). \quad (17-1)$$

Note that using the sine function requires a different, nonzero initial phase angle given by $\pi/2$. If we locate our slit at another nonzero value of x as shown in Fig. 17-5, then the initial phase (at $t = 0$ s) will often turn out to be different from $\pi/2$. In fact this initial phase is a function of the location x of the piece of string we are considering.

A Snapshot: Sinusoidal Wave Displacement at $t = 0$

Imagine that the man has been moving the end of the string up and down as shown in Fig. 17-3b for a long time using a sinusoidal motion. Instead of looking through a slit as time varies, we take a snapshot of the string at a time $t = 0$ s similar to that shown in Fig. 17-3b. Then we expect our snapshot to be described by the equation

$$y(x,0) = Y\sin(kx + \pi/2) \quad (17-2)$$

where k is a constant and the “initial” phase when x is zero must also be $\pi/2$. Note that if the snapshot of the string were taken at another time, the initial phase would probably be different.

Combining Expressions for x and t

Equation 17-1 describes the displacement at all times for just the piece of string located at $x = 0$ m. Equation 17-2 describes the displacement of all the pieces of string at $t = 0$ s. We can make an intelligent guess that the equation describing $y(x,t)$ is some combination of these two expressions given by

$$y(x,t) = Y \sin[(kx \pm \omega t) + \pi/2], \quad (17-3)$$

where $\pi/2$ represents the initial phase when $x = 0$ m and $t = 0$ s for the special case we considered. In general we can describe the motion of our sinusoidal wave with an arbitrary initial phase by modifying Eq. 17-3 to get

$$y(x,t) = Y \sin[(kx \pm \omega t) + \phi_0] \quad (\text{sinusoidal wave motion, arbitrary initial phase}), \quad (17-4)$$

where ϕ_0 is the initial phase (or phase constant) when both $x = 0$ m and $t = 0$ s. The \pm sign refers to the direction of motion of the wave as we shall see in Section 17-5. In cases where the initial phase is not important, we can simplify Eq. 17-3 by choosing an initial time and origin of the x axis that lies along the line of motion of the wave so that $\phi_0 = 0$ rad.

Amplitude and Phase

The argument $\phi(x,t) = (kx \pm \omega t) + \phi_0$ of the sine function is called the **time- and space-dependent phase** of the wave where k and ω are constants that we can determine for a particular wave. Although the phase $\phi(x,t)$ is a function of both time and position, it is *neither* a time *nor* a position. Rather, the phase $\phi(x,t)$ *must* be an angle because we can only take the sine of angles.

As the wave sweeps through a string segment at a particular position x , the phase changes linearly with time t . This means that the sine also changes, oscillating between $+1$ and -1 . Its extreme positive value ($+1$) corresponds to a peak of the wave moving through the segment; then, the value of y at position x is Y . Its extreme negative value (-1) corresponds to a valley of the wave moving through the segment; then, the value of y at position x is $-Y$. Thus, the sine function and the time-dependent phase of a wave correspond to the oscillation of a string segment, and the amplitude of the wave determines the extremes of the segment’s displacement.

Wavelength and Wave Number

In order to come up with a more useful mathematical expression for the wave, we must more carefully investigate the nature of the phase of the wave. We know that the sine function repeats itself every 2π radians. We also know that the wavelength λ of a wave is the distance (parallel to the direction of the wave’s travel) between repetitions of the shape of the wave (or *wave form*). A typical wavelength is marked in Fig. 17-6a, which is a snapshot of the wave at time $t = 0$ s. If we take the simple case for which the initial phase is zero, at that time Eq. 17-4, $y(x,t) = Y \sin[(kx \pm \omega t) + \phi_0]$ becomes

$$y(x,0) = Y \sin(kx). \quad (17-5)$$

By definition, the displacement y is the same at both ends of one wavelength—that is, y is the same at $x = x_1$ and at $x = x_1 + \lambda$. (Again, x does not represent a displacement here but just the horizontal position of a string element. By the equation above,

$$\begin{aligned} Y \sin kx_1 &= Y \sin k(x_1 + \lambda) \\ &= Y \sin(kx_1 + k\lambda). \end{aligned} \quad (17-6)$$

A sine function begins to repeat itself when its angle (or argument) is increased by 2π rad, so in the equation above, we must have $k\lambda = 2\pi$, or

$$k = \frac{2\pi}{\lambda} \quad (\text{wave number}). \quad (17-7)$$

We call k the **wave number**. The wave number is inversely proportional to the wavelength. Its SI unit is the radian per meter, or the inverse meter. (Note that the symbol k here does *not* represent a spring constant as previously.)

FIGURE 17-10 ■ A graph with unspecified units of the displacement of the string segment at $x = 0$ as a function of time, as the sinusoidal wave of Fig. 17-6 passes through it. The amplitude Y is indicated. A typical period T , measured from an arbitrary time t_1 , is also indicated.

Period, Angular Frequency, and Frequency

In contrast to the graphs in Fig. 17-6, which represent pictures of the string at a particular instant, we will now focus on a particular bit of string and consider how it moves as a function of time. As we noted earlier, if you were to peek at the string through a slit, you would see that the single segment of the string at that position moves up and down in simple harmonic motion. Figure 17-10 shows a graph of the displacement y of a bit of string versus time t at a certain position along the string, taken to be $x = 0$. This motion is described by $y(x,t) = Y \sin(kx \pm \omega t + \phi_0)$. Setting $x = 0$ and arbitrarily choosing a zero phase constant and a negative time-dependent term, we get

$$y(0,t) = Y \sin(-\omega t) = -Y \sin(\omega t). \quad (17-8)$$

Here we have made use of the fact that $\sin(-\alpha) = -\sin\alpha$. Figure 17-10 is a graph of this equation. Be careful though: This figure *does not* show the shape of the wave. It shows a graph of the time-dependent variation in the displacement of a small bit of the string.

Since we have defined the period of oscillation T of a wave to be the time any string segment takes to move through one full oscillation, we can apply this equation to both ends of this time interval. Equating the results yields

$$\begin{aligned} Y \sin \omega t_1 &= Y \sin \omega(t_1 + T) \\ Y \sin \omega t_1 &= Y \sin(\omega t_1 + \omega T) \end{aligned} \quad (17-9)$$

which can be true only if $\omega T = 2\pi$. In other words,

$$\omega = \frac{2\pi}{T} \quad (\text{angular frequency}). \quad (17-10)$$

We call ω the **angular frequency** of the wave; its SI unit is the radian per second.

Recall from Chapter 16 that the **frequency** f of an oscillation is defined as $1/T$. Hence, its relationship to angular frequency is

$$f = \frac{1}{T} = \frac{\omega}{2\pi} \quad (\text{frequency}). \quad (17-11)$$

Like the frequency of simple harmonic motion in Chapter 16, this frequency f is a number of oscillations per unit time—here, the number made by a string segment as the wave moves through it. As in Chapter 16, f is usually measured in hertz or its multiples, such as kilohertz.

To summarize our discussion of Eq. 17-4 given by $y(x,t) = Y \sin[(kx \pm \omega t) + \phi_0]$, the names of the quantities are displayed in Fig. 17-11 for your reference.

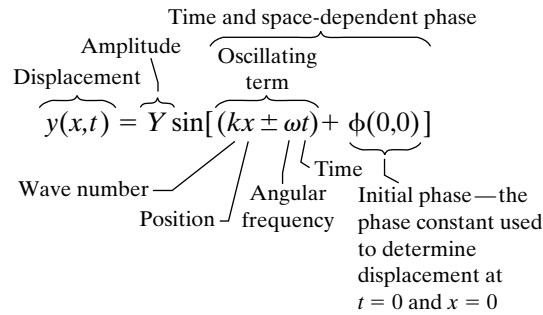

FIGURE 17-11 ■ The names of the quantities in Eq. 17-4, for a transverse sinusoidal wave.

READING EXERCISE 17-2: The figure is a composite of three snapshots, each of a wave traveling along a particular string. The time-dependent phases for the waves are given by (a) $(2 \text{ rad/m})x - (4 \text{ rad/s})t$, (b) $(4 \text{ rad/m})x - (8 \text{ rad/s})t$, and (c) $(8 \text{ rad/m})x - (16 \text{ rad/s})t$. Which phase corresponds to each snapshot?

TOUCHSTONE EXAMPLE 17-2: Traveling Wave Equations

A traveling sinusoidal wave train can be described in terms of a wave number k and an angular frequency ω using Eq. 17-4. If the wave train is moving to the right and has an initial phase of $\phi_0 = 0 \text{ rad}$ then we can write our wave equation as

$$y(x,t) = Y \sin(kx - \omega t).$$

Use the definition of various terms along with Eqs. 17-7, 17-10, and 17-11 to:

(a) Explain what T and λ mean physically.

SOLUTION ■ The symbols λ and T stand for the wavelength and the period of the wave, respectively.

The wavelength, λ , is the distance one has to move along the string at a fixed instant in time (for instance, when looking at a snapshot of the wave) in order to pass by a full oscillation of the wave.

The period, T , is the time one has to wait at a particular point in space (along an axis that is lined up with the undisturbed string) for a small piece of the string to go through one complete oscillation.

(b) Show that displacement of the string from its undisturbed condition given by $y(x,t)$ can also be described by the equation

$$y(x,t) = Y \sin\left[2\pi\left(\frac{x}{\lambda} - ft\right)\right].$$

SOLUTION ■ The **Key Idea** here is that the most important symbols in the sinusoidal wave equation are x and t . They

represent the variables. All the other symbols represent constants that describe a particular wave. As a result, every sinusoidal wave with a zero initial phase will look like $\sin[(\text{mess})x \pm (\text{another mess})t]$. By identifying how the “mess” in each situation is related to the constants in another situation, the transformation of Eq. 17-4 into different forms is straightforward. Also we only need to show that the argument given by terms inside the square brackets are the same as the argument $[kx - \omega t]$. For the situation at hand we can use the relationships in Eqs. 17-7, 17-10, and 17-11 ($k = 2\pi/\lambda$, $\omega = 2\pi/T$, and $f = 1/T = \omega/2\pi$) to verify that

$$2\pi\left(\frac{x}{\lambda} - ft\right) = \frac{2\pi}{\lambda}x - 2\pi ft = kx - \frac{2\pi}{T}t = kx - \omega t. \quad (\text{Answer})$$

(c) Show that displacement of the string from its undisturbed condition given by $y(x,t)$ can also be described by the equation

$$y(x,t) = Y \sin\left[2\pi\left(\frac{x}{\lambda} - \frac{t}{T}\right)\right].$$

SOLUTION ■ Using the same approach as we used in part (b), we see that

$$2\pi\left(\frac{x}{\lambda} - \frac{t}{T}\right) = 2\pi\left(\frac{x}{\lambda} - ft\right),$$

but we showed in part (a) that

$$2\pi\left(\frac{x}{\lambda} - ft\right) = kx - \omega t. \quad (\text{Answer})$$

FIGURE 17-12 ■ One end of a string that is under tension is moved up and down continuously in a sinusoidal fashion as shown in Fig. 17-3b. Two snapshots of the sinusoidal wave that results are shown, at time $t = t_1$ and then at time t_2 . As the wave moves to the right with an x -component of velocity v_x^{wave} , the entire sine curve shifts by Δx during $\Delta t = t_2 - t_1$, while the piece of string at x_1 moves down during Δt , while the piece of string at x_2 moves up as the local wave crest moves from left to right.

17-5 Wave Velocity

Figure 17-12 shows two snapshots of a sinusoidal wave taken a small time interval Δt apart. The wave is traveling in the positive x direction (to the right in Fig. 17-12b), and the entire wave pattern is moving a distance Δx in that direction during the interval Δt . The ratio $\Delta x/\Delta t$ (or, in the differential limit, dx/dt) is the **wave velocity** component along the x axis, which we denote as v_x^{wave} . How can we find the wave velocity?

As the wave in Fig. 17-12 moves, each point of the moving wave form, such as point A marked on a peak, retains its displacement y . (Points on the string do not retain their displacement, but points on the wave *form* do.) That is, time passes and the location of point A changes (so x and t are both changing), but the value of $y(x,t)$ associated with point A does not change; it remains the maximum value. If point A retains its displacement as it moves, the phase in $y(x,t) = Y \sin(kx \pm \omega t)$ must remain a constant. So,

$$kx \pm \omega t = \text{a constant.} \quad (17-12)$$

Note that although this argument is constant, in this case, both x and t are increasing. [The time t always increases and x increases because the wave is moving in the (rightward) positive direction]. In order for the phase $kx \pm \omega t$ to remain constant with both t and x increasing, the negative sign must be chosen. In other words,

The equation for a sinusoidal wave traveling right is $y(x,t) = Y \sin(kx - \omega t)$ and the equation for a sinusoidal wave moving left is $y(x,t) = Y \sin(kx + \omega t)$.

By assuming that the wave moves at a constant velocity \vec{v}^{wave} , we can express its velocity in terms of how far an imaginary point on the wave form has moved in a short time interval. Since the wave form only moves parallel to the x axis, we can write

$$\vec{v}^{\text{wave}} \equiv \frac{\Delta \vec{x}}{\Delta t} \quad (\text{definition of wave velocity}),$$

or in component form
$$v_x^{\text{wave}} = \frac{\Delta x}{\Delta t}.$$

If we take the time interval under consideration to be the period of the wave T , then we know that the wave travels one wavelength λ . So the magnitude of the wave velocity, or wave speed, is

$$|v_x^{\text{wave}}| = v^{\text{wave}} = \frac{\lambda}{T} = \lambda f = \frac{\omega}{k} \quad (\text{speed related to wave length and period}). \quad (17-13)$$

Are all traveling waves sinusoidal? Not necessarily. Consider a wave of arbitrary shape, given by

$$y(x,t) = h(kx \pm \omega t), \quad (17-14)$$

where h represents *any* function, the sine or cosine function being one possibility. Since the variables x and t enter in the combination $kx \pm \omega t$, it is possible for waves to have other shapes associated with them. For example, a wave pulse traveling from left to right could be represented by

$$y(x,t) = \frac{Y}{(kx - \omega t)^2 + 1} \quad (\text{a possible traveling wave pulse}).$$

Particle Velocity and Acceleration in Mechanical Waves

In discussing the velocity of a wave as we did above, it is important to remember that the magnitude of this velocity is the speed at which the wave disturbance moves, *not* the speed of the bits or pieces of string through which the wave travels. To repeat the quote of Leonardo da Vinci, consider “. . . waves made in a field of grain by the wind, where we see the waves running across the field while the grain remains in place.”

We have already begun to develop an understanding of the velocity of the wave itself. We now consider the velocity of the particles that are displaced as a transverse wave moves through. A piece of string can only move in the y direction as a disturbance passes by. Thus, at a given time t we can denote the velocity of the piece of string that is located at x in terms of its y -component $v_y^{\text{string}} = v_y(x, t)$. Since only the string pieces can move in the y direction, we often shorten this y -component notation to simplify $v_y(x, t)$. To find the velocity component $v_y(x, t)$ as a sinusoidal disturbance passes through, we simply need to differentiate the expression for the displacement of the string segment, $y(x, t) = Y \sin[(kx \pm \omega t) + \phi_0]$ with respect to time while holding x constant. This is similar to what we did to find the velocity of a mass oscillating at the end of a spring in Section 16-4,

$$v_y = \frac{\partial y(x, t)}{\partial t} = \pm \omega Y \cos[(kx \pm \omega t) + \phi_0], \quad (17-15)$$

where the use of the symbol $\partial/\partial t$ signifies that we are taking a partial derivative in which the location along the string, x , is considered to be a constant. If we find a second partial derivative using Eq. 17-15, we have the following expression for the acceleration of the piece of string at location x at a time t ,

$$a_y = \frac{\partial v_y}{\partial t} = \frac{\partial^2 y(x, t)}{\partial t^2} = \mp \omega^2 Y \sin[(kx \pm \omega t) + \phi_0]. \quad (17-16)$$

TOUCHSTONE EXAMPLE 17-3: Wave on a String

A wave traveling along a string is described by

$$y(x, t) = (0.00327 \text{ m}) \sin[(72.1 \text{ rad/m})x - (2.72 \text{ rad/s})t], \quad (17-17)$$

where $y(x, t)$ represents the transverse displacement from equilibrium of a small piece of string with a horizontal location of x at time t .

(a) What is the amplitude of this wave?

SOLUTION ■ The **Key Idea** is that Eq. 17-17 is of the same form as Eq. 17-4, with $\phi_0 = 0$ rad,

$$y = Y \sin(kx - \omega t + \phi_0), \quad (17-18)$$

so we have a sinusoidal wave. By comparing the two equations, we see that the amplitude is

$$Y = 0.00327 \text{ m} = 3.27 \text{ mm}. \quad (\text{Answer})$$

(b) What are the wavelength, period, and frequency of this wave?

SOLUTION ■ By comparing Eqs. 17-17 and 17-18, we see that the wave number and angular frequency are

$$k = 72.1 \text{ rad/m} \quad \text{and} \quad \omega = 2.72 \text{ rad/s}.$$

We then relate wavelength λ to k via Eq. 17-7:

$$\begin{aligned} \lambda &= \frac{2\pi}{k} = \frac{2\pi \text{ rad}}{72.1 \text{ rad/m}} \\ &= 0.0871 \text{ m} = 8.71 \text{ cm}. \end{aligned} \quad (\text{Answer})$$

Next, we relate T to ω using Eq. 17-10:

$$T = \frac{2\pi}{\omega} = \frac{2\pi \text{ rad}}{2.72 \text{ rad/s}} = 2.31 \text{ s}, \quad (\text{Answer})$$

and from Eq. 17-11 we have

$$f = \frac{1}{T} = \frac{1}{2.31 \text{ s}} = 0.433 \text{ Hz}. \quad (\text{Answer})$$

(c) What is the velocity with which the wave moves along the string?

SOLUTION ■ The speed of the wave is given by Eq. 17-13:

$$v^{\text{wave}} = \frac{\omega}{k} = \frac{2.72 \text{ rad/s}}{72.1 \text{ rad/m}} = 0.0377 \text{ m/s} \quad (\text{Answer})$$

$$= 3.77 \text{ cm/s.}$$

Because the phase in Eq. 17-17 contains the variable x , the wave is moving along the x axis. According to Eq. 17-4, the *minus* sign in front of the ωt term indicates that the wave is moving in the *positive* x direction. (Note that the (b) and (c) answers are independent of the wave amplitude.)

(d) What is the displacement y of the small piece of string located at $x = 22.5 \text{ cm}$ when $t = 18.9 \text{ s}$?

SOLUTION ■ The **Key Idea** here is that Eq. 17-17 gives the displacement as a function of position x and time t . Substituting the given values into the equation yields

$$y = (0.00327 \text{ m}) \sin[(72.1 \text{ rad/m}) \times (0.225 \text{ m}) - (2.72 \text{ rad/s})$$

$$\times (18.9 \text{ s})]$$

$$= (0.00327 \text{ m}) \sin[-35.1855 \text{ rad}] = (0.00327 \text{ m})(0.588)$$

$$= 0.00192 \text{ m} = 1.92 \text{ mm.} \quad (\text{Answer})$$

Thus, the transverse displacement from the string's equilibrium position is positive.

TOUCHSTONE EXAMPLE 17-4: Transverse String Motion

In Touchstone Example 17-3d, we showed that at $t = 18.9 \text{ s}$ the transverse displacement component y of the piece of string at $x = 0.255 \text{ m}$ due to the wave of Eq. 17-17 is 1.92 mm .

(a) What is v_y , the transverse velocity component of the same element of the string, at that time? (This speed, which is associated with the transverse oscillation of an element of the string, is in the y direction. Do not confuse it with \vec{v}^{wave} , the constant velocity at which the *wave form* travels along the x axis.)

SOLUTION ■ The **Key Idea** here is that as the wave travels, the displacement of each piece of string is transverse, where x represents the horizontal position of a piece of string. Another **Key Idea** is that the horizontal position, x , of a piece of string never changes. In general, the displacement of a piece of string is given by

$$y(x,t) = Y \sin(kx - \omega t + \phi_0). \quad (17-19)$$

For a piece of string at a certain location (x, y) we find the rate of change of y by taking the partial derivative of Eq. 17-19 with respect to t while treating x as a constant. Here we have $\phi_0 = 0 \text{ rad}$, so according to Eq. 17-15,

$$v_y = \frac{\partial y}{\partial t} = -\omega Y \cos(kx - \omega t), \quad (17-20)$$

where the amplitude Y is always taken as positive. Next, substituting numerical values from Touchstone Example 17-3 we obtain

$$v_y = (-2.72 \text{ rad/s})(3.27 \text{ mm}) \cos(-35.1855 \text{ rad})$$

$$= 7.20 \text{ mm/s.} \quad (\text{Answer})$$

Thus, at $t = 18.9 \text{ s}$, the piece of string at the horizontal location $x = 22.5 \text{ cm}$ is moving in the y direction, with a velocity of 7.20 mm/s .

(b) What is the transverse acceleration component a_y of the same element at that time?

SOLUTION ■ The **Key Idea** here is that the transverse acceleration component a_y is the rate at which the transverse velocity of a given piece of string is changing. From Eq. 17-20, again treating x as constant but allowing t to vary, we find

$$a_y = \frac{\partial v_y}{\partial t} = -\omega^2 Y \sin(kx - \omega t).$$

Comparison with Eq. 17-19 shows that we can write this as

$$a_y = -\omega^2 y.$$

We see that the transverse acceleration component of a piece of string that is oscillating is proportional to its transverse component of displacement but opposite in sign. This is completely consistent with the action of the string piece—namely, that it is moving transversely in simple harmonic motion. Substituting numerical values yields

$$a_y = -(2.72 \text{ rad/s})^2(1.92 \text{ mm})$$

$$= -14.2 \text{ mm/s}^2. \quad (\text{Answer})$$

Thus, at $t = 18.9 \text{ s}$, the piece of string at $x = 22.5 \text{ cm}$ is displaced from its equilibrium position by 1.92 mm in the positive direction and has an acceleration of magnitude 14.2 mm/s^2 in the negative y direction.

17-6 Wave Speed on a Stretched String

If we distort a string that is under tension, we observe that this distortion (or wave) will travel rapidly along the string (Fig. 17-1). This is true whether the distortion is a single pulse (Figs. 17-2 or 17-3a) or continuous sinusoidal pattern (Fig. 17-3b). In Section 17-3 we asserted that a net force on a piece of string could result from forces exerted on its ends by the pieces of string just adjacent to it. If these end forces act in different directions on a string segment, the string piece can move in a vertical direction. As it moves vertically, it can exert a force on adjacent string pieces. This could cause a set of disturbances to propagate along the string as a wave.

In general, the speed of a wave is determined by the properties of the medium through which it travels. For instance, how do the properties of the stretched string affect the speed of a traveling wave? Intuitively we expect that the wave will travel faster when the string is stretched to a higher tension and that the wave will travel more slowly on a thicker string where each segment of string has a greater mass. In this section we use the impulse-momentum theorem—a form of Newton’s Second Law—to derive an equation that relates the speed of the traveling wave to the tension of the string and its massiveness. In our derivation we imagine that the string consists of many tiny segments or pieces that are connected together.

Consider a horizontal stretched string as shown in Fig. 17-13. Suppose the string is under tension—a nonvector quantity we denote as F^{tension} . What happens if the tiny segment at one end of the string is jerked abruptly upward and then returned to its equilibrium position? The pulse that results propagates along the pieces of string as a wave like the one shown in Fig. 17-13. Although the amplitude in Fig. 17-13 is exaggerated for clarity, we assume the wave amplitude is small enough that: (1) the tension in the string does not change significantly except at the boundary between a displaced and undisplaced segment of string (as shown in Fig. 17-13a) and (2) the angle θ between the horizontal and any segment (or small piece) of string that is displaced is so small that $\sin \theta \approx \tan \theta \approx \theta$. We also assume that the pulse propagates along the string at a *constant* wave velocity $\vec{v}^{\text{wave}} = v_x^{\text{wave}} \hat{i}$. As is often the case in physics, we can test the validity of our assumptions by seeing whether the expression we derive for the wave speed is consistent with observation.

Let us consider how a segment of string moves as a wave pulse travels by it in a short time interval. If we define the mass per unit length of the string as its linear mass density, μ , then the mass of the segment of string that the wave pulse affects in a time interval Δt is given by

$$m = \mu v^{\text{wave}} \Delta t, \quad (17-21)$$

where v^{wave} is the speed of propagation of the wave pulse. We start by examining the tension forces that act at each end of our small string segment. For example, in Fig. 17-13a the segment at the crest of the wave experiences a net downward force, but the segment at the leading edge of the wave pulse experiences a net upward force. Thus a short time Δt later, the front segment has moved up while the segment at the crest has moved down. If we take all the string segments into account, we see that the entire pulse shape “moves” to the right even though each of the string segments has only moved vertically—either up or down. This is shown in Fig. 17-13b.

What happens when the leading edge of the pulse encounters a segment of the string? A vertical net force $\vec{F}^{\text{net}} = F_y^{\text{net}} \hat{j}$ due to the unbalanced tension forces at

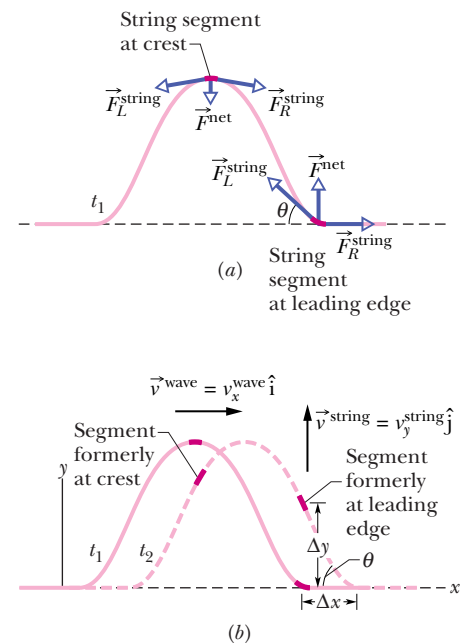

FIGURE 17-13 ■ Depictions of a traveling wave pulse. The amplitude is exaggerated for clarity. (a) A single pulse travels to the right along a string under constant tension. The piece of string at the wave crest experiences a net force downward while the string segment at the leading edge experiences a net upward force. (b) Two snapshots of the wave at times t_1 and t_2 show the wave form traveling with velocity \vec{v}^{wave} , so it shifts right a distance Δx during a time interval $\Delta t = t_2 - t_1$. As a result of the net forces on the piece of strings, the string segment at the wave crest moves down during Δt while the piece of string at the leading edge moves up.

*To avoid confusing wave period, denoted as T , with tension, we use the notation F^{tension} for tension here and in the next chapter.

the string segment's ends shown in Fig. 17-13a causes the segment to accelerate upward. In fact, the piece of string just to the left of the leading edge is stretched so its tension is greater than in the undisturbed string piece just to the right. As a result, the string piece at the leading edge undergoes a change in vertical position of Δy and a momentum change, $\Delta \vec{p}_y$, during the time Δt . We can use the impulse-momentum theorem to describe the motion of the piece of string in terms of the vertical components of net force and momentum as

$$F_y^{\text{net}} \Delta t = \Delta p_y. \quad (17-22)$$

The segment of string has a mass m , and we assume the segment has no vertical velocity at time t_1 . If we denote the vertical velocity change imparted to the segment of string in the short time interval Δt as $\Delta \vec{v}_y^{\text{string}}$, then

$$F_y^{\text{net}} \Delta t = m \Delta v_y^{\text{string}} = m(v_y^{\text{string}} - 0) = m v_y^{\text{string}}.$$

But we can see from Fig. 17-13a that the magnitude of the net force on the string segment is approximately $F^{\text{tension}} \sin \theta$, where F^{tension} is a scalar quantity denoting the tension in the string. The impulse delivered to the string segment by the traveling wave can be related to the newly acquired vertical velocity of the string segment by

$$(F^{\text{tension}} \sin \theta) \Delta t \approx m |v_y^{\text{string}}| = m |\vec{v}^{\text{string}}|.$$

From Fig. 17-13b we also see that the ratio of the magnitude of the vertical velocity of the leading edge mass segment and the magnitude of the horizontal wave velocity of the temporary disturbance is given by

$$\tan \theta = \frac{\Delta y}{\Delta x} = \frac{|\vec{v}^{\text{string}}|}{|\vec{v}^{\text{wave}}|} = \frac{v^{\text{string}}}{v^{\text{wave}}}. \quad (17-23)$$

Combining the last two expressions we derived gives us

$$(F^{\text{tension}} \sin \theta) \Delta t = m v^{\text{wave}} \tan \theta \quad \text{or} \quad F^{\text{tension}} = \frac{m}{\Delta t} \left(\frac{v^{\text{wave}}}{\cos \theta} \right). \quad (17-24)$$

At this point we need to express the mass of the segment in terms of the length of the string segment and the linear density of the string. Thus the mass of the segment in the string can be determined as the density multiplied by the length of the segment so that $m = \mu \Delta x$. However, during the time interval Δt the waveform has moved a distance $\Delta x = |\vec{v}^{\text{wave}}| \Delta t$. We can now rewrite Eq. 17-24 as

$$F^{\text{tension}} = \mu (v^{\text{wave}})^2 \frac{1}{\cos \theta},$$

but for small-amplitude waves the angle of string displacement relative to the horizontal, $\cos \theta$ is approximately 1, so

$$(v^{\text{wave}})^2 = \frac{F^{\text{tension}}}{\mu}.$$

Therefore,
$$v^{\text{wave}} = \sqrt{\frac{F^{\text{tension}}}{\mu}} \quad (\text{speed}). \quad (17-25)$$

Equation 17-25 gives the speed of the pulse in Fig. 17-13 and the speed of *any* other wave pulse or continuous wave on the same string under the same tension. If we take the square root of the ratio of F^{tension} (dimension MLT^{-2}) and μ (dimension ML^{-1}) we get a dimension of velocity. Thus Eq. 17-25 is dimensionally correct.

Equation 17-25 tells us that

The speed of a small-amplitude pulse traveling along a stretched string depends only on the tension and linear density of the string and not on the amplitude or frequency of the disturbance.

The amplitude independence is much like that for systems oscillating with simple harmonic motion. It indicates a proportionality between the net forces exerted on a piece of string and its displacement from equilibrium.

If the simplifying assumptions we used in the derivation of Eq. 17-25 are reasonable, then we expect that measurements of wave speed, tension, and linear mass density can be used to verify Eq. 17-25. Indeed, this theoretical prediction has been experimentally confirmed many times. In fact, it turns out that Eq. 17-25 is just as valid for continuous waves as it is for a single wave pulse, and so the speed of a continuous wave is not a function of frequency. The frequency of the wave is fixed entirely by whatever generates the wave (for example, the person jerking the string up and down in Fig. 17-3*b*). However, once the frequency of a continuous wave is set, the wave speed determines the relationship between frequency and wavelength since $\lambda = v^{\text{wave}}/f$ (Eq. 17-13).

READING EXERCISE 17-3: In the derivation of the wave speed in a string shown above, there are references to two different velocities; one is referred to as $\vec{v}_y^{\text{string}}$ and one is referred to as \vec{v}_x^{wave} . As completely as possible, describe the differences between these two velocities. Explain which velocity is used in deriving the expression for the mass, m , of a string piece being displaced and why. Explain which velocity is used to find the y -component of momentum change, Δp_y , of a piece of string and why. ■

READING EXERCISE 17-4: You send a continuous traveling wave along a string by moving one end up and down sinusoidally. If you increase the frequency of the oscillations, do (a) the speed of the wave and (b) the wavelength of the wave increase, decrease, or remain the same? If, instead, you increase the tension in the string, do (c) the speed of the wave and (d) the wavelength of the wave increase, decrease, or remain the same? ■

17-7 Energy and Power Transported by a Traveling Wave in a String

When we start up a wave or pulse in a stretched string, we provide the energy for the motion of the string. We impart a momentum to a segment of the string. As the wave or pulse moves away, the momentum is transferred from one segment of the string to the next. In addition, the wave transports energy as both kinetic energy and elastic potential energy. Let us consider each of these forms of energy in turn.

Kinetic Energy

A segment of the string of mass dm , oscillating transversely in simple harmonic motion as the wave passes through it, has kinetic energy associated with its transverse velocity v_y . When the segment is rushing through its $y = 0$ position (segment b in Fig. 17-14), its transverse velocity—and thus its kinetic energy—is a maximum. When

FIGURE 17-14 ■ A snapshot of a traveling wave on a string at time $t = 0$. String segment a is at displacement $y = Y$, and string segment b is at displacement $y = 0$. The kinetic energy of the string segment at each position depends on the transverse velocity of the segment. The potential energy depends on the amount by which the string is displaced from equilibrium as the wave passes through it.

the segment is at its extreme position $y = Y$ (as is segment a), its transverse velocity—and thus its kinetic energy—is zero.

Elastic Potential Energy

To send a sinusoidal wave along a previously straight string, the wave must necessarily stretch the string. As a string segment of length dx oscillates transversely, its length must increase and decrease in a periodic way if the string segment is to fit the sinusoidal wave form. Elastic potential energy is associated with these length changes, just as for a spring.

When the string segment is at its $y = Y$ position (segment a in Fig. 17-14), its length has its normal undisturbed value dx , so its elastic potential energy is zero. However, when the segment is rushing through its $y = 0$ position, it is stretched to its maximum extent, and its elastic potential energy then is a maximum.

Energy Transport

The oscillating string segment thus has both its maximum kinetic energy and its maximum elastic potential energy at $y = 0$. In the snapshot of Fig. 17-14, the regions of the string at maximum displacement have no energy, and the regions at zero displacement have maximum energy. As the wave travels along the string, forces due to the tension in the string continuously do work to transfer energy from regions with energy to regions with no energy.

Suppose we set up a wave on a string stretched along a horizontal x axis so that Eq. 17-4 describes the string's displacement. We might send a wave along the string by oscillating one end of the string, as in Fig. 17-3*b*. In doing so, we provide energy for the motion and stretching of the string—as the string sections oscillate perpendicularly to the x axis, they have kinetic energy and elastic potential energy. As the wave moves into sections that were previously at rest, energy is transferred into those new sections. Thus, we say that the wave *transports* the energy along the string.

The Rate of Energy Transmission

The kinetic energy dK associated with a string segment of mass dm is given by

$$dK = \frac{1}{2} dm (v_y^{\text{string}})^2, \quad (17-26)$$

where v_y^{string} is the transverse component of velocity of the oscillating string segment. If we assume the initial phase ϕ_0 is zero, then the y -component of the string element velocity is given by Eq. 17-15 as

$$v_y^{\text{string}} = -\omega Y \cos(kx - \omega t).$$

Using this relation and putting $dm = \mu dx$, we rewrite Eq. 17-26 as

$$dK = \frac{1}{2} (\mu dx) [(-\omega Y) \cos(kx - \omega t)]^2. \quad (17-27)$$

Dividing both sides of Eq. 17-27 by dt , we get the rate at which the kinetic energy of a string segment changes and thus the rate at which kinetic energy is carried along by the wave. The result is given by

$$\frac{dK}{dt} = \frac{1}{2} \mu \frac{dx}{dt} \omega^2 Y^2 \cos^2(kx - \omega t) = \frac{1}{2} \mu v^{\text{wave}} \omega^2 Y^2 \cos^2(kx - \omega t), \quad (17-28)$$

where the ratio dx/dt , which is positive for a wave moving from left to right, has been replaced by the wave speed v^{wave} . The *average* rate at which kinetic energy is transported is

$$\begin{aligned}\frac{dK}{dt} &= \left\langle \frac{1}{2} \mu v^{\text{wave}} \omega^2 Y^2 [\cos^2(kx - \omega t)] \right\rangle \\ &= \frac{1}{4} \mu v^{\text{wave}} \omega^2 Y^2.\end{aligned}\quad (17-29)$$

Here we have taken the average over an integer number of wavelengths and have used the fact that the average value of the square of a cosine function over an integer number of periods is $\frac{1}{2}$.

Elastic potential energy is also carried along with the wave, and at the same average rate given by Eq. 17-29. Although we shall not examine the proof, you should recall that, in an oscillating system such as a pendulum or a spring–block system, the average kinetic energy and the average potential energy are indeed equal.

The **average power**, which is the average rate at which energy of both kinds is transmitted by the wave, is then

$$\langle P \rangle = 2 \left\langle \frac{dK}{dt} \right\rangle, \quad (17-30)$$

or, from Eq. 17-29,

$$\langle P \rangle = \frac{1}{2} \mu v^{\text{wave}} \omega^2 Y^2 \quad (\text{average power}). \quad (17-31)$$

The factors μ and v^{wave} in this equation depend on the material and tension of the string. The factors ω and Y depend on the process that generates the wave.

The dependence of the average power of a wave on the square of its amplitude and also on the square of its angular frequency is a general result, true for sinusoidal waves of all types.

17-8 The Principle of Superposition for Waves

It often happens that two or more waves pass simultaneously through the same region. When we listen to a concert, for example, sound waves from many instruments fall simultaneously on our eardrums. The electrons in the antennas of our radio and television receivers are set in motion by the net effect of many electromagnetic waves from many different broadcasting centers. The water of a lake or harbor may be churned up by waves in the wakes of many boats.

In many real-world cases, we find the interaction between two overlapping waves to be quite complex. However, we also observe that when wave disturbances move along the same straight line and their amplitudes are small, like those shown in Fig. 17-15, their interaction is well behaved. We observe that when well behaved waves interact, they produce a resultant wave with an amplitude equal to the sum of the amplitudes of the two original waves. This effect is seen in Fig. 17-15, where a sequence of snapshots of two pulses traveling in opposite directions on the same stretched string is shown.

When two well behaved linear waves overlap, the displacement of each point on the string is the sum of the two displacements it would have had from each wave independently.

FIGURE 17-15 ■ An experimental demonstration of wave pulse superposition. In this sequence of movie frames two pulses are set in motion in opposite directions along a taut string. The pulses have almost the same shape except that the one starting on the right has positive displacements while the other starting on the left has negative displacements. In the fourth frame the two pulses almost cancel each other.

Moreover, we observe that each pulse moves through the other, as if the other were not present:

When well behaved linear waves overlap, one wave does not in any way alter the travel of the other.

This superposition is one of the many ways that waves and particles differ. When particles overlap by colliding they alter each other's motions.

In order to make these two important observations quantitative, let $y_1(x,t)$ and $y_2(x,t)$ be the displacements associated with two waves traveling simultaneously along the same stretched string. Since the result of the overlapping waves is a resultant wave that is the sum of the two, the displacement of the string when the waves overlap is given by the algebraic sum

$$y'(x,t) = y_1(x,t) + y_2(x,t). \quad (17-32)$$

This is an example of the **principle of superposition**, which says that when several effects occur simultaneously, their net effect is the sum of the individual effects.

We can look in more detail at how the sum of two waves passing through each other can look rather odd while the waves overlap, but after they pass each other they look more normal again. This situation is shown in the visualization of the superposition of two waves having different amplitudes in Figs. 17-16 and 17-17.

FIGURE 17-16 ■ A visualization of two pulses on a taut string passing through each other. A short broad pulse moves from left to right while a sharp tall pulse moves from right to left. When they overlap at times t_2 , t_3 , and t_4 , the wave form is the sum or superposition of the displacement of each pulse at each location along the string. A close-up of this type of superposition is shown in Fig. 17-17.

FIGURE 17-17 ■ Closeup view of a short, broad pulse and a tall sharp pulse passing through each other. The vertical scale relative to the horizontal scale has been enlarged to show more details. Note that the resultant wave is the sum of the displacements contributed by each of the two pulses at each location along the string.

TOUCHSTONE EXAMPLE 17-5: Overlapping Pulses

At the time $t = 0$ s, the string has the shape shown in Fig. 17-18. The pulse on the left is moving toward the right and the pulse on the right is moving toward the left. Assume that each box in Fig. 17-18 is 1 cm square.

(a) The leading edges of the pulses will just touch in a time of 0.05 s. What is the speed with which each pulse is traveling?

SOLUTION ■ The **Key Ideas** here are that (1) since these waves travel on the same string they must have the same speed so their leading edges will meet in the middle, and (2) if the wave pulses don't change shape, the motion of any location on the wave shape tells us about the velocity and speed of the wave as a whole. At first the leading edges of the waves are 4.0 cm apart, so each wave has time to travel 2.0 cm in the 0.05 s. This gives us a wave speed of

$$v^{\text{wave}} = |\vec{v}^{\text{wave}}| = \left(\frac{2.0 \text{ cm}}{0.05 \text{ s}} \right) = 40 \text{ cm/s} \quad (\text{speed of each wave}). \quad (\text{Answer})$$

(b) Two points on the string are marked with red dots and with the letters *A* and *B*. At the instant shown, what are the velocities of the dots? Give magnitude and direction (up, down, left, right, or some combination of them).

SOLUTION ■ There are three **Key Ideas** here. (1) The piece of string located at a given point can only move up or down but NOT along the string. (2) If the displacement of the string is less just behind a point on a wave (relative to its direction of motion),

then the velocity of the piece of string is downward in the negative y direction. The opposite is true if the displacement behind the string is greater, then the velocity is upward. (3) The change Δy of a point on a string as a wave disturbance passes depends on both the wave velocity component $v_x^{\text{wave}} = \Delta x / \Delta t$ and the current slope of the wave shape $\Delta y / \Delta x$ at the point of interest along the string.

At point A: Wave slope is $\Delta y / \Delta x = -2$ so that $\Delta y = -2\Delta x$. But the x -component of the wave speed is given by $v_x^{\text{wave}} = \Delta x / \Delta t = 40 \text{ cm/s}$, so

$$v_{Ay} = \frac{\Delta y}{\Delta t} = -\frac{2\Delta x}{\Delta t} = -80 \text{ cm/s} \quad (\text{downward motion}). \quad (\text{Answer})$$

At point B: Wave slope is $\Delta y / \Delta x = +\frac{2}{3}$ so that $\Delta y = +(\frac{2}{3})\Delta x$. Therefore,

$$v_{By} = \frac{\Delta y}{\Delta t} = +\left(\frac{2}{3}\right)\frac{\Delta x}{\Delta t} = 27 \text{ cm} \quad (\text{upward motion}). \quad (\text{Answer})$$

(c) In Fig. 17-19 are dashed lines indicating where the pulses would be at a time $t = 0.075$ s. Draw a heavy line to show what the shape of the string would look like at this instant. Explain why you think it would look like your sketch.

SOLUTION ■ The **Key Idea** here is that we can use the principle of superposition to sum the contribution of each wave. Right in the middle where the waves overlap, they add up to a constant because the two overlapping slopes are equal in magnitude and opposite in sign (Fig. 17-20).

FIGURE 17-18 ■ Two pulses move toward each other on a string.

FIGURE 17-19 ■ Overlapping pulses at time $t = 0.075$ s.

FIGURE 17-20 ■ Answer to the question posed in part (c).

17-9 Interference of Waves

Suppose we send two sinusoidal waves of the same wavelength and amplitude in the same direction along a stretched string. The superposition principle applies. What resultant wave does it predict for the string?

The resultant wave depends on the extent to which the waves are *in phase* (in step) with respect to each other—that is, how much one wave form is shifted from the other wave form. If the waves are exactly in phase (so that the peaks and valleys of one are exactly aligned with those of the other), they combine to double the displacement

of either wave acting alone. If they are exactly out of phase (the peaks of one are exactly aligned with the valleys of the other), they combine to cancel everywhere, and the string remains straight. We call this phenomenon of combining waves **interference**, and the waves are said to **interfere**. (These terms refer only to the displacements of the waves; the travel of the waves is unaffected.)

Let one wave traveling along a stretched string be given by

$$y_1(x,t) = Y \sin(kx - \omega t), \quad (17-33)$$

and another, shifted from the first, by an initial phase of ϕ_0 so that

$$y_2(x,t) = Y \sin(kx - \omega t + \phi_0). \quad (17-34)$$

The waves in question have the same angular frequency ω (that is, the same frequency f), the same wave number k (that is, the same wavelength λ), and the same amplitude Y . They both travel in the positive direction of the x axis, with the same speed, given by $|v_{\text{wave}}| = \sqrt{F^{\text{tension}}/\mu}$ (Eq. 17-25). They differ only by the nonzero initial phase ϕ_0 of wave 2, which we call the **phase difference**. These waves are said to be *out of phase* by ϕ_0 or to have a *phase difference* of $\Delta\phi = (\phi_0)_2 - (\phi_0)_1 = \phi_0$, or one wave is said to be *phase-shifted* from the other by ϕ_0 .

From the principle of superposition, the resultant wave is the algebraic sum of the two interfering waves and has displacement

$$\begin{aligned} y'(x,t) &= y_1(x,t) + y_2(x,t) \\ &= Y \sin(kx - \omega t) + Y \sin(kx - \omega t + \phi_0). \end{aligned} \quad (17-35)$$

In Appendix E we see that we can write the sum of the sines of two angles α and β as

$$\sin \alpha + \sin \beta = 2 \sin \frac{1}{2}(\alpha + \beta) \cos \frac{1}{2}(\alpha - \beta). \quad (17-36)$$

Applying this relation to Eq. 17-35 leads to

$$y'(x,t) = [2Y \cos \frac{1}{2}\phi_0] \sin(kx - \omega t + \frac{1}{2}\phi_0), \quad (17-37)$$

where ϕ_0 represents the phase difference $\Delta\phi$ between the two waves. As Fig. 17-21 shows, the resultant wave is also a sinusoidal wave traveling in the direction of increasing x . It is the only wave you would actually see on the string (you would *not* see the two interfering waves of Eqs. 17-33 and 17-34).

If two sinusoidal waves of the same amplitude and wavelength travel in the *same* direction along a stretched string, they interfere to produce a resultant sinusoidal wave traveling in that direction.

$$y'(x,t) = \underbrace{[2Y \cos \frac{1}{2}\phi_0]}_{\text{Amplitude}} \underbrace{\sin(kx - \omega t + \frac{1}{2}\phi_0)}_{\substack{\text{Time and} \\ \text{space-dependent} \\ \text{phase} \\ \text{Oscillating} \\ \text{term}}}$$

FIGURE 17-21 ■ The resultant wave of Eq. 17-37, due to the interference of two sinusoidal transverse waves, is also a sinusoidal wave, with an amplitude and an oscillating term.

The resultant wave differs from the interfering waves in two respects: (1) its initial *phase* is $\frac{1}{2}\phi_0$, and (2) its amplitude Y' is the quantity in the brackets in Eq. 17-37:

$$Y' = 2Y \cos \frac{1}{2}\phi_0 \quad (\text{amplitude}). \quad (17-38)$$

The resultant wave of Eq. 17-37, due to the interference of two sinusoidal transverse waves, is also a sinusoidal transverse wave, with an amplitude and an oscillating term.

Let's consider a couple of special and very important cases. If $\phi_0 = 0$ rad (or 0°), the two interfering waves are exactly in phase, as in Fig. 17-22a. Then Eq. 17-37 reduces to

$$y'(x,t) = 2Y \sin(kx - \omega t) \quad (\phi_0 = 0 \text{ rad}). \quad (17-39)$$

This resultant wave is plotted in Fig. 17-22d. Note from both that figure and $y'(x,t) = 2Y\sin(kx - \omega t)$ that the amplitude of the resultant wave is twice the amplitude of either interfering wave. That is the greatest amplitude the resultant wave can have, because the cosine term in $y'(x,t) = [2Y\cos\frac{1}{2}\phi_0]\sin(kx - \omega t + \frac{1}{2}\phi_0)$ has its greatest value (unity) when $\phi_0 = 0$. Interference that produces the greatest possible amplitude is called *fully constructive interference*.

If $\Delta\phi = \phi_0\pi$ rad (or 180°), the interfering waves are exactly out of phase as in Fig. 17-22b. Then $\cos\frac{1}{2}\phi_0$ becomes $\cos\pi/2 = 0$, and the amplitude of the resultant wave as given by Eq. 17-38 is zero. We then have, for all values of x and t ,

$$y'(x,t) = 0 \quad (\phi = \pi \text{ rad}). \quad (17-40)$$

The resultant wave is plotted in Fig. 17-22e. Although we sent two waves along the string, we see no motion of the string. This type of interference is called *fully destructive interference*.

Because a sinusoidal wave repeats its shape every 2π rad, a phase difference $\Delta\phi_0 = 2\pi$ rad (or 360°) corresponds to a shift of one wave relative to the other wave by a distance equivalent to one wavelength. Thus, phase differences can be described in terms of wavelengths as well as angles. For example, in Fig. 17-22b the waves may be said to be 0.50 wavelength out of phase. Table 17-1 shows some other examples of phase differences and the interference they produce. Note that when interference is neither fully constructive nor fully destructive, it is called *intermediate interference*. The amplitude of the resultant wave is then intermediate between 0 and $2Y$. For example, from Table 17-1, if the interfering waves have a phase difference of 120° ($\Delta\phi = \frac{2}{3}\pi$ rad = 0.33 wavelength), then the resultant wave has an amplitude of Y , the same as the interfering waves (see Figs. 17-22c and f).

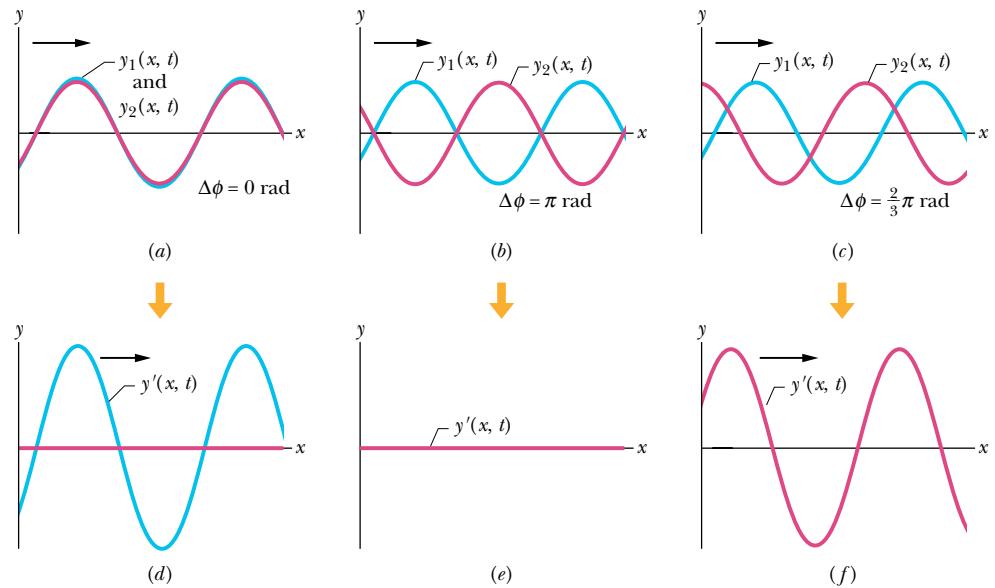

FIGURE 17-22 ■ Two sinusoidal waves with the same k , ω , and y , $y_1(x,t)$ and $y_2(x,t)$, travel along a string in the positive x direction. Here the units for ϕ_0 and t are unspecified. They interfere to give a resultant wave $y'(x,t)$. The resultant wave is what is actually seen on the string. The phase difference $\Delta\phi$ between the two interfering waves is (a) 0 rad or 0° , (b) π rad or 180° , and (c) $\frac{2}{3}\pi$ rad or 120° . The corresponding resultant waves are shown in (d), (e), and (f).

TABLE 17-1
Phase Differences and Resulting Interference Types^a

Phase Difference, ($\Delta\phi$), in			Amplitude of Resultant Wave	Type of Interference
Degrees	Radians	Wavelengths		
0	0	0	$2Y$	Fully constructive
120	$\frac{2}{3}\pi$	0.33	Y	Intermediate
180	π	0.50	0	Fully destructive
240	$\frac{4}{3}\pi$	0.67	Y	Intermediate
360	2π	1.00	$2Y$	Fully constructive
865	15.1	2.40	$0.60Y$	Intermediate

^a The phase difference is between two otherwise identical waves, with amplitude Y , moving in the same direction.

TOUCHSTONE EXAMPLE 17-6: Two Sine Waves

Two identical sinusoidal waves, moving in the same direction along a stretched string, interfere with each other. The amplitude Y of each wave is 9.8 mm, and the phase difference $\Delta\phi = \phi_0$ between them is 100° .

(a) What is the amplitude Y' of the resultant wave due to the interference of these two waves, and what type of interference occurs?

SOLUTION ■ The **Key Idea** here is that these are identical sinusoidal waves traveling in the *same direction* along a string, so they interfere to produce a sinusoidal traveling wave. Because they are identical except for their initial phase, they have the *same amplitude*. Thus, the amplitude Y' of the resultant wave is given by Eq. 17-38:

$$\begin{aligned} Y' &= 2Y \cos \frac{1}{2}\phi_0 = (2)(9.8 \text{ mm}) \cos(100^\circ/2) \\ &= 12.6 \text{ mm}. \end{aligned} \quad (\text{Answer})$$

Here we have assumed that wave 2 has an initial phase of 100° relative to wave 1. We can tell that the interference is *intermediate* in two ways. The phase difference is between 0 and 180° and, correspondingly, amplitude Y' is between 0 and $2Y (= 19.6 \text{ mm})$.

(b) What phase difference, in radians and wavelengths, will give the resultant wave an amplitude of 4.9 mm?

SOLUTION ■ The same **Key Idea** applies here as in part (a), but now we are given Y' and seek ϕ_0 . From Eq. 17-38,

$$Y' = 2Y \cos \frac{1}{2}\phi_0.$$

We now have

$$4.9 \text{ mm} = (2)(9.8 \text{ mm}) \cos \frac{1}{2}\phi_0,$$

which gives us (with a calculator in the radian mode)

$$\begin{aligned} \phi_0 &= 2 \cos^{-1} \frac{4.9 \text{ mm}}{(2)(9.8 \text{ mm})} \\ &= \pm 2.636 \text{ rad} \approx \pm 2.6 \text{ rad}. \end{aligned} \quad (\text{Answer})$$

There are two solutions because we can obtain the same resultant wave by letting the first wave *lead* (travel ahead of) or *lag* (travel behind) the second wave by 2.6 rad. In wavelengths, the phase difference is

$$\begin{aligned} \frac{\phi_0}{2\pi \text{ rad/wavelength}} &= \frac{\pm 2.636 \text{ rad}}{2\pi \text{ rad/wavelength}} \\ &= \pm 0.42 \text{ wavelength}. \end{aligned} \quad (\text{Answer})$$

17-10 Reflections at a Boundary and Standing Waves

In the preceding two sections, we discussed two sinusoidal waves of the same wavelength and amplitude traveling *in the same direction* along a stretched string. What if they travel in opposite directions? We can again find the resultant wave by applying the superposition principle. Figure 17-23 suggests the situation graphically. It shows the two combining waves, one traveling to the left in Fig. 17-23a, the other to the right

FIGURE 17-23 ■ (a) Five snapshots of a wave traveling to the left, at the times t indicated below part (c) (T is the period of oscillation). (b) Five snapshots of a wave identical to that in (a) but traveling to the right, at the same times t . (c) Corresponding snapshots for the superposition of the two waves on the same string. At $t = 0, \frac{1}{2}T,$ and T , fully constructive interference occurs because of the alignment of peaks with peaks and valleys with valleys. At $t = \frac{1}{4}T$ and $\frac{3}{4}T$, fully destructive interference occurs because of the alignment of peaks with valleys. Some points (the nodes, marked with dots) never oscillate; some points (the antinodes) oscillate the most.

in Fig. 17-23*b*. Figure 17-23*c* shows their sum, obtained by applying the superposition principle graphically.

The outstanding feature of the resultant wave is that there are places along the string, called **nodes**, where the string never moves. Four such nodes are marked by dots in Fig. 17-23*c*. Halfway between adjacent nodes are **antinodes**, where the amplitude of the resultant wave is a maximum. Wave patterns such as that of Fig. 17-23*c* are called **standing waves** because the wave patterns do not move left or right; the locations of the maxima and minima do not change.

If two sinusoidal waves of the same amplitude and wavelength travel in *opposite* directions along a stretched string, their interference with each other produces a standing wave.

To analyze a standing wave, we represent the two combining waves with the equations

$$y_1(x,t) = Y \sin(kx - \omega t) \quad (17-41)$$

and
$$y_2(x,t) = Y \sin(kx + \omega t). \quad (17-42)$$

The principle of superposition gives, for the combined wave,

$$y'(x,t) = y_1(x,t) + y_2(x,t) = Y \sin(kx - \omega t) + Y \sin(kx + \omega t).$$

Applying the trigonometric relation of $\sin \alpha + \sin \beta = 2 \sin \frac{1}{2}(\alpha + \beta) \cos \frac{1}{2}(\alpha - \beta)$ leads to

$$y'(x,t) = [2Y \sin kx] \cos \omega t, \quad (17-43)$$

which is displayed in Fig. 17-24. This equation does not describe a traveling wave because it is not of the form of $y(x,t) = h(kx \pm \omega t)$. Instead, it describes a standing wave.

The quantity $2Y \sin kx$ in the brackets of $y'(x,t) = [2Y \sin kx] \cos \omega t$ can be viewed as the amplitude of oscillation of the string segment that is located at position x . However, since an amplitude is always positive and $\sin kx$ can be negative, we take the absolute value of the quantity $2Y \sin kx$ to be the amplitude at x .

In a traveling sinusoidal wave, the amplitude of the wave is the same for all string segments. That is not true for a standing wave, in which the amplitude *varies with position*. In the standing wave of $y'(x,t) = [2Y \sin kx] \cos \omega t$, for example, the amplitude is zero for values of kx that give $\sin kx = 0$. Those values are

$$kx = n\pi, \quad \text{for } n = 0, 1, 2, \dots \quad (17-44)$$

Substituting $k = 2\pi/\lambda$ in this equation and rearranging, we get

$$x = n \frac{\lambda}{2}, \quad \text{for } n = 0, 1, 2, \dots \quad (\text{nodes}), \quad (17-45)$$

as the positions of zero amplitude—the nodes—for the standing wave of Eq. 17-43. Note that adjacent nodes are separated by $\lambda/2$, half a wavelength.

The amplitude of the standing wave of $y'(x,t) = [2Y \sin kx] \cos \omega t$ has a maximum value of $2Y$, which occurs for values of kx that give $|\sin kx| = 1$. Those values are

$$\begin{aligned} kx &= \frac{1}{2}\pi, \frac{3}{2}\pi, \frac{5}{2}\pi, \dots \\ &= (n + \frac{1}{2})\pi, \quad \text{for } n = 0, 1, 2, \dots \end{aligned} \quad (17-46)$$

$$\overbrace{y'(x,t)}^{\text{Displacement}} = \underbrace{[2Y \sin kx]}_{\text{Amplitude at position } x} \underbrace{\cos \omega t}_{\text{Oscillating term}}$$

FIGURE 17-24 ■ The resultant wave of Eq. 17-43 is a standing wave and is due to the interference of two sinusoidal waves of the same amplitude and wavelength that travel in opposite directions with the same initial phase.

FIGURE 17-25 (a) A pulse incident from the right is reflected at the left end of the string, which is tied to a wall. Note that the reflected pulse is inverted from the incident pulse. (b) Here the left end of the string is tied to a ring that can slide without friction up and down the rod. Now the pulse is not inverted by the reflection.

FIGURE 17-26 Stroboscopic photographs reveal (imperfect) standing wave patterns on a string being made to oscillate by a vibrator at the left end. The patterns occur at certain frequencies of oscillation.

Substituting $k = 2\pi/\lambda$ in Eq. 17-43 and rearranging, we get

$$x = \left(n + \frac{1}{2}\right)\frac{\lambda}{2} \quad \text{for } n = 0, 1, 2, \dots \quad (\text{antinodes}), \quad (17-47)$$

as the positions of maximum amplitude—the antinodes—of the standing wave of Eq. 17-43. The antinodes are separated by $\lambda/2$ and are located halfway between pairs of nodes.

Reflections at a Boundary

We can set up a standing wave in a stretched string by allowing a traveling wave to be reflected from the far end of the string so that it travels back through itself. The incident (original) wave and the reflected wave can then be described by Eqs. 17-41 and 17-42, respectively, and they can combine to form a pattern of standing waves.

In Fig. 17-25, we use a single pulse to show how such reflections take place. In Fig. 17-25a, the string is fixed at its left end. When the pulse arrives at that end, it exerts an upward force on the support (the wall). By Newton's Third Law, the support exerts an opposite force of equal magnitude on the string. This force generates a pulse at the support. This pulse travels back along the string in the direction opposite that of the incident pulse causing transverse string displacements that are inverted. In a “hard” reflection of this kind, there must be a node at the support because the string is fixed there. The reflected and incident pulses must have opposite signs, so as to cancel each other at that point.

In Fig. 17-25b, the left end of the string is fastened to a light ring that is free to slide without friction along a rod. When the incident pulse arrives, the ring moves up the rod. As the ring moves, it pulls on the string, stretching the string and producing a reflected pulse with the same sign and amplitude as the incident pulse. This reflected pulse is not inverted. Thus, in such a “soft” reflection, the incident and reflected pulses reinforce each other, creating an antinode at the end of the string; the maximum displacement of the ring is twice the amplitude of either of these pulses. The same types of reflections occur for continuous sinusoidal waves.

READING EXERCISE 17-5: Two waves with the same amplitude and wavelength interfere in three different situations to produce resultant waves with the following equations:

- (1) $y'(x,t) = (0.004 \text{ m})\sin((5 \text{ rad/m})x - (4 \times 10^3 \text{ rad/s})t)$,
- (2) $y'(x,t) = [(0.004 \text{ m})\sin((5 \text{ rad/m})x)] \cos((4 \times 10^3 \text{ rad/s})t)$, and
- (3) $y'(x,t) = (0.004 \text{ m})\sin((5 \text{ rad/m})x + (4 \times 10^3 \text{ rad/s})t)$.

In which situation are the two combining waves traveling (a) toward positive x , (b) toward negative x , and (c) in opposite directions? ■

17-11 Standing Waves and Resonance

Consider a string, such as a guitar string, that is stretched between two clamps. Suppose we send a sinusoidal wave of a certain frequency along the string, say, toward the right. When the wave reaches the right end, it reflects and begins to travel back to the left. That left-going wave then overlaps the wave that is still traveling to the right. When the left-going wave reaches the left end, it reflects again and the newly reflected wave begins to travel to the right, overlapping the left-going and right-going waves. In short, we very soon have many overlapping traveling waves, which interfere with one another.

For certain frequencies, the interference produces a standing wave pattern (or normal **oscillation mode**) with nodes and large antinodes like those in Fig. 17-26. Such a standing wave is said to be produced at **resonance**, and the string is said to *resonate*

at these certain frequencies, called **resonant frequencies**. This standing wave resonance is not unlike the harmonic oscillator resonance discussed in Section 16-8. If the string is oscillated at some frequency other than a resonant frequency, a standing wave is not set up. Then the interference of the right-going and left-going traveling waves results in only small (perhaps imperceptible) oscillations of the string.

Let a string be stretched between two clamps separated by a fixed distance L . To find expressions for the resonant frequencies of the string, we note that a node must exist at each of its ends, because each end is fixed and cannot oscillate. The simplest pattern that meets this key requirement is that in Fig. 17-27a, which shows the string at both its extreme displacements (one solid and one dashed, together forming a single “loop”). There is only one antinode, which is at the center of the string. Note that half a wavelength spans the length L , which we take to be the string’s length. Thus, for this pattern, $\lambda/2 = L$. This condition tells us that if the left-going and right-going traveling waves are to set up this pattern by their interference, they must have the wavelength $\lambda = 2L$.

A second simple pattern meeting the requirement of nodes at the fixed ends is shown in Fig. 17-27b. This pattern has three nodes and two antinodes and is said to be a two-loop pattern. For the left-going and right-going waves to set it up, they must have a wavelength $\lambda = L$. A third pattern is shown in Fig. 17-27c. It has four nodes, three antinodes, and three loops, and the wavelength is $\lambda = \frac{2}{3}L$. We could continue this progression by drawing increasingly more complicated patterns. In each step of the progression, the pattern would have one more node and one more antinode than the preceding step, and an additional $\lambda/2$ would be fitted into the distance L .

Thus, a standing wave can be set up on a string of length L by a wave with a wavelength equal to one of the values

$$\lambda = \frac{2L}{n}, \quad \text{for } n = 1, 2, 3, \dots \quad (17-48)$$

The resonant frequencies that correspond to these wavelengths follow from Eq. 17-16:

$$f = \frac{v^{\text{wave}}}{\lambda} = n \frac{v^{\text{wave}}}{2L}, \quad \text{for } n = 1, 2, 3, \dots \quad (\text{string fixed at both ends}), \quad (17-49)$$

where v^{wave} is the speed of traveling waves on the string.

Equation 17-49 tells us that the resonant frequencies are integer multiples of the lowest resonant frequency, $f = v^{\text{wave}}/2L$, which corresponds to $n = 1$. The oscillation mode with that lowest frequency is called the *fundamental mode* or the *first harmonic*. The *second harmonic* is the oscillation mode with $n = 2$, the *third harmonic* is that with $n = 3$, and so on. The frequencies associated with these modes are often labeled f_1, f_2, f_3 and so on. The collection of all possible oscillation modes is called the **harmonic series**, and n is called the **harmonic number** of the n th harmonic.

The phenomenon of resonance is common to all oscillating systems and can occur in two and three dimensions. For example, Fig. 17-28 shows a two-dimensional standing wave pattern on the oscillating head of a kettledrum.

READING EXERCISE 17-6: In the following series of resonant frequencies, one frequency (lower than 400 Hz) is missing: 150, 225, 300, 375 Hz. (a) What is the missing frequency? (b) What is the frequency of the seventh harmonic? ■

FIGURE 17-27 ■ A string, stretched between two clamps, is made to oscillate in standing-wave patterns. (a) The simplest possible pattern consists of one *loop*, which refers to the composite shape formed by the string in its extreme displacements (the solid and dashed lines). (b) The next simplest pattern has two loops. (c) The next has three loops.

FIGURE 17-28 ■ One of many possible standing wave patterns for a kettledrum head, made visible by dark powder sprinkled on the drumhead. As the head is set into oscillation at a single frequency by a mechanical vibrator at the upper left of the photograph, the powder collects at the nodes, which are circles and straight lines (rather than points) in this two-dimensional example.

TOUCHSTONE EXAMPLE 17-7: String Harmonics

In Fig. 17-29, a string, tied to a sinusoidal vibrator at P and running over a fixed pulley at Q , is stretched by a block of mass m . The separation L between P and Q is 1.2 m, the linear density of the string is 1.6 g/m, and the frequency f of the vibrator is fixed at 120 Hz. The amplitude of the motion at P is small enough for that point to be considered a node. A node also exists at Q .

FIGURE 17-29 ■ A string under tension connected to a vibrator. For a fixed vibrator frequency, standing wave patterns will occur for certain values of the string tension.

(a) What mass m allows the vibrator to set up the fourth harmonic on the string?

SOLUTION ■ One **Key Idea** here is that the string will resonate at only certain frequencies, determined by the wave speed $|\vec{v}^{\text{wave}}|$ on the string and the length L of the string. From Eq. 17-49, these resonant frequencies are

$$f = n \frac{v^{\text{wave}}}{2L}, \quad \text{for } n = 1, 2, 3, \dots \quad (17-50)$$

To set up the fourth harmonic (for which $n = 4$), we need to adjust the right side of this equation, with $n = 4$, so that the left side equals the frequency of the vibrator (120 Hz).

We cannot adjust L in Eq. 17-50; it is set. However, a second **Key Idea** is that we *can* adjust v^{wave} because it depends on how much mass m we hang on the string. According to Eq. 17-25, wave speed $v^{\text{wave}} = \sqrt{F^{\text{tension}}/\mu}$. Here the tension F^{tension} in the string is equal to the magnitude of the weight mg of the block. Thus,

$$v^{\text{wave}} = \sqrt{\frac{F^{\text{tension}}}{\mu}} = \sqrt{\frac{mg}{\mu}}. \quad (17-51)$$

Substituting v^{wave} from Eq. 17-51 into Eq. 17-50, setting $n = 4$ for the fourth harmonic, and solving for m give us

$$m = \frac{4L^2 f^2 \mu}{n^2 g} = \frac{(4)(1.2 \text{ m})^2 (120 \text{ Hz})^2 (0.0016 \text{ kg/m})}{(4)^2 (9.8 \text{ m/s}^2)} \\ = 0.846 \text{ kg} \approx 0.85 \text{ kg}. \quad (\text{Answer}) \quad (17-52)$$

(b) What standing wave mode is set up if $m = 1.00 \text{ kg}$?

SOLUTION ■ If we insert this value of m into Eq. 17-52 and solve for n , we find that $n = 3.7$. A **Key Idea** here is that n must be an integer, so $n = 3.7$ is impossible. Thus, with $m = 1.00 \text{ kg}$, the vibrator cannot set up a standing wave on the string, and any oscillation of the string will be small, perhaps even imperceptible.

17-12 Phasors

We can represent a wave on a string (or any other type of wave) with a **phasor**. In essence, a phasor is an arrow that has a magnitude equal to the amplitude of the wave and that rotates around an origin; the angular speed of the phasor is equal to the angular frequency ω of the wave. For example, the wave

$$y_1(x, t) = Y_1 \sin(kx - \omega t), \quad (17-53)$$

which has an initial phase of $(\phi_0)_1 = 0 \text{ rad}$. It is represented at a time $t > 0 \text{ s}$, and location x along a string by the phasor shown in Fig. 17-30a. The magnitude of the phasor is the amplitude Y_1 of the wave. As the phasor rotates around the origin at angular speed ω , its projection y_1 on the vertical axis varies sinusoidally, from a maximum of Y_1 through zero to a minimum of $-Y_1$ and then back to Y_1 . This variation corresponds to the sinusoidal variation in the displacement $y_1(x, t)$ of any chosen point x along the string as the wave passes through it.

When two waves travel along the same string in the same direction, we can represent them and their resultant wave in a *phasor diagram*. The phasors in Fig. 17-30b represent the wave of Eq. 17-53 and a second wave given by

$$y_2(x, t) = Y_2 \sin(kx - \omega t + \phi_0), \quad (17-54)$$

and has an initial phase of $(\phi_0)_2$. So, this second wave is phase-shifted from the first wave with a phase difference of $\Delta\phi = (\phi_0)_2 - (\phi_0)_1 = \phi_0 - 0 = \phi_0$. Because

FIGURE 17-30 (a) A phasor of magnitude Y_1 rotating about an origin at angular speed ω represents a sinusoidal wave with an initial phase of zero. The phasor's projection y_1 on the vertical axis represents the displacement at a point X at a time t through which the wave passes. (b) A second phasor, also of angular speed ω but of magnitude Y_2 and rotating at a constant angle ϕ_0 from the first phasor, represents a second wave, with an initial phase of ϕ_0 . (c) The resultant wave of the two waves is represented by the vector-like phasor sum Y' of the two phasors. The projection y' on the vertical axis represents the displacement of the some point x and time t as that resultant wave passes through it.

the phasors rotate at the same angular speed ω , the angle between the two phasors is always $\Delta\phi = \phi_0$. If $\Delta\phi$ is a *positive* quantity, then the phasor for wave 2 *lags* the phasor for wave 1 as they rotate, as drawn in Fig. 17-30b. If $\Delta\phi$ is a *negative* quantity, then the phasor for wave 2 *leads* the phasor for wave 1.

Since waves y_1 and y_2 have the same wave number k and angular frequency ω , we know from Eq. 17-37 that if the two waves have the same amplitude ($Y = Y_1 = Y_2$) then their resultant is of the form

$$y'(x,t) = Y'\sin(kx - \omega t + \phi'_0), \quad (17-55)$$

where $Y' = 2Y\cos(\frac{1}{2}\phi_0)$ is the amplitude of the resultant wave and $\phi'_0 = \frac{1}{2}\phi_0$ is its phase. We used Eq. 17-37 to determine the equations for Y' and ϕ'_0 by superimposing the two combining waves.

Finding the superimposed wave is much easier using a phasor diagram. This is because even though phasors are not really vectors that have defined vector dot and cross products, they add like vectors. So even if the amplitudes Y_1 and Y_2 and frequencies ω_1 and ω_2 of two waves are not the same, we can use a vector-like phasor sum to find an equation for the resultant wave at any instant during their rotation. For example, we simply use the rules of vector addition to sum of the two phasors at any instant during their rotation. Fig. 17-30c shows how phasor Y_2 can be shifted to the head of phasor Y_1 . The magnitude of the phasor sum equals the amplitude Y' in Eq. 17-55. The angle between the phasor sum and the phasor for y_1 equals the initial phase of the combined wave given in Eq. 17-55 as $\phi'_0 = \frac{1}{2}\phi_0$.

Although we have shown how phasors can be combined for a situation for which the amplitudes and frequencies are the same, it is important to note that:

We can use phasors to combine waves *even if their amplitudes and frequencies are different.*

TOUCHSTONE EXAMPLE 17-8: Combining Two Waves

Two sinusoidal waves $y_1(x, t)$ and $y_2(x, t)$ have the same wavelength and travel together in the same direction along a string. Their amplitudes are $Y_1 = 4.0$ mm and $Y_2 = 3.0$ mm, and their initial phases are 0 and $\pi/3$ rad, respectively. What are the amplitude Y' and initial phase ϕ'_0 of the resultant wave (in the form of Eq. 17-55)?

SOLUTION ■ One **Key Idea** here is that the two waves have a number of properties in common: they travel along the same string and so have the same speed v^{wave} , angular wave number $k (= 2\pi/\lambda)$, and the same angular frequency $\omega (= kv^{\text{wave}})$.

A second **Key Idea** is that the waves can be represented by phasors rotating at the same angular speed ω about an origin. Because the initial phase for wave 2 is *greater* than that for wave 1 by

$\pi/3$, phasor 2 must *lag* phasor 1 by $\pi/3$ rad in their clockwise rotation, as shown in Fig. 17-31. The resultant wave due to the interference of waves 1 and 2 can then be represented by a phasor that is a vector-like sum of phasors 1 and 2.

To simplify the phasor summation, we drew phasors 1 and 2 in Fig. 17-31a at the instant when phasor 1 lies along the horizontal axis and the lagging phasor 2 at positive angle $\pi/3$ rad. In Fig. 17-31b we shifted phasor 2 so its tail is at the head of phasor 1. Then we draw the phasor Y' of the resultant wave from the tail of phasor 1 to the head of phasor 2. The initial phase ϕ'_0 of the combined is the angle phasor 2 makes with respect to phasor 1.

Though phasors are not really vectors, they can be added using vector addition rules. To find values for Y' and ϕ'_0 we can sum phasors 1 and 2 directly on a vector-capable calculator, by

FIGURE 17-31 (a) Two phasors of magnitudes Y_1 and Y_2 with phase difference $\pi/3$. (b) Phasor addition at any instant during their rotation gives the magnitude Y' of the phasor for the resultant wave.

adding a vector of magnitude 4.0 mm and angle 0 rad to a vector of magnitude 3.0 mm and angle $\pi/3$ rad, or we can add the phasors using vector components. For the horizontal components we have

$$\begin{aligned} Y'_h &= Y_1 \cos 0 + Y_2 \cos \pi/3 \\ &= 4.0 \text{ mm} + (3.0 \text{ mm}) \cos \pi/3 = 5.50 \text{ mm}. \end{aligned}$$

For the vertical components we have

$$\begin{aligned} Y'_v &= Y_1 \sin 0 + Y_2 \sin \pi/3 \\ &= 0 + (3.0 \text{ mm}) \sin \pi/3 = 2.60 \text{ mm}. \end{aligned}$$

Thus, the resultant wave has an amplitude of

$$\begin{aligned} Y' &= \sqrt{(5.50 \text{ mm})^2 + (2.60 \text{ mm})^2} \\ &= 6.1 \text{ mm} \end{aligned} \quad (\text{Answer})$$

and an initial resultant wave phase of

$$\phi'_0 = \tan^{-1} \frac{2.60 \text{ mm}}{5.50 \text{ mm}} = 0.44 \text{ rad}. \quad (\text{Answer})$$

From Fig. 17-31b, the initial phase for wave 2, given by ϕ_0 , is a *positive* angle relative to the initial phase of wave 1. Thus, the resultant wave *lags* wave 1 by an initial phase of $\phi'_0 = 0.44$ rad. From Eq. 17-55, we can write the resultant wave as

$$y'(x,t) = (6.1 \text{ mm}) \sin(kx - \omega t + 0.44 \text{ rad}). \quad (\text{Answer})$$

Problems

SEC. 17-5 ■ WAVE VELOCITY

1. Angular Frequency A wave has an angular frequency of 110 rad/s and a wavelength of 1.80 m. Calculate (a) the angular wave number and (b) the speed of the wave.

2. Electromagnetic Waves The speed of electromagnetic waves (which include visible light, radio, and x-rays) in vacuum is 3.0×10^8 m/s. (a) Wavelengths of visible light waves range from about 400 nm in the violet to about 700 nm in the red. What is the range of frequencies of these waves? (b) The range of frequencies for shortwave radio (for example, FM radio and VHF television) is 1.5 to 300 MHz. What is the corresponding wavelength range? (c) X-ray wavelengths range from about 5.0 nm to about 1.0×10^{-2} nm. What is the frequency range for x-rays?

3. Sinusoidal Wave A sinusoidal wave travels along a string. The time for a particular point to move from maximum displacement to zero is 0.170 s. What are the (a) period and (b) frequency? (c) The wave length is 1.40 m; what is the wave speed?

4. Write the Equation Write the equation for a sinusoidal wave traveling in the negative direction along an x axis and having an amplitude of 0.010 m, a frequency of 550 Hz, and a speed of 330 m/s.

5. Show That Show that

$$y(x,t) = Y \sin k(x - vt), \quad y(x,t) = Y \sin 2\pi \left(\frac{x}{\lambda} - ft \right),$$

$$y(x,t) = Y \sin \omega \left(\frac{x}{v} - t \right), \quad y(x,t) = Y \sin 2\pi \left(\frac{x}{\lambda} - \frac{t}{T} \right)$$

are all equivalent to $y(x,t) = Y \sin(kx - \omega t)$.

6. Equation of a Transverse The equation of a transverse wave traveling along a very long string is $y(x,t) = (6.0 \text{ cm}) \sin \{(0.020 \pi \text{ rad/cm})x + (4.0 \pi \text{ rad/s})t\}$ where x and y are expressed in centimeters and t is in seconds. Determine (a) the amplitude, (b) the wavelength, (c) the frequency, (d) the speed, (e) the direction of propagation of the wave, and (f) the maximum transverse speed of a particle in the string. (g) What is the transverse displacement at $x = 3.5$ cm when $t = 0.26$ s?

7. Write an Equation (a) Write an equation describing a sinusoidal transverse wave traveling on a cord in the $+x$ direction with a wavelength of 10 cm, a frequency of 400 Hz, and an amplitude of 2.0 cm. (b) What is the maximum speed of a point on the cord? (c) What is the speed of the wave?

8. Transverse Sinusoidal A transverse sinusoidal wave of wavelength 20 cm is moving along a string in the positive x direction. The transverse displacement of the string particle at $x = 0$ cm as a function of time is shown in Fig. 17-32. (a) Make a rough sketch of one wavelength of the wave (the portion between $x = 0$ cm and $x = 20$ cm) at time $t = 0$ s. (b) What is the speed of the wave? (c) Write the equation for the wave with all the constants evaluated. (d) What is the transverse velocity of the particle at $x = 0$ m at $t = 5.0$ s?

FIGURE 17-32 Problem 8.

9. Sinusoidal Wave Two A sinusoidal wave of frequency 500 Hz has a speed of 350 m/s. (a) How far apart are two points that differ in phase by $\pi/3$ rad? (b) What is the phase difference between two displacements at a certain point at times 1.00 ms apart?

SEC. 17-6 ■ WAVE SPEED ON A STRETCHED STRING

10. Violin Strings The heaviest and lightest strings on a certain violin have linear densities of 3.0 and 0.29 g/m. (a) What is the ratio of the diameter of the heaviest string to that of the lightest string, assuming that the strings are of the same material? (b) What is the ratio of speeds if the strings have the same tension?

11. What Is the Speed What is the speed of a transverse wave in a rope of length 2.00 m and mass 60.0 g under a tension of 500 N?

12. Wire Clamped The tension in a wire clamped at both ends is doubled without appreciably changing the wire's length between the clamps. What is the ratio of the new to the old wave speed for transverse waves traveling along this wire?

13. Linear Density The linear density of a string is 1.6×10^{-4} kg/m. A transverse wave on the string is described by the equation

$$y(x,t) = (0.021 \text{ m}) \sin[(2.0 \text{ rad/m})x + (30 \text{ rad/s})t].$$

What is (a) the wave speed and (b) the tension in the string?

14. The Equation of The equation of a transverse wave on a string is

$$y(x,t) = (2.0 \text{ mm}) \sin[(20 \text{ rad/m})x - (600 \text{ rad/s})t].$$

The tension in the string is 15 N. (a) What is the wave speed? (b) Find the linear density of the string in grams per meter.

15. Stretched String A stretched string has a mass per unit length of 5.0 g/cm and a tension of 10 N. A sinusoidal wave on this string has an amplitude of 0.12 mm and a frequency of 100 Hz and is traveling in the negative direction of x . Write an equation for this wave.

16. The Fastest Wave What is the fastest transverse wave that can be sent along a steel wire? For safety reasons, the maximum tensile stress to which steel wires should be subjected is 7.0×10^8 N/m². The density of steel is 7800 kg/m³. Show that your answer does not depend on the diameter of the wire.

17. Single Particle A sinusoidal transverse wave of amplitude Y and wavelength λ travels on a stretched cord. (a) Find the ratio of the maximum particle speed (the speed with which a single particle in the cord moves transverse to the wave) to the wave speed. (b) If a wave having a certain wavelength and amplitude is sent along a cord, would this speed ratio depend on the material of which the cord is made such as wire or nylon?

18. Displacement of Particles A sinusoidal wave is traveling on a string with speed 40 cm/s. The displacement of the particles of the string at $x = 10$ cm is found to vary with time according to the equation $y(x,t) = (5.0 \text{ cm}) \sin [1.0 \text{ rad/cm} - (4.0 \text{ rad/s})t]$. The linear density of the string is 4.0 g/cm. What are the (a) frequency and (b) wavelength of the wave? (c) Write the general equation

giving the transverse displacement of the particles of the string as a function of position and time. (d) Calculate the tension in the string.

19. As a Function of Position

A sinusoidal transverse wave is traveling along a string in the negative direction of an x axis. Figure 17-33 shows a plot of the displacement as

FIGURE 17-33 ■ Problem 19.

a function of position at time $t = 0$ s; the y intercept is 4.0 cm. The string tension is 3.6 N, and its linear density is 25 g/m. Find the (a) amplitude, (b) wavelength, (c) wave speed, and (d) period of the wave. (e) Find the maximum transverse speed of a particle in the string. (f) Write an equation describing the traveling wave.

20. Three Pulleys, One Mass

In Fig. 17-34a string 1 has a linear density of 3.00 g/m, and string 2 has a linear density of 5.00 g/m. They are under tension owing to the hanging block of mass $M = 500$ g. Calculate the wave speed on (a) string 1 and (b) string 2. (*Hint:* When a string loops halfway around a pulley, it pulls on the pulley with a net force that is twice the tension in the string.) Next the block is divided into two blocks (with $M_1 + M_2 = M$) and the apparatus is rearranged as shown in Fig. 17-34b. Find (c) M_1 and (d) M_2 such that the wave speeds in the two strings are equal.

FIGURE 17-34 ■ Problem 20.

21. Two Pulses Two A wire 10.0 m long and having a mass of 100 g is stretched under a tension of 250 N. If two pulses, separated in time by 30.0 ms, are generated, one at each end of the wire, where will the pulses first meet?

22. Baseball Rubber Band The type of rubber band used inside some baseballs and golf balls obeys Hooke's law over a wide range of elongation of the band. A segment of this material has an unstretched length ℓ and a mass m . When a force \vec{F} is applied, the band stretches an additional length $\Delta\ell$. (a) What is the speed (in terms of m , $\Delta\ell$, and the spring constant k) of transverse waves on this stretched rubber band? (b) Using your answer to (a), show that the time required for a transverse pulse to travel the length of the rubber band is proportional to $1/\sqrt{\Delta\ell}$ if $\Delta\ell \ll \ell$ and is constant if $\Delta\ell \gg \ell$.

23. Uniform Rope A uniform rope of mass m and length L hangs from a ceiling. (a) Show that the speed of a transverse wave on the rope is a function of y , the distance from the lower end, and is given by $v^{\text{wave}} = \sqrt{gy}$. (b) Show that the time a transverse wave takes to travel the length of the rope is given by $t = 2\sqrt{L/g}$.

SEC. 17-7 ■ ENERGY AND POWER TRANSPORTED BY A TRAVELING WAVE IN A STRING

24. Average Power A string along which waves can travel is 2.70 m long and has a mass of 260 g. The tension in the string is 36.0 N. What must be the frequency of traveling waves of amplitude 7.70 mm for the average power to be 85.0 W?

SEC. 17-9 ■ INTERFERENCE OF WAVES

25. Two Identical Traveling Waves Two identical traveling waves, moving in the same direction, are out of phase by $\pi/2$ rad. What is the amplitude of the resultant wave in terms of the common amplitude Y of the two combining waves?

26. What Phase Difference What phase difference between two otherwise identical traveling waves, moving in the same direction along a stretched string, will result in the combined wave having an amplitude 1.50 times that of the common amplitude of the two combining waves? Express your answer in (a) degrees, (b) radians, and (c) wavelengths.

27. Identical Except for Phase Two sinusoidal waves, identical except for phase, travel in the same direction along a string and interfere to produce a resultant wave given by $y'(x,t) = (3.0 \text{ mm}) \sin [(20 \text{ rad/m})x - (4.0 \text{ rad/s})t + 0.820 \text{ rad}]$, with x in meters and t in seconds. What are (a) the wavelength λ of the two waves, (b) the phase difference between them, and (c) their amplitude Y ?

SEC. 17-11 ■ STANDING WAVES AND RESONANCE

28. A String Under Tension A string under tension F^{tension} oscillates in the third harmonic at frequency f_3 , and the waves on the string have wavelength λ_3 . If the tension is increased to $\tau_f = 4\tau_i$ and the string is again made to oscillate in the third harmonic, what then are (a) the frequency of oscillation in terms of f_3 and (b) the wavelength of the waves in terms of λ_3 ?

29. Nylon Guitar String A nylon guitar string has a linear density of 7.2 g/m and is under a tension of 150 N . The fixed supports are 90 cm apart. The string is oscillating in the standing wave pattern shown in Fig. 17-35. Calculate the (a) speed, (b) wavelength, and (c) frequency of the traveling waves whose superposition gives this standing wave.

FIGURE 17-35 ■ Problem 29.

30. Two Sinusoidal Waves Two sinusoidal waves with identical wavelengths and amplitudes travel in opposite directions along a string with a speed of 10 cm/s . If the time interval between instants when the string is flat is 0.50 s , what is the wavelength of the waves?

31. String Fixed at Both Ends A string fixed at both ends is 8.40 m long and has a mass of 0.120 kg . It is subjected to a tension of 96.0 N and set oscillating. (a) What is the speed of the waves on the string? (b) What is the longest possible wavelength for standing wave? (c) Give the frequency of that wave.

32. Between Fixed Supports A 125 cm length of string has a mass of 2.00 g . It is stretched with a tension of 7.00 N between fixed supports. (a) What is the wave speed for this string? (b) What is the lowest resonant frequency of this string?

33. Three Lowest Frequencies What are the three lowest frequencies for standing waves on a wire 10.0 m long having a mass of 100 g , which is stretched under a tension of 250 N ?

34. String A, String B String A is stretched between two clamps separated by distance L . String B , with the same linear density and under the same tension as string A , is stretched between two clamps separated by distance $4L$. Consider the first eight harmonics of string B . Which, if any, has a resonant frequency that matches a resonant frequency of string A ?

35. Resonant Frequencies A string that is stretched between fixed supports separated by 75.0 cm has resonant frequencies of 420 and 315 Hz , with no intermediate resonant frequencies. What are (a) the lowest resonant frequency and (b) the wave speed?

36. Two Pulses In Fig. 17-36, two pulses travel along a string in opposite directions. The wave speed v^{wave} is 2.0 m/s and the pulses are 6.0 cm apart at $t = 0$. (a) Sketch the wave patterns when t is equal to $5.0, 10, 15, 20,$ and 25 ms . (b) In what form (or type) is the energy of the pulses at $t = 15 \text{ ms}$?

FIGURE 17-36 ■ Problem 36.

37. A String Oscillates A string oscillates according to the equation

$$y'(x,t) = (0.50 \text{ cm}) \sin \left[\left(\frac{\pi}{3} \text{ rad/cm} \right) x \right] \cos [(40\pi \text{ rad/s})t].$$

What are the (a) amplitude and (b) speed of the two waves (identical except for direction of travel) whose superposition gives this oscillation? (c) What is the distance between nodes? (d) What is the speed of a particle of the string at the position $x = 1.5 \text{ cm}$ when $t = \frac{9}{8} \text{ s}$?

38. Standing Wave A standing wave results from the sum of two transverse waves traveling in opposite directions given by

$$y_1 = (0.05 \text{ m}) \cos ((\pi \text{ rad/m})x - (4\pi \text{ rad/s})t)$$

and

$$y_2 = (0.05 \text{ m}) \cos ((\pi \text{ rad/m})x + (4\pi \text{ rad/s})t).$$

(a) What is the smallest positive value of x that corresponds to a node? (b) At what times during the interval $0 \leq t \leq 0.50 \text{ s}$ will the particle at $x = 0.00 \text{ m}$ have zero velocity?

39. Three-Loop Standing Wave A string 3.0 m long is oscillating as a three-loop standing wave with an amplitude of 1.0 cm . The wave speed is 100 m/s . (a) What is the frequency? (b) Write equations for two waves that, when combined, will result in this standing wave.

40. In an Experiment In an experiment on standing waves, a string 90 cm long is attached to the prong of an electrically driven tuning fork that oscillates perpendicular to the length of the string at a frequency of 60 Hz . The mass of the string is 0.044 kg . What tension must the string be under (weights are attached to the other end) if it is to oscillate in four loops?

41. Tuning Fork Oscillation of a 600 Hz tuning fork sets up standing waves in a string clamped at both ends. The wave speed for the string is 400 m/s . The standing wave has four loops and an amplitude of 2.0 mm . (a) What is the length of the string? (b) Write an equation for the displacement of the string as a function of position and time.

42. Second Harmonic A rope, under a tension of 200 N and fixed at both ends, oscillates in a second-harmonic standing wave pattern. The displacement of the rope is given by

$$y(x,t) = (0.10 \text{ m}) \sin \left(\left(\frac{\pi}{2} \text{ rad/m} \right) x \right) \sin ((12\pi \text{ rad/s})t),$$

where $x = 0.00 \text{ m}$ at one end of the rope, x is in meters, and t is in seconds. What are (a) the length of the rope, (b) the speed of the waves on the rope, and (c) the mass of the rope? (d) If the rope oscillates in a third-harmonic standing wave pattern, what will be the period of oscillation?

43. A Generator A generator at one end of a very long string creates a wave given by

$$y(x,t) = (6.0 \text{ cm}) \cos \frac{\pi}{2} [(2.0 \text{ rad/m})x + (8.0 \text{ rad/s})t],$$

and one at the other end creates the wave

$$y(x,t) = (6.0 \text{ cm}) \cos \frac{\pi}{2} [(2.0 \text{ rad/m})x - (8.0 \text{ rad/s})t].$$

Calculate the (a) frequency, (b) wavelength, and (c) speed of each wave. At what x values are the (d) nodes and (e) antinodes?

44. Standing Wave Pattern A standing wave pattern on a string is described by

$$y(x,t) = (0.040 \text{ m}) \sin((5\pi \text{ rad/m})x) \cos((40\pi \text{ rad/s})t).$$

(a) Determine the location of all nodes for $0 \leq x \leq 0.40 \text{ m}$.
 (b) What is the period of the oscillatory motion of any (nonnode) point on the string? What are (c) the speed and (d) the amplitude of the two traveling waves that interfere to produce this wave?
 (e) At what times for $0.000 \text{ s} \leq t \leq 0.050 \text{ s}$ will all the points on the string have zero transverse velocity?

45. Maximum Kinetic Energy Show that the maximum kinetic energy in each loop of a standing wave produced by two traveling waves of identical amplitudes is $2\pi^2\mu Y^2 f \nu^{\text{wave}}$.

46. Antinode For a certain transverse standing wave on a long string, an antinode is at $x = 0.00 \text{ m}$ and a node is at $x = 0.10 \text{ m}$. The displacement $y(t)$ of the string particle at $x = 0.00 \text{ m}$ is shown in Fig. 17-37. When $t = 0.50 \text{ s}$, what are the displacements of the string particles at (a) $x = 0.20 \text{ m}$ and (b) $x = 0.30 \text{ m}$? At $x = 0.20 \text{ m}$, what are the transverse velocities of the string particles at (c) $t = 0.50 \text{ s}$ and (d) $t = 1.0 \text{ s}$? (e) Sketch the standing wave at $t = 0.50 \text{ s}$ for the range $x = 0.00 \text{ m}$ to $x = 0.40 \text{ m}$.

FIGURE 17-37 ■ Problem 46.

47. Aluminum Wire In Fig. 17-38, an aluminum wire, of length $L_1 = 60.0 \text{ cm}$, cross-sectional area $1.00 \times 10^{-2} \text{ cm}^2$, and density 2.60 g/cm^3 , is joined to a steel wire, of density 7.80 g/cm^3 and the same cross-sectional area. The compound wire, loaded with a block of mass $m = 10.0 \text{ kg}$, is arranged so that the distance L_2 from the joint to the supporting pulley is 86.6 cm . Transverse waves are set up in the wire by using an external source of variable frequency; a node is located at the pulley. (a) Find the lowest frequency of excitation for which standing waves are observed such that the joint in the wire is one of the nodes. (b) How many nodes are observed at this frequency?

FIGURE 17-38 ■ Problem 47.

SEC. 17-12 ■ PHASORS

48. Of the Same Period Two sinusoidal waves of the same period, with amplitudes of 5.0 and 7.0 mm , travel in the same direction along a stretched string; they produce a resultant wave with an amplitude of 9.0 mm . The initial phase of the 5.0 mm wave is 0.0 rad . What is the initial phase of the 7.0 mm wave?

49. Amplitude of the Resultant Determine the amplitude of the resultant wave when two sinusoidal string waves having the same frequency and traveling in the same direction on the same string are combined, if their amplitudes are 3.0 cm and 4.0 cm and they have initial phases of 0.0 and $\pi/2 \text{ rad}$, respectively.

50. Three Sinusoidal Waves Three sinusoidal waves of the same frequency travel along a string in the positive direction of an x axis. Their amplitudes are y_1 , $y_1/2$, and $y_1/3$, and their initial phases are 0 , $\pi/2$, and $\pi \text{ rad}$, respectively. What are (a) the amplitude and (b) the phase constant of the resultant wave? (c) Plot the wave form of the resultant wave at $t = 0.00 \text{ s}$, and discuss its behavior as t increases.

Additional Problems

51. Graphing a Pulse on a String Consider the motion of a pulse on a long taut string. We will choose our coordinate system so that when the string is at rest, the string lies along the x axis of the coordinate system. We will take the positive direction of the x axis to be to the right on this page and the positive direction of the y axis to be up. Ignore gravity. A pulse is started on the string moving to the right. At a time $t_1 = 0 \text{ s}$ a photograph of the string would look like Fig. 17-39A. A point on the string to the right of the pulse is marked by a spot of red paint.

For each of the items that follow, identify which figure (B-F) would look most like the graph of the indicated quantity. (Take the positive axis as up.) If none of the figures look like you expect the graph to look, write N. Assume that the axes would be labeled with correct units.

(a) The graph of the y displacement of the spot of red paint as a function of time.

(b) The graph of the x velocity of the spot of red paint as a function of time.

(c) The graph of the y velocity of the spot of red paint as a function of time.

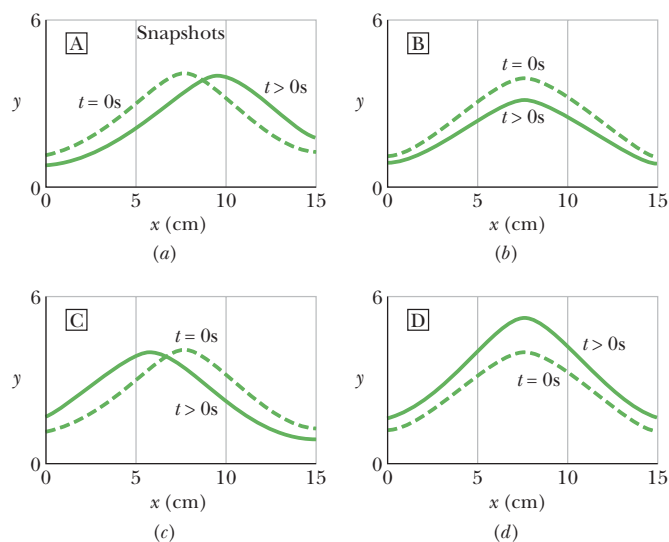

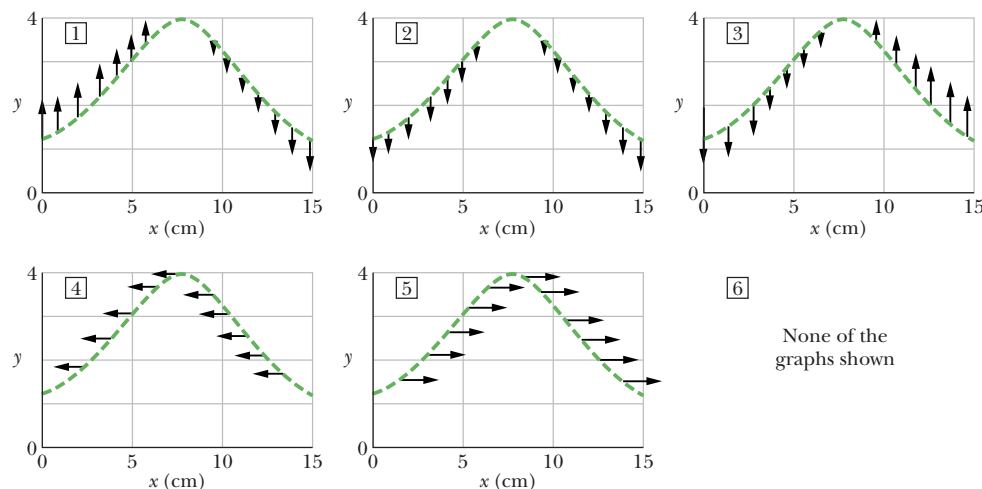

FIGURE 17-39 ■ Problem 51.

FIGURE 17-40 ■ Problem 52.

FIGURE 17-41 ■ Problem 53.

FIGURE 17-42(a) ■ Problem 55.

FIGURE 17-42(b) ■ Problem 55.

(d) The graph of the y -component of the force on the piece of string marked by the red spot as a function of time.

52. Motion in a Standing Wave A string is connected at one end to a vibrating reed and on the other to a weight pulling the string tight over a pulley. At the time $t = 0.00$ s a photograph of the string looks like Fig. 17-40a. The displacement of the wave is then observed to grow, reaching a maximum of 3 cm at $t = 0.02$ s. The displacement of the wave then decreases with time and at time $t = 0.06$ s appears flat, as shown in Fig. 17-40b.

Each box in the grid has a side of 1 cm. (a) Two points on the string are marked with heavy black dots and with the letters A and B. At $t = 0.00$ s, in what direction is each of them moving and which one (if any) is moving faster? (b) At $t = 0.06$ s, mark the position of the two points on the string in the figure (b). In what direction is each of

them moving and which one (if any) is moving faster? (c) What is the period of the oscillation? (d) Explain what could be changed to make the velocity of point A zero throughout the oscillation. Give two different ways to do this, and explain why such a change would work.

53. Displacement and Velocity Patterns in Waves Each graph shown in Fig. 17-41 may represent either a picture of the shape of a wave on a string at a particular instant in time, t_1 , or the transverse (up and down) velocity of the mass points of that string at that time. Depending on which it is, the wave on the string may be:

(a) A right-moving traveling wave, (b) A left-moving traveling wave, (c) A part of a standing wave with a displacement that increases in time and is shown at time t_1 , (d) A part of a standing wave with a displacement that decreases in time and is shown at time t_1 . For each of the following cases, decide what the wave is doing and choose one of the four letters (a)–(d).

- Graph A is a graph of the string's shape and graph B is a graph of the string's velocity.
- Graph A is a graph of both the string's shape and the string's velocity.
- Graph B is a graph of the string's shape and graph A is a graph of the string's velocity.

54. Interpreting an Oscillatory Equation

Consider the equation

$$y(x,t) = Y \cos(at) \sin(bx)$$

Let x represent some position and t represent time. (a) Describe a physical situation represented by this equation. As part of your description include a sketch and a written description. Indicate what y and x correspond to in the situation you describe. (b) How, if at all, would the physical situation you described in part (a) be different if a were twice as large? Explain how you determined your answer. (c) How, if at all, would the physical situation you described in part (a) be different if b were twice as large? Explain how you determined your answer.

55. Waves and Velocities The four graphs labeled (A)–(D) in Fig. 17-42a show snapshots of waves on a long, taut

string. The dashed line shows a picture of a part of the string at the time $t = 0$ s. The solid line is a picture at a time a little bit later. Each of these pictures looks the same at $t = 0$ s, but the results differ because the parts of the string have different velocities at $t = 0$ in each case.

For each of the four cases, select one of the six patterns shown in Fig. 17-42b as the correct velocity pattern for the motion of adjacent string elements to lead to the solid line in Fig. 17-42a, showing the displacement y . (Note the arrows indicate mainly direction. Their lengths are scaled somewhat in proportion to their magnitude, but not strictly so.)

56. Making a Pulse Move A transverse wave pulse is traveling in the $+x$ direction along a long stretched string. The origin is taken at a point on the string that is far from the ends. The speed of the wave is v (a positive number). At time $t = 0$ s, the displacement of the string is described by the function

$$y = f(x,0) = \begin{cases} A\left(1 - \frac{|x|}{\ell}\right) & |x| \leq \ell \\ 0 & |x| \geq \ell \end{cases}$$

(a) Construct a graph that portrays the actual shape of the string at $t = 0$ s for the case $A = \ell/2$. (b) Sketch a graph of the wave form at the following times: 1. $t = \ell/v$, 2. $t = 2\ell/v$, 3. $t = -3\ell/2v$.

57. Comparing Waves Figure 17-43 shows a snapshot of a piece of a wave at a time $t = 0$ s. Make four sketches of this picture and use a dotted line to sketch what each pulse would look like at a slightly later time (a time that is small compared to the time it would take the pulse to move a distance equal to its own width but large enough to see a change in the shape of the string) for the following four cases:

FIGURE 17-43 ■ Problem 57.

- A. The pulse is a traveling wave moving to the right.
- B. The pulse is a traveling wave moving to the left.
- C. The pulse is a standing wave with a displacement that increases in time.
- D. The pulse is a standing wave with a displacement that decreases in time.

On each picture, draw arrows to show the velocity of the marked points at time $t = 0$ s.

58. Combining Pulses Figure 17-44 shows graphs that could represent properties of pulses on a stretched string. For the situation and the properties (a)–(e), select which graph provides the best representation of the given property. If none of the graphs are correct, write “none.”

Two pulses are started on a stretched string. At time $t = t_1$, an upward pulse is started on the right that moves to the left. At the same instant, a downward pulse is started on the left that moves to the right. At t_1 their peaks are separated by a distance $2s$. The distance between the pulses is much larger than their individual widths. The pulses move on the string with a speed v_1 . The scales in

FIGURE 17-44 ■ Problem 58.

the graphs are arbitrary and not necessarily the same. (a) Which graph best represents the appearance of the string at time t_1 ? (b) Which graph best represents the appearance of the string at a time $t_1 + s/v_1$? (c) Which graph best represents the appearance of the string at a time $t_1 + 2s/v_1$? (d) Which graph best represents the velocity of the string at a time $t_1 + s/v_1$? (e) Which graph best represents the appearance of the string at a time $t_1 + s/v_1 + \epsilon$ where ϵ is small compared to s/v_1 ?

59. Moving a Nonsymmetric Triangular Pulse A long taut spring is started at a time $t = 0$ with a pulse moving in the $+x$ direction in the shape given by the function $f(x)$ with

$$f(x) = \begin{cases} \frac{1}{4}x + 1 & -4 < x < 0 \\ -x + 1 & 0 < x < 1 \\ 0 & \text{otherwise} \end{cases}$$

(The units of x and f are in centimeters.) (a) Draw a labeled graph showing the shape of the string at $t = 0$. (b) If the mass density of the string is 50 g/m and it is under a tension of 5 N, draw a labeled graph that shows the shape and position of the string at a time $t = 0.001$ s. (c) Write the solution of the wave equation that explicitly gives the displacement of any piece of the string at any time. (d) What is the speed of a piece of string that is moving up after the pulse has reached it but before it has risen to its maximum displacement? What is its speed while it is returning to its original position after the pulse’s peak has passed it?

60. Which Wave Is Which? Figure 17-45a shows a picture of a string at a time t_1 . The pieces of the string are each moving with velocities that are indicated by arrows in the picture. (The vertical displacements are small and don’t show up in the picture.) Figure 17-45b shows five graphs that could give the shape of the string at the instant for which the velocities are displayed above. (Note: The vertical scale magnifies the displacement by a factor of 100.)

FIGURE 17-45 ■ Problem 60.

On your paper, place the letters A–E. Next to these letters, indicate for the graphs labeled by those letters, whether the string is moving as a: (L) left-traveling wave, (R) right-traveling wave, (S+) standing wave with a displacement that increases in time, (S–) standing wave with a displacement that decreases in time, or (N) none of the above.

61. Spring vs. String In this course, we analyzed the motion of a mass on a spring and the oscillations of a taut string. Discuss these two systems, explaining similarities and differences, and give an equation of motion for each.

62. Parsing a Pulse

An instructor is demonstrating the motion of waves on a long, taut spring. He is holding the spring at

FIGURE 17-46 ■ Problem 62.

one end and will move it so the spring will move back and forth on the floor. The spring is rigidly connected to a metal rod at its other end. The spring is under a tension T and it has a mass density μ . The instructor starts a pulse moving toward the right as shown in Fig. 17-46. The pulse is triangular and is *not* symmetric. The figure is shown at a time t_1 . (a) Calculate the time τ it will take the peak of the pulse to reach the wall (to travel a distance s). (b) What will the spring look like at the time $t_1 + \tau$? Draw a carefully constructed and labeled diagram to show what it looks like and how you got your result. (c) What will the spring look like a bit later—say, at a time $t_1 + 2\tau$? What is responsible for this result? (d) The width of the pulse is 0.5 m. If the tension in the spring is 5 N and it has a mass density of 0.1 kg/m, how much time did the professor take to generate the pulse?

63. Modified Harmonics A taut string is tied down at both ends. Assume that the fundamental mode of oscillation of the string has a period T_0 . For each of the changes described below give the factor by which the period changes. For example, if the change described resulted in a period twice as long, you would put the number “2.” Do not accumulate changes. That is, before each change, assume you are back at the original starting situation. (a) The string is replaced by one of twice the mass but of the same length. (b) The wave length of the starting shape is divided by three. (c) The amplitude of the oscillation is doubled. (d) The tension of the string is halved.

64. Spring vs. String: Graphs Consider two physical systems: System A is a mass hanging from a light spring fixed at one end to a ringstand on a table above the floor. System B is a long spring of uniform density held under tension and able to move transversely in a horizontal plane.

Figure 17-47 shows three graphs labeled #1, #2, and #3, with unmarked axes. They could represent many quantities in the physical systems A and B. For the five physical quantities below, indicate which of the

FIGURE 17-47 ■ Problem 64.

graphs could be obtained for the system indicated. If more than one graph applies, give *all* the possible choices. If none applies, write N.

- (a) The height of the mass hanging from the spring (system A) above the ground as a function of time for some time interval after the mass has been set into oscillation
- (b) The transverse displacement from equilibrium of some portion of the long spring (system B) as a function of position at a particular instant of time while it is carrying a harmonic wave
- (c) The velocity of the mass hanging from the spring (system A) as a function of time given that its displacement from equilibrium as a function of time is given by graph #1
- (d) The transverse velocity of a small piece of the long spring (system B) as a function of time as a single pulse moves down the spring
- (e) The velocity of a small piece of the long spring (system B) as a function of time given that its displacement from equilibrium as a function of time is given by graph #2

65. Explaining the Wave Equation The wave equation

$$\frac{\partial^2 y}{\partial x^2} = \frac{1}{v_1^2} \frac{\partial^2 y}{\partial t^2}$$

is often used to describe the transverse displacement of waves on a stretched spring. Explain the meaning of each of the elements of this equation with reference to the physical spring and discuss under what circumstances you expect it to be a good description.

66. Propagating a Gaussian Pulse

Figure 17-48 shows the shape of a pulse on a stretched spring at the time $t = 0$ s. The displacement of the spring from its equilibrium position at that time is given by

FIGURE 17-48 ■ Problem 66.

$$F(x) = Ae^{-(x/b)^2}$$

The pulse is moving in the positive x direction with a velocity v_1 . (a) Sketch a graph showing the shape of the spring at a later time, $t = t_2$. Specify the height and position of the peak in terms of the symbols given. (b) Write an equation for the displacement of any portion of the spring at any time $y(x,t)$. (c) Sketch a graph of the velocity of the piece of the spring at the position $x = 2b$ as a function of time.

67. Varying a Pulse* A long, taut string is attached to a distant wall as shown in Fig. 17-49. A demonstrator moves her hand and creates a very small amplitude pulse that reaches the wall in a time t_1 . A small red dot is painted on the string halfway between the demonstrator’s hand and the wall. For each situation below, state which of the actions 1–10 listed (taken by itself) will produce the desired result. For each question, *more than one answer may be correct*. If so, give them all.

FIGURE 17-49 ■ Problem 67.

*From the *Wave Test* by M. Wittmann.

Tell how, if at all, the demonstrator can repeat the original experiment to produce: (a) A pulse that takes a longer time to reach the wall (b) A pulse that is wider than the original pulse (c) A pulse that makes the red dot travel a further distance than in the original experiment

1. Move her hand more quickly (but still only up and down once and still by the same amount)
2. Move her hand more slowly (but still only up and down once and still by the same amount)
3. Move her hand a larger distance but up and down in the same amount of time
4. Move her hand a smaller distance but up and down in the same amount of time
5. Use a heavier string of the same length under the same tension
6. Use a lighter string of the same length under the same tension
7. Use a string of the same density, but decrease the tension
8. Use a string of the same density, but increase the tension
9. Put more force into the wave
10. Put less force into the wave

68. Reflecting on a Textbook Error Figure 17-50 is taken from the first edition of a popular standard textbook. Column (a) shows a pulse approaching and reflecting from a fixed end. Column (b) a pulse approaching and reflecting from a free end (ring sliding on a frictionless rod). At least six (6!) of the figures are incorrect. State which and explain why. (*Hint:* The second edition of the book fixed most of the problems by making the pulses symmetric.)

FIGURE 17-50 ■ Problem 68.

69. Graphing Another Pulse on a String Figure 17-51a shows a photograph of a pulse on a taut string moving to the right. The red dot the right of the figure is a small bead of negligible mass attached to the string.

FIGURE 17-51(a) ■ Problem 69.

For each of the following quantities, select the letter of the graph in Fig. 17-51b that could provide a correct graph of the quantity (if the vertical axis were assigned the proper units) and write it on your answer sheet. If none of the graphs could work, write N.

- (a) The vertical (up-down) displacement of the bead
- (b) The vertical velocity of the bead
- (c) The horizontal (left-right) displacement of the bead
- (d) The horizontal velocity of the bead

FIGURE 17-51(b) ■ Problem 69.

18

Sound Waves

This horseshoe bat not only can locate a moth flying in total darkness, but can also determine the moth's relative speed, to home in on the insect.

How does the bat's detection system work, and how can a moth "jam" the system or otherwise reduce its effectiveness?

The answer is in this chapter.

18-1 Sound Waves

What Is a Sound Wave?

As we saw in Chapter 17, there are two types of mechanical waves that require a material medium to exist: *transverse waves* that involve displacements of a medium perpendicular to the direction in which the wave travels, and *longitudinal waves* that have displacements of a medium parallel to the direction of wave travel. Examples of longitudinal waves include the expansion/compression waves in the Slinky described in the last chapter (Fig. 17-1) and the waves in an air-filled pipe shown in Fig. 18-1.

When we hear sounds, we are detecting longitudinal waves passing through air that have frequencies within the range of human hearing. A **sound wave** can be defined more broadly as a longitudinal wave of any frequency passing through a medium. The medium can be a solid, liquid, or gas. For example, geological prospecting teams use sound waves to probe the Earth's crust for oil. Ships carry sound-emitting gear (sonar) to detect underwater obstacles. Medical personnel use high-frequency sound waves (ultrasound) to create computer-processed images of soft tissues (as shown in Fig. 18-2). Physics students use ultrasound pulses to track the motion of objects in the laboratory.

In this chapter we focus on the characteristics of audible sound waves that travel through air. We start by considering some differences in how waves propagate in one-, two-, and three-dimensional spaces.

Wave Dimensions

Unlike the wave pulses that travel in a straight line along a string, a sound wave from a small “point-like” source is usually not constrained to travel in only one direction. The same is true for the electromagnetic waves that we will study in Chapters 34–38. In order to understand how sound waves and electromagnetic waves travel in more than one dimension, we need to consider how the dimensionality of the space through which a wave propagates affects it.

In the previous chapter we observed that the crest of a wave passing along a one-dimensional string moves along a line. If we constrain a sound wave to travel in

FIGURE 18-1 ■ A sound wave is set up in an air-filled pipe by moving a piston back and forth. Because the oscillations of a segment of the air (represented by the black dot) are parallel to the direction in which the wave travels, the wave is a *longitudinal wave*.

FIGURE 18-2 ■ An image of a fetus flexing an arm. This image is made with ultrasound waves that have a frequency of 4 MHz—two hundred times higher than the threshold of human hearing.

FIGURE 18-3 ■ Water on the surface of a tank of water is disturbed as a steel ball of diameter 0.79 cm falls into the water. The wave crest propagates outward from the source of the disturbance in a widening circle. The wave crest moves at a constant speed of approximately 30 cm/s.

a long tube, its compression wave crests would lie in planes perpendicular to the axis of the tube as shown in Fig. 18-1. Such a one-dimensional wave is known as a **plane wave**. For example, the relatively narrow beam of sound waves that are emitted from an ultrasonic motion detector described in Section 1-8 behave like one-dimensional plane waves.

On the other hand, if you put a small sound source between two large sheets of plywood, the sound wave crests will propagate outward in expanding circles. Although we cannot see sound waves as they propagate in two dimensions, we have all seen two-dimensional surface waves on water. For example, when a pebble is dropped onto the surface of a pond, a wave crest propagates out from the pebble in an expanding circle as shown in Fig. 18-3. This two-dimensional wave is known as a **circular wave**.

If you snap your fingers or ring a tiny sleigh bell, a compression wave is created. At distances that are large relative to the size of the source, compression wave crests travel out in three dimensions as expanding spheres (Fig. 18-4). A three-dimensional wave is defined as a **spherical wave**, provided there is no preferred direction for the propagation of the wave energy.

It is important to understand that the dimensionality of a sound source (such as a one-dimensional wave in a guitar string) and the dimensionality of a sound wave produced by the source are not necessarily the same. Sound waves often travel through a medium with uniform density such as air or water. In this case, we can associate the dimensionality of a wave with the curvature of its wave crest as it spreads, rather than with the dimensionality of the source. In general, we can define the dimensionality of a wave in terms of any point on a propagating waveform. This is because for a wave of a given dimension, the *shape* of the wave crests (maxima) and wave troughs (minima) and points of no deflection (nodes) are the same. For example, in a two-dimensional wave the crests, troughs, and points of zero deflection are all circular or at least circular arcs.

It is useful for us to define a **wavefront** as the collection of all adjacent points on an expanding wave that have the same phase. For example, a wavefront can be the collection of all adjacent crest points. Or it can be taken to be a collection of all adjacent nodes, or all adjacent troughs. **Rays** are defined as lines directed perpendicular to the wavefronts that indicate the direction of travel of the wavefronts. The short double arrows superimposed on the rays of Fig. 18-4 indicate that the longitudinal oscillations of the air, which transmits the wave, are parallel to the rays.

A one-dimensional or plane wave is defined as any wave that has a wavefront that lies in a plane. The wavefront of a two-dimensional or circular wave lies along an expanding circle. The wavefront of a three-dimensional or spherical wave lies along an expanding sphere. These definitions are often still useful in situations where we do not have ideal point sources. For instance, a flat speaker mounted in the door of a car only emits waves in a “forward” direction. In this case we would have half-spherical three-dimensional wavefronts.

As the wavefronts move outward and their radii become larger, their curvatures decrease. Far from the source, these spheres associated with a three-dimensional wave are so large that we lose track of their curved nature all together. For example, when you listen to a singer in a concert hall, your ear is so far away from her that you cannot detect any curvature in the wavefronts she sends out. In such cases we can treat the *local* portion of a wavefront as if it lies in a plane. Thus, there are times in our study of sound when we will treat sound waves as if they are one-dimensional plane waves. Similarly, in Chapter 36 when we study how light waves interfere when passing through slits and traveling parallel to a two-dimensional surface, we can treat light waves as if they were two-dimensional rather than three-dimensional.

At this point let us return to our primary task in this chapter, which is to learn more about the nature of sound waves.

(a)

(b)

FIGURE 18-4 (a) A small sleigh bell that is rung at a steady rate. (b) If the distances from the bell to its listeners are large compared to the size of the bell, then the bell acts as a three-dimensional point source of sound. Each compression wave crest moves out in an expanding sphere. The two-dimensional cross-section of each of four wave crest spheres is shown. The short double arrows signify that the air particles oscillate parallel to the direction of motion of the wave crests. The lines drawn perpendicular to the wave crests are *rays*.

18-2 The Speed of Sound

The ability to calculate the speed of a sound wave as a function of the properties of the medium through which it travels is of great practical importance. For example, we can use our knowledge of the speed of sound in air to estimate how far away a lightning bolt is. Since sound travels approximately 0.2 mi/s in air, it will take about 5 s to travel one mile. Thus a 5 s interval between a lightning flash and a thunderclap tells us that the electrical storm is about a mile away. The ultrasonic motion detectors used in many physics laboratories bounce sound pulses off objects in their surroundings. The time of travel of the sound pulses emitted and then reflected from the motion detector is used to measure the distance between it and the reflecting object.

What properties of a medium does the speed of sound depend on? Let's draw an analogy between the speed of sound and the speed of a wave traveling along a string (Section 17-6). We found that the wave speed increases with the tension, T , in the string. However, the tension determines the magnitude of the restoring force that brings a displaced section of string back toward its equilibrium position. We also found, as expected, that the wave speed decreases with the mass of each disturbed length of the string. This makes sense since the linear mass density of the string, μ , is an inertial property that determines how rapidly, or slowly, the string can respond to the restoring forces acting on it. Thus, we can generalize (Eq. 17-25), which we derived for the wave speed along a stretched string, to

$$v_{\text{wave}} = |\vec{v}^{\text{wave}}| = \sqrt{\frac{F^{\text{tension}}}{\mu}} = \sqrt{\frac{\text{restoring property}}{\text{inertial property}}}. \quad (\text{Eq. 17-25})$$

If the medium is a fluid (such as air or water) and the wave is longitudinal, we can guess that the inertial property, corresponding to the linear density of the string μ , is the volume density ρ of the fluid. What shall we define as its restoring property?

As a sound wave passes through a fluid, elements of mass in the fluid undergo compressions and expansions due to pressure differences within the fluid. When a mass element in the fluid is compressed it has a higher pressure and pushes on adjacent fluid. This new mass element of fluid becomes compressed into a smaller volume. Then it pushes in turn on another mass element, and so on. This is how the compression wave travels through a fluid.

As shown in Fig. 18-5, the restoring property of the fluid is determined by the extent to which an element of mass changes volume when it experiences a difference in pressure (force per unit area). As a compression wave travels, the density of each mass element increases temporarily. When a fluid mass element becomes more dense its pressure rises, causing a difference in pressure between it and the mass element down the line. Just as the factor k tells us how stiff a spring is, we would like to define a factor B that tells us how “stiff” a three-dimensional medium is. The ratio of the pressure difference to the relative volume change is a property of the fluid we will call the **bulk modulus**, and define as

$$B \equiv -\frac{\Delta P}{\Delta V/V} \quad (\text{definition of bulk modulus}), \quad (18-1)$$

where $\Delta V/V$ is the fractional change in volume produced by a change in pressure ΔP . [As explained in Section 15-3, the SI unit for pressure is the newton per square meter, which is given a special name, the *pascal* (Pa).] The minus sign signifies that a rise in pressure on a medium causes its volume to decrease.

For the pressure changes associated with small amplitude sound waves, the bulk modulus in a given material is approximately constant and is a restoring factor just as

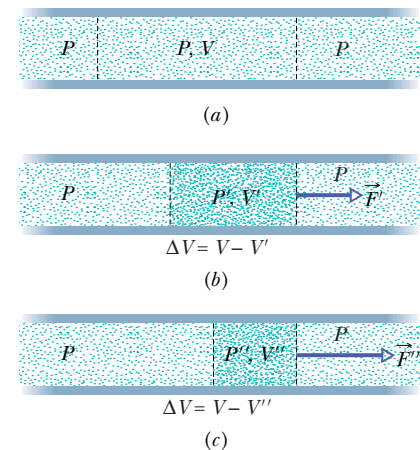

FIGURE 18-5 (a) An undisturbed tube of fluid at pressure P . (b) A compression wave passing through a fluid with a small bulk modulus causes a mass element to be compressed to a smaller volume, V' . (c) The same type of compression wave with a larger bulk modulus. It causes a mass element to undergo a greater volume reduction.

tension is in a string or k is in a spring. So we can substitute B for F^{tension} and ρ for μ in Eq. 17-25 ($v^{\text{wave}} = \sqrt{F^{\text{tension}}/\mu}$) to get

$$v^{\text{wave}} = |\vec{v}^{\text{wave}}| = \sqrt{\frac{B}{\rho}} \quad (\text{speed of sound in a fluid}). \quad (18-2)$$

Notice that as is the case for waves on a string, we expect the wave velocity to be independent of frequency and amplitude.

It can be easily shown that the dimensions of $\sqrt{B/\rho}$ are those of a velocity. It is possible to derive Eq. 18-2 mathematically using methods similar to those used in Section 17-6 to find the expression for the wave speed along a stretched string. Once again experimental results confirm the validity of Eq. 18-2.

Table 18-1 lists the speed of sound in various media.

TABLE 18-1
The Speed of Sound^a

Medium	Speed (m/s)	Density (kg/m ³)	Bulk Modulus (N/m ²)
Gases			
Air (0°C)	331		
Air (20°C)	343	1.21	1.4×10^5
Helium	965		
Hydrogen	1284		
Liquids			
Water (0°C)	1402		
Water (20°C)	1482	990	2.2×10^9
Seawater ^b	1522		
Solids			
Aluminum	6420		
Steel	5941	7850	1.6×10^{11}
Granite	6000		

^aAt 0°C and 1 atm pressure, except where noted.

^bAt 20°C and 3.5% salinity.

Note that the density of water is almost 1000 times greater than the density of air. If this were the only relevant factor, we would expect from Eq. 18-2 that the speed of sound in water would be considerably less than the speed of sound in air. However, Table 18-1 shows us that the reverse is true. We conclude (again from Eq. 18-2) that the bulk modulus of water must be more than 1000 times greater than that of air. This is indeed the case. Water is less compressible than air, which (see Eq. 18-1) is another way of saying that its bulk modulus is much greater.

FIGURE 18-6 ■ Measurement of the speed of sound. The sound pressure variations from a finger snap travel down a 2.4 m tube and back. A microphone sensor connected to a computer data acquisition system is used to measure the time between the initial sound pulses and the reflected pulses.

A graph that shows the outcome of a simple measurement of the speed of sound in air is shown in Fig. 18-6. Analysis of the data shows a speed, which is temperature-dependent, of about 345 m/s.

More About Traveling Sound Waves in Air

If the hanging Slinky discussed in Chapter 17 is pushed back and forth at one end with a continuous sinusoidal motion, we can set up a series of compressions and rarefactions like those shown in Fig. 18-7*a*. We can do the same thing when pushing a piston back and forth in a column of air as shown in Fig. 18-1. Figure 18-7*b* displays such a wave traveling rightward through a long air-filled tube. The piston's rightward motion compresses the air next to it; the piston's leftward motion allows the element of air to move back to the left and the pressure to decrease. As each element of air pushes on the next element in turn, the right-left motion of the air and the change in its pressure is passed to the next bit of air along the tube.

FIGURE 18-7 (a) A continuous longitudinal wave traveling along a hanging Slinky. (b) A sound wave, traveling through a long air-filled tube with speed \vec{v}^{wave} , consists of a moving, periodic pattern of expansions and compressions of the air. The wave is shown at an arbitrary instant. As the wave passes, a fluid element of thickness Δx (not shown) oscillates left and right in simple harmonic motion about its equilibrium position.

The alternating compressions and rarefactions (reductions in pressure) propagate as a sound wave. As a reminder of what we learned in Chapter 17, note that it is the oscillations of pressure that propagate, not the air molecules. However, the air molecules (or molecules of another fluid) are disturbed and oscillate back and forth about their initial positions.

As the wave moves, the air pressure changes at any position x in Fig. 18-7*b* in a sinusoidal fashion, like the displacement of a string element in a transverse wave, however the pressure variations are not transverse, they are longitudinal. To describe this pressure change from the local atmospheric pressure as a function of position and time for purely sinusoidal oscillations, consider Fig. 18-8. We can model our equation on Eq. 17-4, which describes the propagation of a sinusoidal transverse wave along a string. However, instead of the vertical displacement of a bit of string, we are interested in how pressure varies from an equilibrium value. Modifying Eq. 17-4 gives us

$$\Delta P(x, t) = \Delta P^{\text{max}} \sin[(kx \pm \omega t) + \phi_0], \quad (18-3)$$

where ΔP^{max} is called the **pressure amplitude**, which is the maximum change from local atmospheric pressure due to the wave. It turns out that for typical sound waves that

FIGURE 18-8 A computer data acquisition system is used to measure air pressure variations from equilibrium using a small microphone. The sampling rate was 25 000 data points/second. This pressure variation was caused by a speaker cone that oscillated sinusoidally.

we hear, ΔP^{\max} is extremely small compared to the equilibrium pressure P^{atm} present when no wave is present.

The wave number k , angular frequency ω , frequency f , wavelength λ , wave speed v^{wave} , period T , and time- and space-dependent phase $\phi(x, t)$ for a longitudinal sound wave are defined and interrelated exactly as for a transverse wave. However, note that the wavelength λ is now the distance (again along the direction of travel) in which the pattern of compression and expansion due to the wave begins to repeat itself (see Fig. 18-7b). Also note that Eq. 17-13 still holds so that the wave speed is given by $v^{\text{wave}} = \lambda f = \omega/k$.

A negative value of ΔP in Fig. 18-8 and Eq. 18-3 corresponds to an expansion of a packet of air, and a positive value corresponds to a compression.

READING EXERCISE 18-1: Verify that Eq. 18-2 is dimensionally correct. In other words, show that the term $\sqrt{B/\rho}$ has the dimensions of velocity in SI units. ■

READING EXERCISE 18-2: Examine Fig. 18-6. The maximum of the finger snap pulse set is at 0.0002 s and the maximum of the reflected pulse is at 0.0133 s. Use these times to calculate the measured value of the wave speed for the set of sound pulses as they travel back and forth through the air inside the 2.26-m-long tube. Is your calculated speed approximately the same as the speed of sound of air at room temperature as reported in Table 18-1? *Note:* The air temperature in the room was not recorded. ■

TOUCHSTONE EXAMPLE 18-1: Sound Arrival Delay

One clue used by your brain to determine the direction of a source of sound is the time delay Δt between the arrival of the sound at the ear closer to the source and the arrival at the farther ear. Assume that the source is distant so that a wavefront from it is approximately planar when it reaches you, and let D represent the separation between your ears.

(a) Find an expression that gives Δt in terms of D and the angle θ between the direction of the source and the forward direction.

FIGURE 18-9 ■ A wavefront travels a distance $d (= D \sin \theta)$ farther to reach the left ear (L) than to reach the right ear (R).

SOLUTION ■ The situation is shown (from an overhead view) in Fig. 18-9, where wavefronts approach you from a source that is located in front of you and to your right. The **Key Idea** here is that the time delay Δt is due to the distance d that each wavefront must travel to reach your left ear (L) after it reaches your right ear (R). From Fig. 18-9, we find

$$\Delta t = \frac{d}{v^{\text{air}}} = \frac{D \sin \theta}{v^{\text{air}}}, \quad (\text{Answer}) \quad (18-4)$$

where v^{air} is the speed of the sound wave in air. Based on a lifetime of experience, your brain correlates each detected value of Δt (from zero to the maximum value) with a value of θ (from zero to 90°) for

the direction of the sound source.

(b) Suppose that you are submerged in water at 20°C when a wavefront arrives from directly to your right ($\theta = 90^\circ$). Based on the time-delay clue, at what angle θ from the forward direction does the source seem to be?

SOLUTION ■ The **Key Idea** here is that the speed is now the speed of the sound wave in water, v^{water} , so in Eq. 18-4 we substitute v^{water} for v^{air} and 90° for θ , finding that

$$\Delta t_w = \frac{D \sin \theta}{v^{\text{water}}} = \frac{D}{v^{\text{water}}}, \quad (18-5)$$

Since v^{water} is about four times v^{air} , delay Δt_w is about one-fourth the maximum time delay in air. Based on experience, your brain will process the water time delay as if it occurred in air. Thus, the sound source appears to be at an angle θ smaller than 90° . To find that apparent angle we substitute the time delay D/v^{water} from Eq. 18-5 for Δt in Eq. 18-4, obtaining

$$\frac{D}{v^{\text{water}}} = \frac{D \sin \theta}{v^{\text{air}}}. \quad (18-6)$$

Then, to solve for θ we substitute $v^{\text{air}} = 343 \text{ m/s}$ and $v^{\text{water}} = 1482 \text{ m/s}$ (from Table 18-1) into Eq. 18-5, finding

$$\sin \theta = \frac{v^{\text{air}}}{v^{\text{water}}} = \frac{343 \text{ m/s}}{1482 \text{ m/s}} = 0.231,$$

and thus $\theta = 13^\circ$. (Answer)

18-3 Interference

Like transverse waves, sound waves undergo interference when two waves pass through the same point at the same time. Let us consider, in particular, the interference between two sound waves with the same frequency, wavelength, amplitude, and phase. The only difference between these waves is that they are traveling in slightly different directions. Figure 18-10 shows how we can set up such a situation: Two point sources S_1 and S_2 emit sound waves that are in phase. Thus, the sources themselves are said to be in phase; that is, as the waves emerge from the sources, their displacements are always identical. We are interested in the waves that then travel through point P in Fig. 18-10. We assume that the distance to P is much greater than the distance between the sources so that the waves are traveling in almost the same direction at P .

If the waves (which both start out at the same point in their pressure oscillation, i.e., *in phase*) traveled along paths with identical lengths to reach point P , they would still be in phase there. In this case, the displacements of the two waves would add. As with transverse waves, this means that they would undergo fully constructive interference there. However, in Fig. 18-10, path L_2 traveled by the wave from S_2 is longer than path L_1 traveled by the wave from S_1 . The difference in path lengths means that the waves may not be in phase at point P and so might be at different points in their oscillations.

We can use the definition of phase (from Section 17-4) to determine the phase difference. We specified that the waves had the same phase at locations S_1 and S_2 . So we can set $(\phi_0)_1 = (\phi_0)_2$. Thus, the phase difference when the two waves arrive at point P at a common time t is given by

$$\Delta\phi = \phi_2(x, t) - \phi_1(x, t) = [kL_2 - \omega t + (\phi_0)_2] - [kL_1 - \omega t + (\phi_0)_1] = k(L_2 - L_1). \quad (18-7)$$

Indeed the magnitude of the phase difference $\Delta\phi$ at P depends on the **path length difference** $\Delta L = |L_2 - L_1|$ of the two waves. Since the wave number $k = 2\pi/\lambda$, we can rewrite $\Delta\phi = k\Delta L$ as

$$|\Delta\phi| = \frac{\Delta L}{\lambda} 2\pi \quad (\text{path length-phase difference relation}). \quad (18-8)$$

Fully constructive interference occurs when the phase difference, $\Delta\phi$, is zero, 2π , or any integer multiple of 2π .

We can write this condition as

$$|\Delta\phi| = m(2\pi), \quad \text{for } m = 0, 1, 2, \dots \quad (\text{fully constructive interference}), \quad (18-9)$$

or from Eq. 18-8, this also occurs when the ratio $\Delta L/\lambda$ is

$$\frac{\Delta L}{\lambda} = m \quad (\text{fully constructive interference}), \quad (18-10)$$

where m is zero or any positive integer.

For example, if the magnitude of the path length difference $\Delta L = |L_2 - L_1|$ in Fig. 18-10 is equal to 2λ , then $\Delta L/\lambda = 2$ and the waves undergo fully constructive interference at point P . The interference is fully constructive because the wave from S_2 is phase-shifted relative to the wave from S_1 by 2λ , putting the two waves *exactly in phase* at P .

Fully destructive interference occurs when the magnitude of the phase difference between the two waves $\Delta\phi$ is an odd multiple of π .

FIGURE 18-10 ■ Two point sources S_1 and S_2 emit spherical sound waves in phase. The rays indicate that the waves pass through a common point P . (Recall that rays are lines that run perpendicular to the wavefront and indicate direction of travel.)

We can write this as

$$|\Delta\phi| = (2m + 1)\pi \quad (\text{fully destructive interference}), \quad (18-11)$$

where once again m is zero or any positive integer. From $|\Delta\phi| = (\Delta L/\lambda)2\pi$ (Eq. 18-8), this we see occurs when the ratio $\Delta L/\lambda$ is

$$\frac{\Delta L}{\lambda} = \frac{2m + 1}{2} = m + \frac{1}{2} \quad (\text{fully destructive interference}). \quad (18-12)$$

For example, if the path length difference $\Delta L = |L_2 - L_1|$ in Fig. 18-10 is equal to 2.5λ , then $\Delta L/\lambda = 2.5$ and the waves undergo fully destructive interference at point P . The interference is fully destructive because the wave from S_2 is phase-shifted relative to the wave from S_1 by 2.5 wavelengths, which puts the two waves *exactly out of phase* at P .

Of course, two waves could produce intermediate interference as, say, when $\Delta L/\lambda = 1.2$. This would be closer to fully constructive interference ($\Delta L/\lambda = 1.0$) than to fully destructive interference ($\Delta L/\lambda = 1.5$).

If the initial phase of one of the interfering waves is different than that of the other, we would have to derive a different set of conditions for constructive and destructive interference.

TOUCHSTONE EXAMPLE 18-2: Constructive Interference

In Fig. 18-11a, two point sources S_1 and S_2 , which are in phase and separated by distance $D = 1.5\lambda$, emit identical sound waves of wavelength λ .

FIGURE 18-11 (a) Two point sources S_1 and S_2 , separated by distance D , emit spherical sound waves in phase. The waves travel equal distances to reach point P_1 . Point P_2 is on the line extending through S_1 and S_2 . (b) The path length difference (in terms of wavelength) between the wave from S_1 and S_2 , at eight points on a large circle around the sources.

(a) What is the path length difference of the waves from S_1 and S_2 at point P_1 , which lies on the perpendicular bisector of distance D , at a distance greater than D from the sources? What type of interference occurs at P_1 ?

SOLUTION The **Key Idea** here is that, because the waves travel identical distances to reach P_1 , their path length difference is

$$\Delta L = 0.0\lambda. \quad (\text{Answer})$$

From Eq. 18-10, this means that the waves undergo fully constructive interference at P_1 .

(b) What are the path length difference and type of interference at point P_2 in Fig. 18-11a?

SOLUTION Now the **Key Idea** is that the wave from S_1 travels the extra distance $D (= 1.5\lambda)$ to reach P_2 . Thus, the path length difference is

$$\Delta L = 1.5\lambda. \quad (\text{Answer})$$

From Eq. 18-12, this means that the waves are exactly out of phase at P_2 and undergo fully destructive interference there.

(c) Figure 18-11b shows a circle with a radius much greater than D , centered on the midpoint between sources S_1 and S_2 . What is the number of points N around this circle at which the interference is fully constructive?

SOLUTION Imagine that, starting at point a , we move clockwise along the circle to point d . One **Key Idea** here is that as we move to point d , the path length difference ΔL increases and so the type of interference changes. From (a), we know that the path length difference is $\Delta L = 0.0\lambda$ at point a . From (b), we know that $\Delta L = 1.5\lambda$ at point d . Thus, there must be one point along the circle between a and d at which $\Delta L = \lambda$, as indicated in Fig. 18-11b. From Eq. 18-10, fully constructive interference occurs at that point. Also, there can be no other point along the way from point a to point d at which fully constructive interference occurs, because there is no other integer than 1 between 0.0 and 1.5.

Another **Key Idea** here is to use symmetry to locate the other points of fully constructive interference along the rest of the circle. Symmetry about line cd gives us point b , at which $\Delta L = 0\lambda$. Also, there are three more points at which $\Delta L = \lambda$. In all we have constructive interference at

$$N = 6 \text{ points.} \quad (\text{Answer})$$

18-4 Intensity and Sound Level

In Section 17-7 we derived the fact that the average power in a one-dimensional continuous sinusoidal wave that propagates along a string depends on the squares of both the frequency and amplitude as shown in Eq. 17-31 ($\langle \text{Power} \rangle = \frac{1}{2} \mu v^{\text{wave}} \omega^2 Y^2$).^{*} Let's compare Eq. 17-31 to the equation for the power transmission of a sinusoidal one-dimensional sound wave. Suppose our sound is produced by an oscillating piston in an air-filled pipe of cross-sectional area A shown in Fig. 18-1. The relationship for the average power transmission of the sound waves is given by

$$\langle \text{Power} \rangle = \frac{1}{2} (\rho A) v^{\text{wave}} \omega^2 S^2, \quad (18-13)$$

where S represents a maximum displacement. In this case S denotes the maximum longitudinal displacement about an equilibrium point that particles in the medium carrying the sound undergo. This power relationship can be derived by calculating the average kinetic and potential energy of a given volume of air that undergoes simple harmonic motion. But without using a formal derivation we can see that Eq. 17-31 and Eq. 18-13 are essentially the same. Both S and Y are displacements and the term ρA is equal to the linear density μ of the air in the tube.

In previous sections we have been using maximum pressure difference, ΔP^{max} , rather than maximum particle displacement, S , as an indicator of how strong a sinusoidal sound disturbance is. It can be shown that these two measures of wave strength are related, by the expression

$$\Delta P^{\text{max}} = v^{\text{wave}} \rho \omega S.$$

If you have ever tried to sleep while someone played loud music nearby, you are well aware that there is more to sound than frequency, wavelength, and speed. Humans also detect how *loud* a sound is. Although the human ear does detect pressure amplitudes, it turns out that we are more sensitive to the *energy fluctuations* in a propagating wave than we are to the pressure alone. Hence, we will define a new energy related quantity associated with waves. The **intensity** I of a sound wave at a surface is the average rate per unit area, A , at which energy is transferred by the wave through or onto the surface. This is what we commonly refer to as loudness. By definition, the intensity of a wave is

$$I \equiv \frac{\langle \text{Power} \rangle}{A}, \quad (18-14)$$

where “Power” is the time rate of energy transfer (the power) of the sound wave, and A is the area of the surface intercepting the sound.

We can use Eq. 18-13 to show the relationship between the energy-related quantity *intensity* and the maximum particle displacement associated with a sound wave,

$$I = \frac{1}{2} \rho v^{\text{wave}} \omega^2 S^2. \quad (18-15)$$

The equation $\Delta P^{\text{max}} = v^{\text{wave}} \rho \omega S$ shown above can be used to express the intensity as a function of pressure change, so that

The intensity of a continuous sinusoidal wave is proportional to both the square of its displacement amplitude and the square of maximum pressure change in the medium caused by the sound waves.

Sound can cause the wall of a drinking glass to oscillate. If the sound produces a standing wave of oscillations and if the intensity of the sound is large enough, the glass will shatter.

^{*}In order to avoid confusion between power, usually denoted as P , and pressure, also denoted as P , we choose to spell out the word Power in this section.

FIGURE 18-12 ■ A point source S emits sound waves uniformly in all directions. The waves pass through an imaginary sphere of radius r that is centered on S .

Variation of Intensity with Distance

How intensity varies with distance from a real sound source is often complex. Some real sources (like loudspeakers) may transmit sound only in particular directions, and objects in the surroundings usually produce echoes (reflected sound waves) that overlap the direct sound waves. In some situations, however, we can ignore echoes and assume that the sound source is a point source that emits the sound *isotropically*—that is, with equal intensity in all directions. The wavefronts spreading from such an isotropic point source S at a particular instant are shown in Fig. 18-12.

Let us assume that the mechanical energy of the sound waves is conserved as they spread from this source. Let us also center an imaginary sphere of radius r on the source, as shown in Fig. 18-12. All the energy emitted by the source must pass through the surface of the sphere. Thus, the time rate at which energy is transferred through the surface by the sound waves must equal the time rate at which energy is emitted by the source (that is, the power, Power_s , of the source). From the fact that intensity is equal to the ratio of power to area (Eq. 18-14), the intensity I at the sphere must then be

$$I = \frac{\text{Power}_s}{4\pi r^2}, \quad (18-16)$$

where $4\pi r^2$ is the area of the sphere. Equation 18-16 tells us that the intensity of sound from an isotropic point source decreases with the square of the distance r from the source.

The Decibel Scale

The displacement amplitude at the human ear ranges from about 10^{-5} m for the loudest tolerable sound to about 10^{-11} m for the faintest detectable sound, a ratio of 10^6 . From our discussions above, we know that the intensity of a sound varies as the *square* of its amplitudes, so the ratio of intensities at these two limits of the human auditory system is 10^{12} . Humans can hear over an enormous range of intensities.

We deal with such an enormous range of values by using base 10 logarithms. Consider the relation

$$y = \log x,$$

in which x and y are variables. It is a property of this equation that if we *multiply* x by 10, then y increases by 1. To see this, we write

$$y' = \log(10x) = \log 10 + \log x = 1 + y.$$

Similarly, if we multiply x by 10^{12} , y increases by only 12. An important characteristic of human hearing is that we have logarithmic ears. Within the normal range of hearing when the measured sound intensity increases by a factor of 10, the sound only seems twice as loud to us.

Thus, instead of speaking of the intensity I of a sound wave, it is much more convenient to speak of its **sound level** β , defined as

$$\beta = (10 \text{ dB}) \log \frac{I}{I_0}. \quad (18-17)$$

Here dB is the abbreviation for **decibel**, the unit of sound level, a name that was chosen to recognize the work of Alexander Graham Bell. I_0 in Eq. 18-17 is a standard reference intensity ($= 10^{-12} \text{ W/m}^2$), chosen because it is near the lower limit of the human range of hearing at a frequency of 1 kHz. For $I = I_0$, Eq. 18-17 gives $\beta = 10 \log 1 = 0$, so our standard reference level, which we can barely hear, corre-

sponds to zero decibels. Then β increases by 10 dB every time the sound intensity increases by an order of magnitude (a factor of 10). But as we mentioned, a 10 dB increase seems to be twice the loudness. And the sound of a typical conversation, which has a β of 60 dB, corresponds to an intensity that is 10^6 times our normal hearing threshold! Table 18-2 lists the sound levels for a variety of environments.

TABLE 18-2
Some Sound Levels (dB)

Hearing threshold	0	Rock concert	110
Rustle of leaves	10	Pain threshold	120
Conversation	60	Jet engine	130

The decibel scale is one of many logarithmic scales used by scientists. Others include the pH scale, star magnitudes, and the Richter scale used to determine the severity of earthquakes.

READING EXERCISE 18-3: The figure indicates the near edge of three small patches 1, 2, and 3 that lie on the surfaces of two imaginary spheres; the spheres are centered on an isotropic point source S of sound. The rates at which energy is transmitted through the three patches by the sound waves are equal. Rank the patches according to (a) the intensity of the sound on them and (b) their area, greatest first. ■

TOUCHSTONE EXAMPLE 18-3: Spark Sound

An electric spark jumps along a straight line of length $L = 10$ m, emitting a pulse of sound that travels radially outward from the spark. (The spark is said to be a line source of sound.) The power of the emission is $\text{Power}_s = 1.6 \times 10^4$ W.

(a) What is the intensity I of the sound when it reaches a distance $r = 6$ m from the spark?

FIGURE 18-13 ■ A spark along a straight line of length L emits sound waves radially outward. The waves pass through an imaginary cylinder of radius r and length L that is centered on the spark.

SOLUTION ■ Let us center an imaginary cylinder of radius $r = 6$ m and length $L = 10$ m (open at both ends) on the spark, as shown in Fig. 18-13. One **Key Idea** here is that the intensity I at the cylindrical surface is the ratio $\langle \text{Power} \rangle / A$ of the average rate per unit area at which sound energy passes through a surface of area A on the cylinder. Another **Key Idea** is to assume that the principle of conservation of energy applies to the sound energy. This means that the Power or rate at which energy is transferred through the cylinder must equal the rate at which energy is emitted by the source. Putting these ideas together and noting that the area of a length L of the cylindrical surface is $A = 2\pi rL$, and neglecting the relatively small amount of sound energy

that flows out through the ends of the cylinder, we have, from Eq. 18-14,

$$I = \frac{\langle \text{Power} \rangle}{A} = \frac{\langle \text{Power}_s \rangle}{2\pi rL}. \quad (18-18)$$

This tells us that the intensity of the sound from a line source decreases with distance r (rather than with the square of distance r as for the point source described in Eq. 18-16). Substituting the given data, we find

$$I = \frac{1.6 \times 10^4 \text{ W}}{2\pi(6 \text{ m})(10 \text{ m})} = 42.4 \text{ W/m}^2 \approx 42 \text{ W/m}^2. \quad (\text{Answer})$$

(b) At what average $\langle \text{Power}_d \rangle$ is sound energy intercepted by an acoustic detector of area $A_d = 2.0 \text{ cm}^2$? Assume that the detector is aimed at the spark and located a distance $r = 6$ m from the spark.

SOLUTION ■ Applying the first **Key Idea** of part (a), we know that the intensity of sound at the detector is the ratio of the energy transfer rate $\langle \text{Power}_d \rangle$ there to the detector's area A_d :

$$I = \frac{\langle \text{Power}_d \rangle}{A_d}. \quad (18-19)$$

We can imagine that the detector lies on the cylindrical surface of (a). Then the sound intensity at the detector is the intensity $I (= 42.4 \text{ W/m}^2)$ at the cylindrical surface. Solving Eq. 18-19 for $\langle \text{Power}_d \rangle$ gives us

$$\langle \text{Power}_d \rangle = (42.4 \text{ W/m}^2)(2.0 \times 10^{-4} \text{ m}^2) = 8.5 \text{ mW}. \quad (\text{Answer})$$

TOUCHSTONE EXAMPLE 18-4: Concert Sounds

In 1976, the Who set a record for the loudest concert—the sound level 46 m in front of the speaker systems was $\beta_2 = 120$ dB. What is the ratio of the intensity I_2 of the band at that spot to the intensity I_1 of a jackhammer operating at sound level $\beta_1 = 92$ dB?

SOLUTION ■ The **Key Idea** here is that for both the Who and the jackhammer, the sound level β is related to the intensity by the definition of sound level in Eq. 18-17. For the Who, we have

$$\beta_2 = (10 \text{ dB}) \log \frac{I_2}{I_0},$$

and for the jackhammer, we have

$$\beta_1 = (10 \text{ dB}) \log \frac{I_1}{I_0}.$$

The difference in the sound levels is

$$\beta_2 - \beta_1 = (10 \text{ dB}) \left(\log \frac{I_2}{I_0} - \log \frac{I_1}{I_0} \right). \quad (18-20)$$

Using the identity

$$\log \frac{a}{b} - \log \frac{c}{d} = \log \frac{ad}{bc},$$

we can rewrite Eq. 18-20 as

$$\beta_2 - \beta_1 = (10 \text{ dB}) \log \frac{I_2}{I_1}. \quad (18-21)$$

Rearranging and substituting the known sound levels now yield

$$\log \frac{I_2}{I_1} = \frac{\beta_2 - \beta_1}{10 \text{ dB}} = \frac{120 \text{ dB} - 92 \text{ dB}}{10 \text{ dB}} = 2.8.$$

Taking the antilog of the far left and far right sides of this equation (the antilog key on your calculator is probably marked as 10^x), we find

$$\frac{I_2}{I_1} = \log^{-1} 2.8 = 630. \quad (\text{Answer})$$

Thus, the Who was *very* loud.

Temporary exposure to sound intensities as great as those of a jackhammer and the 1976 Who concert results in a temporary reduction of hearing. Repeated or prolonged exposure can result in permanent reduction of hearing (Fig. 18-14). Loss of hearing is a clear risk for any one continually listening to, say, heavy metal at high volume, especially on headphones.

FIGURE 18-14 ■ Pete Townshend of the Who, playing in front of a speaker system. He suffered a permanent reduction in his hearing ability due to his exposure to high-intensity sound, not so much during on-stage performances as from wearing headphones in recording studios and at home.

FIGURE 18-15 ■ The air column within a fujara oscillates when that traditional Slovakian instrument is played.

18-5 Sources of Musical Sound

Musical sounds can be set up by oscillating strings (guitar, piano, violin), membranes (kettledrum, snare drum), air columns (flute, oboe, pipe organ, and the fujara of Fig. 18-15), wooden blocks or steel bars (marimba, xylophone), and many other oscillating bodies. Most instruments involve more than a single oscillating part. In the violin, for example, both the strings and the body of the instrument participate in producing the music.

Standing Waves and Musical Instruments

Recall from Chapter 17 that standing waves can be set up on a stretched string that is fixed at both ends. They arise because waves traveling along the string are reflected back onto the string at each end. If the wavelength of the waves is suitably matched to the length of the string, the superposition of waves traveling in opposite directions produces a standing wave pattern (or oscillation mode). The wavelength required of the waves for such a match is one that corresponds to a *resonant frequency* of the string. The advantage of setting up standing waves is that the string then oscillates with a large, sustained amplitude, pushing back and forth against the surrounding air and thus generating a noticeable sound wave with the same frequency as the oscillations of the string. This production of sound is of obvious importance to, say, a guitarist.

We can set up standing waves of sound in an air-filled pipe in a similar way. As sound waves travel through the air in the pipe, they are reflected at each end and travel back through the pipe. (The reflection occurs even if an end is open, but the reflection is not as complete as when the end is closed.) If the wavelength of the sound waves is suitably matched to the length of the pipe, the superposition of waves traveling in opposite directions through the pipe sets up a standing wave pattern. The wavelength required of the sound waves for such a match is one that corresponds to a resonant frequency of the pipe. The advantage of such a standing wave is that the air in the pipe oscillates with a large, sustained amplitude, emitting at any open end a sound wave that has the same frequency as the oscillations in the pipe. This emission of sound is of obvious importance to, say, an organist.

Many other aspects of standing sound wave patterns are similar to those of string waves: The closed end of a pipe is like the fixed end of a string in that there must be a displacement node (zero displacement in a string, zero motion of molecules in a fluid like air) located there. A zero particle velocity immediately against the closed end of the pipe leads to a large change in pressure (a pressure antinode). The open end of a pipe is like the end of a string attached to a freely moving ring, as in Fig. 17-19b, in that there must be a displacement antinode (maximum displacement in a string, maximum motion of molecules in a fluid like air) located there. This too makes sense, as the molecules of air (or other fluid) are completely unconstrained once they leave the end of the pipe. The large particle velocities here lead to very small changes in pressure (a pressure antinode). To be perfectly precise, the antinode for the open end of a pipe is located slightly beyond the end. We will ignore this difference in our discussions.

So, the simplest standing wave pattern that can be set up in a pipe with two open ends is one with a particle displacement antinode (maximum particle velocities and zero change in pressure) at both ends and no other antinodes between them. Under these conditions, the only way that there can be a standing wave pattern at all is for there to be a displacement node (zero particle velocity and maximum change in pressure) in the middle of the pipe. This is shown in Fig. 18-16a. An alternate representation of the standing wave pattern as a graph of maximum molecular displacement at each position along the length of the pipe is shown in Fig. 18-16b.

Harmonics

The standing wave pattern of Fig. 18-16a is called the *fundamental mode* or *first harmonic*. For it to be set up, the sound waves in a pipe of length L must have a wavelength given by $L = \lambda/2$, so that $\lambda = 2L$. Several more standing sound wave patterns for a pipe with two open ends are shown in Fig. 18-17a with graphs of air molecule displacements from equilibrium shown next to the pipes. The *second harmonic* requires sound waves of wavelength $\lambda = L$, the *third harmonic* requires wavelength $\lambda = 2L/3$, and so on.

More generally, the resonant frequencies for a pipe of length L with two open ends correspond to the wavelengths

$$\lambda = \frac{2L}{n} \quad (\text{pipe, two open ends}). \quad (18-22)$$

Here n is a positive integer (1, 2, 3, . . . etc.) called the *harmonic number*. The resonant frequencies for a pipe with two open ends are then given by

$$f = \frac{v^{\text{air}}}{\lambda} = n \left(\frac{v^{\text{air}}}{2L} \right) \quad (\text{pipe, two open ends}), \quad (18-23)$$

where v^{air} is the speed of the sound wave in air.

Figure 18-17b shows (using pressure variation graphs) some of the standing sound wave patterns that can be set up in a pipe with only one open end. As required, across

FIGURE 18-16 (a) The simplest standing wave pattern of air molecule displacements from equilibrium for (longitudinal) sound waves in a pipe with both ends open. It shows an antinode (A) across each end and a node (N) across the middle of the pipe. (The longitudinal displacements represented by the double arrows are greatly exaggerated.) (b) A graph of maximum molecular displacements versus position.

FIGURE 18-17 Standing wave patterns are shown as graphs of the extremes of maximum and minimum air molecule displacements versus location along the pipe. (a) With *both* ends of the pipe open, any harmonic can be set up in the pipe. (b) With only *one* end open, only odd harmonics can be set up.

the open end there is a displacement antinode (maximum particle velocities and zero pressure change) and across the closed end there is a displacement node (zero particle velocities and maximum pressure change). The simplest pattern requires sound waves having a wavelength given by $L = \lambda/4$, so that $\lambda = 4L$. The next simplest pattern requires a wavelength given by $L = 3\lambda/4$, so that $\lambda = 4L/3$, and so on.

More generally, the resonant frequencies for a pipe of length L with only one open end correspond to the wavelengths

$$\lambda = \frac{4L}{2n + 1} \quad \text{for } n = 0, 1, 2, \dots, \quad (18-24)$$

where n still represents a positive integer with $2n + 1$ giving us odd positive integers. The resonant frequencies are then given by

$$f = \frac{v^{\text{air}}}{\lambda} = (2n + 1) \frac{v^{\text{air}}}{4L} \quad (\text{pipe, one open end}). \quad (18-25)$$

FIGURE 18-18 ■ The saxophone and violin families, showing the relations between instrument length and frequency range. The frequency range of each instrument is indicated by a horizontal bar along a frequency scale suggested by the piano keyboard at the bottom; the frequency increases toward the right.

FIGURE 18-19 ■ The wave forms produced by a violin, a hammer dulcimer struck with a felt and a wood hammer, and a guitar. The fundamental frequency is listed for each wave. These graphs of the relative sound pressure variation versus time are produced using a computer data acquisition system with a microphone sensor attached.

Note again that only odd harmonics can exist in a pipe with one open end. For example, the second harmonic, with $2n + 1 = 2$, cannot be set up in such a pipe. Note also that for such a pipe the numeric adjective (e.g., first, second, third, . . .) before the word harmonic in a phrase such as “the third harmonic” always refers to the harmonic number n and not to the n th possible harmonic.

The length of a musical instrument is related to the range of frequencies over which the instrument is designed to function, and smaller length implies higher frequencies. Figure 18-18, for example, shows the saxophone and violin families, with their frequency ranges suggested by the piano keyboard. Note that, for every instrument, there is overlap with its higher- and lower-frequency neighbors.

What Makes Instruments Distinctive?

In any oscillating system that gives rise to a musical sound, whether it is a violin string or the air in an organ pipe, the fundamental and one or more of the higher harmonics are usually generated simultaneously. Thus, you hear them together—that is, superimposed into a combined wave. When different instruments are playing the same note, they produce the same fundamental frequency but different intensities for the higher harmonics. For example, the fourth harmonic of middle C might be relatively loud on one instrument

and relatively quiet or even missing on another. Thus, different instruments sound different to you even when they are playing the same note. That would be the case for the combined waves shown for the violin, hammer dulcimer and guitar in Fig. 18-19 even if these three instruments were playing the same note (which they are not).

In Fig. 18-19 we can also see that the pressure variation versus time for the hammer dulcimer hit with a wood hammer has more high frequency harmonics than the corresponding graph for the dulcimer hit with a felt hammer. But, in both cases the dulcimer has the same fundamental frequency of 391 Hz. There is a mathematical technique known as **Fourier analysis** that can be used to determine the amplitudes of each of the harmonic frequencies that combines to make a full sound. A fast Fourier transform (FFT) of the two hammer dulcimer sounds is shown in Fig. 18-20. As you can see, the relative amplitudes for harmonic frequencies between 1500 Hz and 2500 Hz are much higher when the dulcimer is hit with a wood hammer than when it is hit with a felt hammer.

FIGURE 18-20 ■ A fast Fourier transform showing the amplitudes of the harmonics for a hammered dulcimer when it is (a) struck with a felt hammer and (b) struck with a wood hammer. The wood hammer stimulates more very high harmonics.

READING EXERCISE 18-4: Pipe A , with length L , and pipe B , with length $2L$, both have two open ends. Which harmonic of pipe B has the same frequency as the fundamental of pipe A ? ■

TOUCHSTONE EXAMPLE 18-5: Sound in a Tube

Weak background noises from a room set up the fundamental standing wave in a cardboard tube of length $L = 67.0$ cm with two open ends. Assume that the speed of sound in the air within the tube is 343 m/s.

(a) What frequency do you hear from the tube?

SOLUTION ■ The **Key Idea** here is that, with both pipe ends open, we have a symmetric situation in which the standing wave has a displacement antinode at each end of the tube. The standing wave displacement variation pattern is that of Fig. 18-16*b*. The frequency is given by Eq. 18-23 with $n = 1$ for the fundamental mode:

$$f = \frac{nv^{\text{air}}}{2L} = \frac{(1)(343 \text{ m/s})}{(2)(0.670 \text{ m})} = 256 \text{ Hz.} \quad (\text{Answer})$$

If the background noises set up any higher harmonics, such as the second harmonic, you must also hear frequencies that are *integer* multiples of 256 Hz.

(b) If you jam your ear against one end of the tube, what fundamental frequency do you hear from the tube?

SOLUTION ■ The **Key Idea** now is that, with your ear effectively closing one end of the tube we have an asymmetric situation—a displacement antinode still exists at the open end but a displacement node is now at the other (closed) end. The standing wave pattern is the top one in Fig. 18-17*b*. The frequency is given by Eq. 18-25 with $n = 1$ for the fundamental mode:

$$f = \frac{nv^{\text{air}}}{4L} = \frac{(1)(343 \text{ m/s})}{4(0.670 \text{ m})} = 128 \text{ Hz.} \quad (\text{Answer})$$

If the background noises set up any higher harmonics, they will be *odd* multiples of 128 Hz. That means that the frequency of 256 Hz (which is an even multiple) cannot now occur.

18-6 Beats

If you listen separately to two sounds whose frequencies are, say, 50 and 52 Hz, most of us cannot tell which one has the higher frequency. However, if the sounds reach our ears simultaneously, what we hear is a sound whose frequency turns out to be 51 Hz, the *average* of the two combining frequencies. We also hear a striking variation in the

intensity of this sound—it increases and decreases in slow, wavering **beats** that repeat at a frequency of 2 Hz, the *difference* between the two combining frequencies. Figure 18-21 shows this beat phenomenon (for sounds of frequencies of 8 Hz and 10 Hz).

FIGURE 18-21 (a) The pressure variations ΔP of two sound waves as they would be detected separately are plotted as a function of time. The frequencies of the waves are nearly equal. (b) If the two waves are detected simultaneously the resultant pressure variation is the superposition of the two waves. Notice how the waves cancel each other at the center of the plot and reinforce each other at the two ends of the plot. (c) When plotted over a longer time period the two waves shown in (a) and (b) show a beat pattern of 2 Hz if the frequencies of the original waves are 10 and 12 Hz.

Let the time-dependent variations of pressure due to two sound waves at a particular location be

$$\Delta P_1 = \Delta P^{\max} \cos \omega_1 t \quad \text{and} \quad \Delta P_2 = \Delta P^{\max} \cos \omega_2 t, \quad (18-26)$$

where $\omega_1 > \omega_2$. We have assumed, for simplicity, that the waves have the same amplitude and initial phase. According to the superposition principle, the resultant pressure variation is

$$\Delta P = \Delta P_1 + \Delta P_2 = \Delta P^{\max} (\cos \omega_1 t + \cos \omega_2 t).$$

Using the trigonometric identity (see Appendix E)

$$\cos \alpha + \cos \beta = 2 \cos \frac{1}{2}(\alpha - \beta) \cos \frac{1}{2}(\alpha + \beta)$$

allows us to write the resultant pressure variation as

$$\Delta P = 2 \Delta P^{\max} \cos \frac{1}{2}(\omega_1 - \omega_2)t \cos \frac{1}{2}(\omega_1 + \omega_2)t. \quad (18-27)$$

If we write

$$\omega' = \frac{1}{2}(\omega_1 - \omega_2) \quad \text{and} \quad \omega = \frac{1}{2}(\omega_1 + \omega_2) \quad (18-28)$$

we can then write Eq. 18-27 as

$$\Delta P(t) = [2 \Delta P^{\max} \cos \omega' t] \cos \omega t. \quad (18-29)$$

We now assume that the angular frequencies ω_1 and ω_2 of the combining waves are almost equal, which means that $\omega \gg \omega'$ in Eq. 18-28. We can then regard Eq. 18-29 as a cosine function whose angular frequency is ω and whose amplitude (which is not constant but varies with angular frequency ω') is the quantity in the square brackets.

A maximum amplitude will occur whenever $\cos \omega' t$ in Eq. 18-29 has the value $+1$ or -1 , which happens twice in each repetition of the cosine function. Because $\cos \omega' t$ has angular frequency ω' , the angular frequency ω_{beat} at which beats occur is $\omega_{\text{beat}} = 2\omega'$. Then, with the aid of Eq. 18-28, we can write

$$\omega_{\text{beat}} = 2\omega' = (2)\left(\frac{1}{2}\right)(\omega_1 - \omega_2) = \omega_1 - \omega_2.$$

Because $\omega = 2\pi f$, we can recast this as

$$f_{\text{beat}} = f_1 - f_2 \quad (\text{beat frequency}). \quad (18-30)$$

Musicians use the beat phenomenon in tuning their instruments. If an instrument is sounded against a standard frequency (for example, the lead oboe's reference A) and tuned until the beat disappears, then the instrument is in tune with that standard. In musical Vienna, concert A (440 Hz) is available as a telephone service for the benefit of the city's many professional and amateur musicians.

Types of Superposition

So far the three simple cases we have discussed involving the superposition of sound waves are:

1. *Standing waves* created by the interference of two identical waves moving the opposite directions with the same speed
2. *Wave interference* caused by waves that have the same frequency, wavelength, and amplitude that are moving in almost the same direction and overlap at some point
3. *Beats* created by two waves with the same amplitude moving in the same direction with slightly different frequencies

There are many other more complex types of interference of interest to scientists and engineers. The mathematical techniques used to analyze these situations are similar to those we introduced in this section.

18-7 The Doppler Effect

An ambulance is parked by the side of the highway, sounding its 1000 Hz siren. If you are also parked by the highway, you will hear that same frequency. However, if there is relative motion between you and the ambulance, either toward or away from each other, you will hear a different frequency. For example, if you are driving *toward* the ambulance at 120 km/h (about 75 mi/h), you will hear a *higher* frequency (1096 Hz, an *increase* of 96 Hz). If you are driving *away from* the ambulance at that same speed, you will hear a *lower* frequency (904 Hz, a *decrease* of 96 Hz).

These motion-related frequency changes are examples of the **Doppler effect**. The effect was proposed (although not fully worked out) in 1842 by Austrian physicist Johann Christian Doppler. It was tested experimentally in 1845 by Buys Ballot in Holland, "using a locomotive drawing an open car with several trumpeters."

The Doppler effect holds not only for sound waves but also for electromagnetic waves, including microwaves, radio waves, and visible light. Here, we shall consider only sound waves for the special case where no wind is present. This means that we shall measure the speeds of a source S of sound waves and a detector D of those waves *relative to a body of air that is not moving*. We shall assume that S and D move

either directly toward or directly away from each other, at speeds less than the speed of sound.

If either the detector or the source is moving, or both are moving, the emitted frequency f and the detected frequency f' are related by

$$f' = f \frac{v^{\text{air}} \pm v_D}{v^{\text{air}} \pm v_S} \quad (\text{1D Doppler effect for sound in still air}), \quad (18-31)$$

where v^{air} is the speed of sound through the air, v_D is the detector's speed relative to the air, and v_S is the source's speed relative to the air. The choice of plus or minus signs is set by this rule:

When a sound source and a detector are moving toward each other, the sign on the sound's speed and the detector's speed must give upward shifts in frequency. When a sound source and a detector are moving away from each other, the signs on the speeds must give downward shifts in frequency.

FIGURE 18-22 ■ A stationary source of sound S emits spherical wavefronts, shown one wavelength apart, that expand outward at speed v^{air} . A sound detector D , represented by an ear, moves with velocity \vec{v}_D toward the source. The detector senses a higher frequency because of its motion.

In short, toward means shift up, and away means shift down.

Here are some examples of the rule. If the detector moves toward the source, use the plus sign in the numerator of Eq. 18-31 to get a shift up in the frequency. If it moves away, use the minus sign in the numerator to get a shift down. If it is stationary, substitute 0 for v_D . If the source moves toward the detector, use the minus sign in the denominator of Eq. 18-31 to get a shift up in the frequency. If it moves away, use the plus sign in the denominator to get a shift down. If the source is stationary, substitute 0 for v_S .

Next, we derive equations for the Doppler effect for two specific situations and then derive Eq. 18-31 for the general situation.

1. When the detector moves relative to the air and the source is stationary relative to the air, the motion changes the frequency at which the detector intercepts wavefronts and thus the detected frequency of the sound wave.
2. When the source moves relative to the air and the detector is stationary relative to the air, the motion changes the wavelength of the sound wave and thus the detected frequency (recall that frequency is related to wavelength).

Detector Moving; Source Stationary

In Fig. 18-22, a detector D (represented by an ear) is moving at speed v_D toward a stationary source S that emits spherical wavefronts, of wavelength λ and frequency f , moving at the speed v^{air} of sound in air. A cross section of the wavefronts are drawn one wavelength apart. The frequency detected by detector D is the rate at which D intercepts wavefronts (or individual wavelengths). If D were stationary, that rate would be f , but since D is moving into the wavefronts, the rate of interception is greater, and thus the detected frequency f' is greater than f .

Let us for the moment consider the situation in which D is stationary (Fig. 18-23). In time t , the wavefronts move to the right a distance $v^{\text{air}}t$. The number of wavelengths in that distance $v^{\text{air}}t$ is the number of wavelengths intercepted by D in time t , and that number is $v^{\text{air}}t/\lambda$. The rate at which D intercepts wavelengths, which is the frequency f detected by D , is

$$f = \frac{v^{\text{air}}t/\lambda}{t} = \frac{v^{\text{air}}}{\lambda}. \quad (18-32)$$

In this situation, with D stationary, there is no Doppler effect—the frequency detected by D is the frequency emitted by S .

FIGURE 18-23 ■ Wavefronts of Fig. 18-22, assumed planar, (a) reach and (b) pass a stationary detector D ; they move a distance $v^{\text{air}}t$ to the right in time t .

Now let us again consider the situation in which D moves opposite the wavefronts (Fig. 18-24). In time t , the wavefronts move to the right a distance $v^{\text{air}}t$ as previously, but now D moves to the left a distance $v_D t$. Thus, in this time t , the distance moved by the wavefronts relative to D is $v^{\text{air}}t + v_D t$. The number of wavelengths in this relative distance $v^{\text{air}}t + v_D t$ is the number of wavelengths intercepted by D in time t , and is $(v^{\text{air}}t + v_D t)/\lambda$. The rate at which D intercepts wavelengths in this situation is the frequency f' , given by

$$f' = \frac{(v^{\text{air}}t + v_D t)/\lambda}{t} = \frac{v^{\text{air}} + v_D}{\lambda}. \quad (18-33)$$

From Eq. 18-32, we have $\lambda = v^{\text{air}}/f$. Then Eq. 18-33 becomes

$$f' = \frac{v^{\text{air}} + v_D}{v^{\text{air}}/f} = f \left(\frac{v^{\text{air}} + v_D}{v^{\text{air}}} \right). \quad (18-34)$$

Note that in Eq. 18-34 f' must be greater than f unless the detector is stationary so that $v_D = 0$.

Similarly, we can find the frequency detected by D if D moves away from the source. In this situation, the wavefronts move a distance $v^{\text{air}}t - v_D t$ relative to D in time t , and f' is given by

$$f' = f \left(\frac{v^{\text{air}} - v_D}{v^{\text{air}}} \right). \quad (18-35)$$

In Eq. 18-35, f' must be less than f unless $v_D = 0$.

We can summarize Eqs. 18-34 and 18-35 with

$$f' = f \left(\frac{v^{\text{air}} \pm v_D}{v^{\text{air}}} \right) \quad (\text{detector moving; source stationary}). \quad (18-36)$$

Source Moving; Detector Stationary

Let detector D be stationary with respect to the body of air, and let source S move toward D at speed $|\vec{v}_S|$ (Fig. 18-25). The motion of S changes the wavelength of the sound waves it emits, and thus the frequency detected by D .

To see this change, let $T (= 1/f)$ be the time between the emission of any pair of successive wavefronts W_1 and W_2 . During T , wavefront W_1 moves a distance $v^{\text{air}}T$ and the source moves a distance $v_S T$. At the end of T , wavefront W_2 is emitted. In the direction in which S moves, the distance between W_1 and W_2 , which is the wavelength λ' of the waves moving in that direction, is $v^{\text{air}}T - v_S T$. If D detects those waves, it detects frequency f' given by

$$\begin{aligned} f' &= \frac{v^{\text{air}}}{\lambda'} = \frac{v^{\text{air}}}{v^{\text{air}}T - v_S T} = \frac{v^{\text{air}}}{v^{\text{air}}/f - v_S/f} \\ &= f \frac{v^{\text{air}}}{v^{\text{air}} - v_S}. \end{aligned} \quad (18-37)$$

Note that f' must be greater than f unless $|\vec{v}_S| = 0$.

In the direction opposite that taken by S , the wavelength λ' of the waves is $v^{\text{air}}T + v_S T$. If D detects those waves, it detects frequency f' , given by

$$f' = f \frac{v^{\text{air}}}{v^{\text{air}} + v_S}. \quad (18-38)$$

Now f' must be less than f unless $v_S = 0$.

We can summarize Eqs. 18-37 and 18-38 with

$$f' = f \frac{v^{\text{air}}}{v^{\text{air}} \pm v_S} \quad (\text{source moving; detector stationary}). \quad (18-39)$$

FIGURE 18-24 ■ Wavefronts (a) reach and (b) pass detector D , which moves opposite the wavefronts. In time t , the wavefronts move a distance $v^{\text{air}}t$ to the right and D moves a distance $v_D t$ to the left.

FIGURE 18-25 ■ A detector D is stationary, and a source S is moving toward it at speed v_S . Wavefront W_1 was emitted when the source was at S_1 , wavefront W_7 when the source was at S_7 . At the moment depicted, the source is at S . The detector perceives a higher frequency because the moving source, chasing its own wavefronts, emits a reduced wavelength λ' in the direction of its motion.

General Doppler Effect Equation for Sound

For the one-dimensional case, we can now derive the general Doppler effect equation by replacing f in Eq. 18-39 (the frequency of the source) with f' of Eq. 18-36 (the frequency associated with motion of the detector). The result is Eq. 18-31 for the general Doppler effect.

That general equation holds not only when both detector and source are moving but also in the two specific situations we just discussed. For the situation in which the detector is moving and the source is stationary, substitution of $v_S = 0$ into Eq. 18-31 gives us Eq. 18-36, which we previously found. For the situation in which the source is moving and the detector is stationary, substitution of $v_D = 0$ into Eq. 18-30 gives us Eq. 18-39, which we previously found. Thus, Eq. 18-31 is the equation to remember.

Similar Doppler frequency shifts occur with electromagnetic waves treated in Chapters 34 and 38, but the equations are slightly different (see Section 38-14).

The Doppler Effect in More Than One Dimension

We can even use Eqs. 18-36 and 18-39 if the source and/or the detector are moving relative to each other at constant velocities that *don't lie along the same line*. Simply draw a line from one object to the other at a particular time when the sound of interest is being emitted and call it the x axis. Start by finding the x -components of the velocities. You can then use the speeds along the x axis in Eq. 18-36 or Eq. 18-37 to determine the frequency shifts. For example, the Doppler shift for light waves is used by astronomers to help them determine how fast a distant object is moving relative to Earth. However, they can only use Doppler shift measurements to find the object's velocity *component* along a line between Earth and the object.

Bat Navigation and Feeding

An example of the use of the three-dimensional Doppler effect in nature is provided by bats. Bats navigate and search out prey by emitting and then detecting reflections of ultrasonic waves. These are sound waves with frequencies greater than can be heard by a human.* For example, a horseshoe bat emits ultrasonic waves at 83 kHz, well above the 20 kHz limit of human hearing.

After the sound is emitted through the bat's nostrils, it might reflect (echo) from a moth, and then return to the bat's ears. The motions of the bat and the moth relative to the air cause the frequency heard by the bat to differ by a few kilohertz from the frequency it emitted. The bat automatically translates this difference into a relative speed between itself and the moth, so it can zero in on the moth.

Some moths evade capture by flying away from the direction in which they hear ultrasonic waves. That choice of flight path reduces the frequency difference between what the bat emits and what it hears, and then the bat may not notice the echo. Some moths avoid capture by clicking to produce their own ultrasonic waves, thus "jamming" the detection system and confusing the bat. (Surprisingly, moths and bats do all this without first studying physics.)

READING EXERCISE 18-5: The figure indicates the directions of motion of a sound source and a detector for six situations in stationary air. In general, $v_0 \neq v_S$. For each situation, is the detected frequency greater than or less than the emitted frequency, or can't we tell without more information about the actual speeds?

	Source	Detector		Source	Detector
(a)	→	• 0 speed	(d)	←	←
(b)	←	• 0 speed	(e)	→	←
(c)	→	→	(f)	←	→

*Ultrasonic motion detectors use the same technique for locating objects.

TOUCHSTONE EXAMPLE 18-6: Rocket Sounds

A rocket moves at a speed of 242 m/s directly toward a stationary pole (through stationary air) while emitting sound waves at frequency $f = 1250$ Hz.

(a) What frequency f' is measured by a detector that is attached to the pole?

SOLUTION ■ We can find f' with Eq. 18-31 for the general Doppler effect. The **Key Idea** here is that, because the sound source (the rocket) moves through the air *toward* the stationary detector on the pole, we need to choose the sign on v_S that gives a *shift up* in the frequency of the sound. Thus, in Eq. 18-31 we use the minus sign in the denominator. We then substitute 0 for the detector speed v_D , 242 m/s for the source speed v_S , 343 m/s for the speed of sound v^{air} (from Table 18-1), and 1250 Hz for the emitted frequency f . We find

$$f' = f \frac{v^{\text{air}} \pm v_D}{v^{\text{air}} \pm v_S} = (1250 \text{ Hz}) \frac{343 \text{ m/s} \pm 0}{343 \text{ m/s} - 242 \text{ m/s}},$$

$$= 4245 \text{ Hz} \approx 4250 \text{ Hz}, \quad (\text{Answer})$$

which, indeed, is a greater frequency than the emitted frequency.

(b) Some of the sound reaching the pole reflects back to the rocket as an echo. What frequency f'' does a detector on the rocket detect for the echo?

SOLUTION ■ Two **Key Ideas** here are the following:

1. The pole is now the source of sound (because it is the source of the echo), and the rocket's detector is now the detector (because it detects the echo).
2. The frequency of the sound emitted by the source (the pole) is equal to f' , the frequency of the sound the pole intercepts and reflects.

We can rewrite Eq. 18-31 in terms of the source frequency f' and the detected frequency f'' as

$$f'' = f' \frac{v^{\text{air}} \pm v_D}{v^{\text{air}} \pm v_S}. \quad (18-40)$$

A third **Key Idea** here is that, because the detector (on the rocket) moves through the air *toward* the stationary source, we need to use the *sign* on v_D that gives a *shift up* in the frequency of the sound. Thus, we use the plus sign in the numerator of Eq. 18-40. Also, we substitute $v_D = 242$ m/s, $v_S = 0$, $v^{\text{air}} = 343$ m/s, and $f' = 4245$ Hz. We find

$$f'' = (4245 \text{ Hz}) \frac{343 \text{ m/s} + 242 \text{ m/s}}{343 \text{ m/s} \pm 0}$$

$$= 7240 \text{ Hz}, \quad (\text{Answer})$$

which, indeed, is greater than the frequency of the sound reflected by the pole.

18-8 Supersonic Speeds; Shock Waves

If a source is moving toward a stationary detector at a speed equal to the speed of sound in a medium—that is, if $v_S = v^{\text{air}}$ or $v_S = v^{\text{water}}$ and so on—Eqs. 18-31 and 18-39 predict that the detected frequency f' will be infinitely great. This means that the

FIGURE 18-26 ■ Cross-sectional drawings of: (a) A source of sound S moves at speed v_S equal to the speed of sound and thus as fast as the wavefronts it generates. (b) A source S moves at speed v_S faster than the speed of sound and thus faster than the wavefronts. When the source was at position S_1 it generated wavefront W_1 , and at position S_6 it generated W_6 . All the spherical wavefronts expand at the speed of sound v^{wave} and bunch along the surface of a cone called the Mach cone, forming a shock wave. The surface of the cone has half-angle θ and is tangent to all the wavefronts.

source is moving so fast that it keeps pace with its own spherical wavefronts, as Fig. 18-26a suggests. What happens when the speed of the source exceeds the speed of sound?

For such supersonic speeds, Eqs. 18-31 and 18-39 no longer apply. Figure 18-26b depicts the spherical wavefronts that originated at various positions of the source. The radius of any wavefront in this figure is $v^{\text{wave}}t$, where v^{wave} is the speed of sound in the medium (for example, v^{air} or v^{water}) and t is the time that has elapsed since the source emitted that wavefront. Note that all the wavefronts bunch along a V-shaped envelope in the two-dimensional drawing of Fig. 18-26b. The wavefronts actually extend in three dimensions, and the bunching forms a cone called the *Mach cone*. A *shock wave* is said to exist along the surface of this cone, because the bunching of wavefronts causes an abrupt rise and fall of air pressure as the surface passes by any point. An observer hears the wavefront bunching as a sharp loud sound known as a **sonic boom**. From Fig. 18-26b, we see that the half-angle θ of the cone, called the *Mach cone angle*, is given by

$$\sin \theta = \frac{v^{\text{wave}}t}{v_S t} = \frac{v^{\text{wave}}}{v_S} \quad (\text{Mach cone angle}). \quad (18-41)$$

FIGURE 18-27 ■ A cloud formation is produced off the wings of this Navy jet. One plausible explanation is that the cloud forms because of the sudden decrease in air pressure that results as a supersonic shock wave propagates. This causes water vapor in the air to condense.

The ratio v_S/v^{wave} is called the *Mach number*. When you hear that a particular plane has flown at Mach 2.3, it means that its speed was 2.3 times the speed of sound in the air through which the plane was flying. There is a common misconception that a sonic boom is a single burst of sound that is generated at the moment a plane breaks the sound barrier. However, the shock wave is generated continuously as long as the speed of the plane is greater than the speed of sound. When a shock wavefront generated by a supersonic aircraft (Fig. 18-27) passes by an observer she hears the sonic boom.

Part of the sound that is heard when a rifle is fired is the sonic boom produced by the bullet. A sonic boom can also be heard from a long bullwhip when it is snapped quickly: Near the end of the whip's motion, its tip is moving faster than sound and produces a small sonic boom—the *crack* of the whip.

Problems

Where needed in the problems, use

speed of sound in air = 343 m/s and

density of air = 1.21 kg/m³

unless otherwise specified.

SEC. 18-2 ■ THE SPEED OF SOUND

1. Devise a Rule Devise a rule for finding your distance in kilometers from a lightning flash by counting the seconds from the time you see the flash until you hear the thunder. Assume that the sound travels to you along a straight line.

2. Outdoor Concert You are at a large outdoor concert, seated 300 m from the speaker system. The concert is also being broadcast live via satellite (at the speed of light, 3.0×10^8 m/s). Consider a listener 5000 km away who receives the broadcast. Who hears the music first, you or the listener and by what time difference?

3. Two Spectators Two spectators at a soccer game in Montjuic Stadium see, and a moment later hear, the ball being kicked on the playing field. The time delay for one spectator is 0.23 s and for the other 0.12 s. Sight lines from the two spectators to the player kicking the ball

meet at an angle of 90°. (a) How far is each spectator from the player? (b) How far are the spectators from each other?

4. Column of Soldiers A column of soldiers, marching at 120 paces per minute, keep in step with the beat of a drummer at the head of the column. It is observed that the soldiers in the rear end of the column are striding forward with the left foot when the drummer is advancing with the right. What is the approximate length of the column?

5. Earthquakes Earthquakes generate sound waves inside Earth. Unlike a gas, Earth can experience both transverse (S) and longitudinal (P) sound waves. Typically, the speed of S waves is about 4.5 km/s, and that of P waves 8.0 km/s. A seismograph records P and S waves from an earthquake. The first P waves arrive 3.0 min before the first S waves (Fig. 18-28). Assuming the waves travel in a straight line, how far away does the earthquake occur?

6. Speed of Sound The speed of sound in a certain metal is v^{metal} . One end of a long pipe of that metal of length L is struck a hard blow. A listener at the other end hears two sounds, one from the wave that travels along the pipe and the other from the wave that travels through the air. (a) If v^{air} is the speed of sound in air, what time interval Δt elapses between the arrivals of the two sounds? (b) Suppose that $\Delta t = 1.00$ s and the metal is steel. Find the length L .

FIGURE 18-28 ■ Problem 5.

7. Stone Is Dropped A stone is dropped into a well. The sound of the splash is heard 3.00 s later. What is the depth of the well?

8. Audible Frequency The audible frequency range for normal hearing is from about 20 Hz to 20 kHz. What are the wavelengths of sound waves at these frequencies?

9. Diagnostic Ultrasound Diagnostic ultrasound of frequency 4.50 MHz is used to examine tumors in soft tissue. (a) What is the wavelength in air of such a sound wave? (b) If the speed of sound in tissue is 1500 m/s, what is the wavelength of this wave in tissue?

10. Pressure in Traveling Wave The pressure in a traveling sound wave is given by the equation

$$\Delta P(x, t) = (1.50 \text{ Pa}) \sin \pi [(0.900 \text{ rad/m})x - (315 \text{ rad/s})t].$$

Find the (a) pressure amplitude, (b) frequency, (c) wavelength, and (d) speed of the wave.

SEC. 18-3 ■ INTERFERENCE

11. Two Loudspeakers In Fig. 18-29, two loudspeakers, separated by a distance of 2.00 m, are in phase. Assume the amplitudes of the sound from the speakers are approximately the same at the position of a listener, who is 3.75 m directly in front of one of the speakers. (a) For what frequencies in the audible range (20 Hz to 20 kHz) does the listener hear a minimum signal? (b) For what frequencies is the signal a maximum?

FIGURE 18-29 ■ Problem 11

12. Two Point Sources Two point sources of sound waves of identical wavelength λ and amplitude are separated by distance $D = 2.0\lambda$. The sources are in phase. (a) How many points of maximum signal (that is, maximum constructive interference) lie along a large circle around the sources? (b) How many points of minimum signal (destructive interference) lie around the circle?

13. Loudspeakers on Outdoor Stage Two loudspeakers are located 3.55 m apart on an outdoor stage. A listener is 18.3 m from one and 19.5 m from the other. During the sound check, a signal generator drives the two speakers in phase with the same amplitude and frequency. The transmitted frequency is swept through the audible range (20 Hz to 20 kHz). (a) What are the three lowest frequencies at which the listener will hear a minimum signal because of destruc-

tive interference? (b) What are the three lowest frequencies at which the listener will hear a maximum signal?

14. Two Sound Waves Two sound waves, from two different sources with the same frequency, 540 Hz, travel in the same direction at 330 m/s. The sources are in phase. What is the phase difference of the waves at a point that is 4.40 m from one source and 4.00 m from the other?

15. Half-Circle In Fig. 18-30, sound with a 40.0 cm wavelength travels rightward from a source and through a tube that consists of a straight portion and a half-circle.

FIGURE 18-30 ■ Problem 15.

Part of the sound wave travels through the half-circle and then re-joins the rest of the wave, which goes directly through the straight portion. This rejoining results in interference. What is the smallest radius r that results in an intensity minimum at the detector?

SEC. 18-4 ■ INTENSITY AND SOUND LEVEL

16. Point Source A 1.0 W point source emits sound waves isotropically. Assuming that the energy of the waves is conserved, find the intensity (a) 10 m from the source and (b) 2.5 m from the source.

17. A Source Emits A source emits sound waves isotropically. The intensity of the waves 2.50 m from the source is $1.91 \times 10^{-4} \text{ W/m}^2$. Assuming that the energy of the waves is conserved, find the power of the source.

18. Differ in Level Two sounds differ in sound level by 1.00 dB. What is the ratio of the greater intensity to the smaller intensity?

19. Increased in Level A certain sound source is increased in sound level by 30 dB. By what multiple is (a) its intensity increased and (b) its pressure amplitude increased?

20. The Source of a Sound The source of a sound wave has a power of $1.00 \mu\text{W}$. If it is a point source, (a) what is the intensity 3.00 m away and (b) what is the sound level in decibels at that distance?

21. One in Air, One in Water (a) If two sound waves, one in air and one in (fresh) water, are equal in intensity, what is the ratio of the pressure amplitude of the wave in water to that of the wave in air? Assume the water and the air are at 20°C . (b) If the pressure amplitudes are equal instead, what is the ratio of the intensities of the waves?

22. Noisy Freight Train Assume that a noisy freight train on a straight track emits a cylindrical, expanding sound wave, and that the air absorbs no energy. How does the amplitude ΔP^{max} of the wave depend on the perpendicular distance r from the source?

23. Ratios Find the ratios (greater to smaller) of (a) the intensities, and (b) the pressure amplitudes for two sounds whose sound levels differ by 37 dB.

24. Point Source Two A point source emits 30.0 W of sound isotropically. A small microphone intercepts the sound in an area of 0.750 cm^2 , 200 m from the source. Calculate (a) the sound intensity there and (b) the power intercepted by the microphone.

FIGURE 18-31 ■ Problem 25.

25. Acoustic Interferometer Figure 18-31 shows an air-filled, acoustic interferometer, used to demonstrate

the interference of sound waves. Sound source S is an oscillating diaphragm; D is a sound detector, such as the ear or a microphone. Path SBD can be varied in length, but path SAD is fixed. At D , the sound wave coming along path SBD interferes with that coming along path SAD . In one demonstration, the sound intensity at D has a minimum value of 100 units at one position of the movable arm and continuously climbs to a maximum value of 900 units when that arm is shifted by 1.65 cm. Find (a) the frequency of the sound emitted by the source and (b) the ratio of the amplitude at D of the SAD wave to that of the SBD wave. (c) How can it happen that these waves have different amplitudes, considering that they originate at the same source?

SEC. 18-5 ■ SOURCES OF MUSICAL SOUND

26. A Violin String A violin string 15.0 cm long and fixed at both ends oscillates in its $n = 1$ mode. The speed of waves on the string is 250 m/s, and the speed of sound in air is 348 m/s. What are (a) the frequency and (b) the wavelength of the emitted sound wave?

27. Organ Pipe Organ pipe A , with both ends open, had a fundamental frequency of 300 Hz. The third harmonic of organ pipe B , with one end open, has the same frequency as the second harmonic of pipe A . How long are (a) pipe A and (b) pipe B ?

28. Glass Tube The water level in a vertical glass tube 1.00 m long can be adjusted to any position in the tube. A tuning fork vibrating at 686 Hz is held just over the open top end of the tube, to set up a standing wave of sound in the air-filled top portion of the tube. (That air-filled top portion acts as a tube with one end closed and the other end open.) At what positions of the water level is there resonance?

29. Speed of Waves (a) Find the speed of waves on a violin string of mass 800 mg and length 22.0 cm if the fundamental frequency is 920 Hz. (b) What is the tension in the string? For the fundamental, what is the wavelength of (c) the waves on the string and (d) the sound waves emitted by the string?

30. Violin String A certain violin string is 30 cm long between its fixed ends and has a mass of 2.0 g. The “open” string (no applied finger) sounds an A note (440 Hz). (a) To play a C note (523 Hz), how far down the string must one place a finger? (b) What is the ratio of the wavelength of the string waves required for an A note to that required for a C note? (c) What is the ratio of the wavelength of the sound wave for an A note to that for a C note?

31. Small Loudspeaker In Fig. 18-32, S is a small loudspeaker driven by an audio oscillator and amplifier, adjustable in frequency from 1000 to 2000 Hz only. Tube D is a piece of cylindrical sheet-metal pipe 45.7 cm long and open at both ends. (a) If the speed of sound in air is 344 m/s at the existing temperature, at what frequencies will resonance occur in the pipe when the frequency emitted by the speaker is varied from 1000 Hz to 2000 Hz? (b) Sketch the standing wave (using the style of Fig. 18-16b) for each resonant frequency.

FIGURE 18-32 ■ Problem 31.

32. Cello String A string on a cello has length L , for which the fundamental frequency is f . (a) By what length l must the string be

shortened by fingering to change the fundamental frequency to rf ? (b) What is l if $L = 0.80$ m and $r = 1.2$? (c) For $r = 1.2$, what is the ratio of the wavelength of the new sound wave emitted by the string to that of the wave emitted before fingering?

33. Well A well with vertical sides and water at the bottom resonates at 7.00 Hz and at no lower frequency. (The air-filled portion of the well acts as a tube with one closed end and one open end.) The air in the well has a density of 1.10 kg/m³ and a bulk modulus of 1.33×10^5 Pa. How far down in the well is the water surface?

34. A Tube A tube 1.20 m long is closed at one end. A stretched wire is placed near the open end. The wire is 0.330 m long and has a mass of 9.60 g. It is fixed at both ends and oscillates in its fundamental mode. By resonance, it sets the air column in the tube into oscillation at that column's fundamental frequency. Find (a) that frequency and (b) the tension in the wire.

35. Pulsating Variable Star The period of a pulsating variable star may be estimated by considering the star to be executing *radial* longitudinal pulsations in the fundamental standing wave mode. That is, the star's radius varies periodically with time, with a displacement antinode at the star's surface. (a) Would you expect the center of the star to be a displacement node or antinode? (b) By analogy with a pipe with one open end, show that the period of pulsation T is given by

$$T = \frac{4R}{\langle v \rangle},$$

where R is the equilibrium radius of the star and $\langle v \rangle$ is the average sound speed in the material of the star. (c) Typical white dwarf stars are composed of material with a bulk modulus of 1.33×10^{22} Pa and a density of 10^{10} kg/m³. They have radii equal to 9.0×10^{-3} solar radius. What is the approximate pulsation period of a white dwarf?

36. Pipes A and B Pipe A , which is 1.2 m long and open at both ends, oscillates at its third lowest harmonic frequency. It is filled with air for which the speed of sound is 343 m/s. Pipe B , which is closed at one end, oscillates at its second lowest harmonic frequency. These frequencies of pipes A and B happen to match. (a) If an x axis extends along the interior of pipe A , with $x = 0$ at one end, where along the axis are the displacement nodes? (b) How long is pipe B ? (c) What is the lowest harmonic frequency of pipe A ?

37. Violin String and Loudspeaker A violin string 30.0 cm long with linear density 0.650 g/m is placed near a loudspeaker that is fed by an audio oscillator of variable frequency. It is found that the string is set into oscillation only at the frequencies 880 and 1320 Hz as the frequency of the oscillator is varied over the range 500–1500 Hz. What is the tension in the string?

SEC. 18-6 ■ BEATS

38. Too Tightly Stretched The A string of a violin is a little too tightly stretched. Four beats per second are heard when the string is sounded together with a tuning fork that is oscillating accurately at concert A (440 Hz). What is the period of the violin string oscillation?

39. Unknown Tuning Fork A tuning fork of unknown frequency makes three beats per second with a standard fork of frequency

384 Hz. The beat frequency decreases when a small piece of wax is put on a prong of the first fork. What is the frequency of this fork?

40. Five Tuning Forks You have five tuning forks that oscillate at close but different frequencies. What are the (a) maximum and (b) minimum number of different beat frequencies you can produce by sounding the forks two at a time depending on how the frequencies differ?

41. Two Piano Wires Two identical piano wires have a fundamental frequency of 600 Hz when kept under the same tension. What fractional increase in the tension of one wire will lead to the occurrence of 6 beats/s when both wires oscillate simultaneously?

SEC. 18-7 ■ THE DOPPLER EFFECT

42. Trooper B Trooper *B* is chasing speeder *A* along a straight stretch of road. Both are moving at a speed of 160 km/h. Trooper *B*, failing to catch up, sounds his siren again. Take the speed of sound in air to be 343 m/s and the frequency of the source to be 500 Hz. What is the Doppler shift in the frequency heard by speeder *A*?

43. Turbine Whine The 16 000 Hz whine of the turbines in the jet engines of an aircraft moving with speed 200 m/s is heard at what frequency by the pilot of a second craft trying to overtake the first at a speed of 250 m/s?

44. Ambulance Siren An ambulance with a siren emitting a whine at 1600 Hz overtakes and passes a cyclist pedaling a bike at 2.44 m/s. After being passed, the cyclist hears a frequency of 1590 Hz. How fast is the ambulance moving?

45. A Whistle A whistle of frequency 540 Hz moves in a circle of radius 60.0 cm at a rotational speed of 15.0 rad/s. What are (a) the lowest and (b) the highest frequencies heard by a listener a long distance away, at rest with respect to the center of the circle?

46. Motion Detector A stationary motion detector sends sound waves of frequency 0.150 MHz toward a truck approaching at a speed of 45.0 m/s. What is the frequency of the waves reflected back to the detector?

47. French Submarine A French submarine and a U.S. submarine move toward each other during maneuvers in motionless water in the North Atlantic (Fig. 18-33). The French sub moves at 50.0 km/h, and the U.S. sub at 70.0 km/h. The French sub sends out a sonar signal (sound wave in water) at 1000 Hz. Sonar waves travel at 5470 km/h. (a) What is the signal's frequency as detected by the U.S. sub? (b) What frequency is detected by the French sub in the signal reflected back to it by the U.S. sub?

FIGURE 18-33 ■ Problem 47.

48. Sound Source A sound source *A* and a reflecting surface *B* move directly toward each other. Relative to the air, the speed of source *A* is 29.9 m/s, the speed of surface *B* is 65.8 m/s, and the speed of sound is 329 m/s. The source emits waves at frequency 1200 Hz as measured in the source frame. In the reflector frame, what are (a) the frequency and (b) the wavelength of the arriving sound waves? In the source frame, what are (c) the frequency and (d) the wavelength of the sound waves reflected back to the source?

49. Burglar Alarm An acoustic burglar alarm consists of a source emitting waves of frequency 28.0 kHz. What is the beat frequency between the source waves and the waves reflected from an intruder walking at an average speed of 0.950 m/s directly away from the alarm?

50. A Bat A bat is flitting about in a cave, navigating via ultrasonic bleeps. Assume that the sound emission frequency of the bat is 39 000 Hz. During one fast swoop directly toward a flat wall surface, the bat is moving at 0.025 times the speed of sound in air. What frequency does the bat hear reflected off the wall?

51. Girl in Window A girl is sitting near the open window of a train that is moving at a velocity of 10.00 m/s to the east. The girl's uncle stands near the tracks and watches the train move away. The locomotive whistle emits sound at frequency 500.0 Hz. The air is still. (a) What frequency does the uncle hear? (b) What frequency does the girl hear? A wind begins to blow from the east at 10.00 m/s. (c) What frequency does the uncle now hear? (d) What frequency does the girl now hear?

52. Civil Defense Official A 2000 Hz siren and a civil defense official are both at rest with respect to the ground. What frequency does the official hear if the wind is blowing at 12 m/s (a) from source to official and (b) from official to source?

53. Two Trains Two trains are traveling toward each other at 30.5 m/s relative to the ground. One train is blowing a whistle at 500 Hz. (a) What frequency is heard on the other train in still air? (b) What frequency is heard on the other train if the wind is blowing at 30.5 m/s toward the whistle and away from the listener? (c) What frequency is heard if the wind direction is reversed?

SEC. 18-8 ■ SUPERSONIC SPEEDS; SHOCK WAVES

54. Bullet Fired A bullet is fired with a speed of 685 m/s. Find the half angle made by the shock cone with the line of motion of the bullet.

55. Jet Plane A jet plane passes over you at a height of 5000 m and a speed of Mach 1.5. (a) Find the Mach cone half angle. (b) How long after the jet passes directly overhead does the shock wave reach you? Use 331 m/s for the speed of sound.

56. Plane Flies A plane flies at 1.25 times the speed of sound. Its sonic boom reaches a man on the ground 1.00 min after the plane passes directly overhead. What is the altitude of the plane? Assume the speed of sound to be 330 m/s.

Additional Problems

57. Building a Pipe Organ You decide to build a pipe organ in your dormitory room using PVC pipe. Estimate whether you could build an organ that would cover the entire range of human hearing without bending any pipes.

58. Arranging the Patio Speakers

You have set up two stereo speakers on your back patio railing as shown in the top view diagram in Fig. 18-34. You are worried that at certain positions you will lose frequencies as a result of interference. The coordinate grid on the edge of the picture has its large tick marks separated by 1 meter. For ease of calculation, make the following assumptions:

- Assume that the relevant objects lie on integer or half-integer grid points of the coordinate system.
- Take the speed of sound to be 343 m/s.

FIGURE 18-34 ■ Problem 58.

- Ignore the reflection of sound from the house, trees, and so on.
- The speakers are in phase.

(a) What will happen if you are sitting in the middle of the bench?
 (b) If you are sitting in the lawn chair on the left, what will be the lowest frequency you will lose to destructive interference?
 (c) Can you restore the frequency lost in part (a) by switching the leads to one of the speakers, thereby reversing the phase of that source?
 (d) With the leads reversed, what will happen to the sound for a person sitting at the center of the bench?

59. Truthful Salesman? A salesperson claimed that a stereo system had a maximum audio power of 120 W. Testing the system with several speakers set up so as to simulate a point source, the consumer noted that she could get as close as 1.2 m with the volume full on before the sound hurt her ears. Was the salesperson truthful? Explain your answer with a calculation.

60. Experimenter An experimenter wishes to measure the speed of sound in an aluminum rod 10 cm long by measuring the time it takes for a sound pulse to travel the length of the rod. If results good to four significant figures are desired, how precisely must the length of the rod be known and how closely must the experimenter be able to resolve time intervals?

The First Law of Thermodynamics

© Masato Ono, Tamagawa University.

The giant hornet *Vespa mandarinia japonica* preys on Japanese bees. However, if one of the hornets attempts to invade a bee hive, several hundred of the bees quickly form a compact ball around the hornet to stop it. After about 20 minutes the hornet is dead, although the bees do not sting, bite, crush, or suffocate it.

Why, then, does the hornet die?

The answer is in this chapter.

19-1 Thermodynamics

In the next three chapters we focus on a new subject—thermodynamics. The development of thermodynamic principles is one of humankind’s most profound intellectual achievements. Why? The steam engine that powered the industrial revolution operates according to thermodynamic principles, as do many modern power plants. Thermodynamics has enriched our fundamental understanding of phenomena ranging from the metabolism of a lizard to the evolution of the universe.

Recall from Chapter 10 that the total mechanical energy of a system is the sum of the *macroscopic* kinetic and potential energies associated with the motion and configuration of the objects within the system. By macroscopic we mean that the particles in a system were large enough so that we could observe how fast they were moving (associated with kinetic energy) and also see their configuration (associated with potential energy). We found that when conservative forces act on the particles in an isolated system, the system’s mechanical energy is conserved even if its potential energy is converted to kinetic energy or vice versa. Also recall that we can add mechanical energy to a system by doing work on it.

Furthermore, in Chapter 10 we observed that when a block slides along a surface and comes to a stop due to a nonconservative friction force, the temperatures of the block and surface rise. A decrease in the total mechanical energy of the block-surface system was accompanied by an increase in the temperature of the parts of the system. In response to this observation, we defined a new kind of energy, **thermal energy**, E^{thermal} , associated with the temperature of an object. Then, the overall system energy would still be conserved.

Our study of thermodynamics begins with learning how to quantify the hidden *internal* energy stored in ordinary matter on a microscopic (and hence invisible) scale. It also involves an examination of the role that temperature plays in determining whether a system’s internal energy will increase or decrease when it comes into contact with another system. But, when hot steam is injected into a cylinder with a piston on top of it, the piston can be raised. So we believe that under other circumstances the internal energy in a system can be transformed back into mechanical energy.

In this chapter we consider temperature and various ways it can be measured. We then quantify the invisible transfer of thermal energy between objects of different temperatures. We also introduce the first law of thermodynamics, a statement of energy conservation, which relates internal energy change to both the thermal energy transferred to or from a system and the mechanical work done on or by it.

In Chapter 20 we introduce **kinetic theory** as an idealized model of how microscopic scale kinetic and potential energies associated with the motions and configurations of atoms and molecules can be added together to explain internal energy. The 19th century development of kinetic theory to explain internal energy is similar in character and importance to Einstein’s 20th century discovery that matter also contains hidden energy by virtue of its mass. We then begin a study of heat engines by considering how the internal energy in hot expanding gases can be transformed into mechanical work.

In Chapter 21 we explain the principles that govern the operation of heat engines. We then introduce the concept of entropy that helps us understand why no one has ever invented a heat engine that can transform internal energy into mechanical work with anything close to 100% efficiency.

19-2 Thermometers and Temperature Scales

Temperature and its measurement are central to understanding the behavior of macroscopic systems that are heated and cooled. Although we have a natural ability to sense hot and cold, we can only use our sense of touch to tell whether an object is

hot or cold over a relatively narrow range of temperatures. But, we will now need to *quantify* our intuitive sense of hotness. Recall that any characteristic of a material or object that is measurable can be referred to as a **quantity** or **measurable property**. In other words, a measurable property is one that can be quantified through physical comparison with a reference (Sections 1-1 and 1-2). Careful observation of our everyday world tells us that some objects such as a balloon full of air or a metal rod have characteristics that change as the object gets hotter or colder. For example, put a balloon full of air into the freezer and you can observe for yourself that it gets smaller. A metal rod may grow a little longer when heated. Volume, length, electrical resistance, and pressure are examples of measurable properties of a material object that can change with temperature. We can use any one of the properties of materials that change as an object gets hotter or colder to design crude (or not so crude) devices that quantify the hotness of an object. Such a device is called a **thermometer**.

Designing an accurate thermometer is not a trivial task. Nevertheless, thermometers are common devices and so many of us have a basic, “common sense” understanding of what a thermometer is and how to use one. We begin our study of thermodynamics with temperature. We will also reconsider this topic later in the chapter when we will refine and expand our understanding of the concept of temperature and its measurement.

Most, but not all, substances expand when heated. You can loosen a tight metal lid on a jar by holding it under a stream of hot water. Both the metal of the lid and the glass of the jar expand as the hot water transfers some of its hidden (or *internal*) thermal energy to both the jar and lid. This happens because with the added energy, the atoms in the lid can move a bit farther from each other than usual, pulling against the spring-like interatomic forces that hold every solid together. (See Chapter 6 if you need to remind yourself of our spring-atom model for solids.) However, the metal lid expands more than the glass, and so the lid is loosened. The familiar sealed liquid-in-glass thermometer (Fig. 19-1a) works in a similar way. The mercury or colored alcohol contained in the hollow glass bulb and tube expands more than the glass that surrounds it.

We call the transfer of energy from a “hotter” system to a “colder” system by invisible atomic and molecular collisions and chemical reactions **thermal energy transfer**. It is important to note that thermal energy transfers often involve no exchange of matter. For example, in the situation described above, no water penetrates the jar or its lid. How is this possible? Imagine a high kinetic energy cue ball colliding with a ball at rest in the middle of a billiard table. The cue ball loses all its energy and the other ball gains the amount that was lost—a massless transfer! So we can imagine that if the molecules in the hot water are vibrating more vigorously than the glass molecules in the jar, energy is transferred from the water molecules to the jar molecules.

Suppose you dip an unmarked liquid thermometer filled with red colored alcohol into a cup of cold water. Since the water feels cold to the touch you can make a scratch in the tube where the liquid stands and define that height as a cold temperature. Then you can transfer your unmarked thermometer to a cup of water that feels hot to the touch. You make another scratch where the liquid now stands and define that height as a hot temperature. What if you dip the thermometer into a cup of water that feels neither hot nor cold to your touch and the height of the alcohol is halfway between the two original temperatures? Is it reasonable to assume that the new temperature is halfway between the two original temperatures? The assumption that this is true has guided the development of the historical Fahrenheit and Celsius temperature scales, and it is not too far from the truth. Thus, it is useful to start our study of thermodynamics with a very crude definition of temperature change as *a quantity that is proportional to changes of the height of the liquid inside a thermometer*. In order to quantify temperature, we need to assign numbers to various heights of the liquid in our glass tube. That is, we must set up a *temperature scale*.

(a)

(b)

(c)

FIGURE 19-1 ■ Two types of thermometers based on changes in measurable properties of materials with hotness. (a) A liquid thermometer in which the liquid in a tube expands more than the glass that contains it when placed in hotter surroundings. (b) and (c) Electronic thermometers in which the electrical resistance of a sensing element embedded at the end of a thin rod changes when placed in hotter surroundings.

FIGURE 19-2 ■ The Celsius and Fahrenheit temperature scales compared for the freezing and boiling points of water at standard atmospheric pressure at sea level. Each tic mark represents 5° .

The Fahrenheit and Celsius scales are the two temperature scales in common use today. You are probably familiar with the Fahrenheit scale from U.S. weather forecasts and you may have worked with the Celsius scale in other science courses. Each scale is set up using a reproducible low temperature “fixed point” and another at a higher temperature. A temperature is assigned to each of the two fixed points on the thermometer column. Then the distance between the two fixed points is divided into equally spaced **degrees**.

The Fahrenheit Scale

The scale set up by Gabriel Fahrenheit in 1714 starts with a zero point (0°F) defined to be the lowest temperature attainable by a mixture of ice and salt. His upper fixed point was set at human body temperature and defined as 96°F . So Fahrenheit put 96 divisions along the glass tube between his two fixed points. The Fahrenheit scale has proven to be quite awkward. For example, the freezing point of water at sea level turns out to be about 32°F and the boiling point of water at sea level turns out to be about 212°F as shown in Fig. 19-2.

The Celsius Scale

In 1742 a Swedish investigator named Celsius devised a more sensible scale that he called the centigrade scale. Celsius defined the freezing point of water at sea level as 0°C and the boiling point as 100°C . The modern Celsius scale was developed based on a degree that is almost the same “size” as the centigrade scale. However, it has been adjusted so one of its fixed points is the triple point of water. The triple point of water is the temperature and pressure at which solid ice, liquid water, and water vapor coexist. The triple point temperature has been defined as 0.01°C . So, a modern Celsius thermometer and the historical centigrade thermometer will give essentially the same reading. We discuss the triple point in more detail later in this chapter. Another refinement has been to define a standard value for the atmospheric pressure at sea level to help make the boiling point temperature more stable.

The Kelvin Scale

A 19th-century British physicist, Lord Kelvin, discovered that there is a natural limit to how cold any object can get. Kelvin defined an important temperature scale used in thermodynamics that is based on this natural zero point for temperature. We discuss the Kelvin scale used by scientists and engineers in more detail in Section 19-9.

Temperature Conversions

The Fahrenheit scale employs a smaller degree than the Celsius scale and a different zero of temperature. You can easily verify both these differences by examining an ordinary room thermometer on which both scales are marked as shown in Fig. 19-2. The equation for converting between these two scales can be derived quite easily by remembering a few corresponding fixed-point temperatures for each scale (see Table 19-1 or Fig. 19-2). The equation is

$$T_F = \frac{9}{5}T_C + 32^\circ, \quad (19-1)$$

where T_F is Fahrenheit temperature and T_C is Celsius temperature.

TABLE 19-1
Some Corresponding Temperatures

Temperature	°C	°F
Boiling point of water ^a	100	212
Normal body temperature	37.0	98.6
Accepted comfort level	20	68
Freezing point of water ^a	0	32
Zero of Fahrenheit scale	≈ -18	0
Scales coincide	-40	-40

^aStrictly, the boiling point of water on the Celsius scale is 99.975°C, and the freezing point is 0.00°C. Thus there is slightly less than 100°C between those two points.

In general, people use the letters C and F to distinguish measurements and degrees on the two scales. Thus,

$$0^{\circ}\text{C} = 32^{\circ}\text{F} \quad (19-2)$$

means that 0° on the Celsius scale measures the same temperature as 32° on the Fahrenheit scale. We might also say

$$\Delta T = 5\text{ C}^{\circ} = 9\text{ F}^{\circ}$$

which means that a temperature difference of 5 Celsius degrees (note the degree symbol appears *after* C) is equivalent to a temperature difference of 9 Fahrenheit degrees.

Problems with the Initial Definition of Temperature

There are several problems with basing our definition of temperature on the height of liquid in a scaled liquid thermometer: (1) the historically chosen fixed points are not highly reproducible since we will find that freezing and boiling points depend on pressure, (2) the height range over which liquids can vary in a glass tube is quite limited (liquids freeze when very cold or vaporize when very hot), (3) the assumption that liquids expand in proportion to temperature may not always be accurate and, the glass bulb thermometer must be small enough compared to the system that it doesn't affect it. We will return to our discussion of how to define temperature and design a better thermometer in Section 19-9. Meanwhile, we use our initial definition of temperature as the height of a liquid in a hollow glass thermometer as the starting point for our study of thermal interactions.

READING EXERCISE 19-1: List several additional measurable properties of an object. List several properties of an object that you believe are not measurable. ■

19-3 Thermal Interactions

Now that we have a means to measure temperature we can explore what happens to temperatures when two systems come into contact with each other. Consider the following two observations:

1. When a metal bucket of hot water is placed in a room, the reading of a thermometer placed in the water always decreases until, eventually, it matches the reading of a (assumed identical) thermometer in the room.

- When a bucket of cold water is placed in a room, the reading of a thermometer in the bucket always increases until, eventually, it matches the reading of a thermometer in the room.

Our common sense tells us these observations indicate that there has been an interaction between the bucket of water and its surroundings. These interactions are examples of **thermal interactions**. We will call the bucket of water our *system*. We first introduced the term “system” in Chapter 8 in regard to the concept of conservation of momentum. Just as we did there, we will define a **system** to be the object or objects that are the primary focus of our interest. That, of course, means that we can make choices about what objects we include in our system. Just as in our study of conservation of energy and momentum, we will often be considering the interaction between two or more systems that can exchange energy with each other without exchanging matter. At other times we will consider the interaction between a single system and its surroundings.

The **environment** is defined as a system’s surroundings or everything outside of it. Many thermal interactions of interest are interactions between a system (for example, the bucket of water) and its environment (for example, the air in the room). For practical purposes, the environment can often be taken as a system’s immediate surroundings (without extending our consideration to the entire universe). All we must do is to be sure that the surroundings are much bigger than the system. For example, the environment for a bucket of water could be the room full of air that surrounds it, rather than the entire planet.

Let’s now consider two additional observations for objects that are insulated from the surrounding environment:

- When two similar objects at different temperatures are brought into contact with one another, the thermometer reading for the hotter object decreases and the thermometer reading of the colder object increases until the two readings are the same. (See Figs. 19-3 and 19-4).
- When two similar objects at the same temperature are brought together, no changes in the thermometer readings occur.

FIGURE 19-3 ■ Two vessels of water that have different temperatures at first are placed in thermal contact. They are surrounded by an insulating Styrofoam cup with a lid so that they don’t interact significantly with their surroundings (room air). What happens to their temperatures?

FIGURE 19-4 ■ A system consisting of $m_1 = 200$ g of cool water at about 5°C in a thin plastic cup is brought into thermal contact with another system consisting of $m_2 = 200$ g of warm water in a larger insulated container at about 45°C . A computer-based data acquisition system is used to monitor their temperatures. Even though no matter is exchanged between the systems (as shown in Fig. 19-3), the temperature of the cool water rises while that of the warm water falls until they reach thermal equilibrium at about 25°C , 400 seconds later.

All four of the observations discussed above include examples of a condition we will call *thermal equilibrium*. If two objects (for example, our system and the surrounding environment) produce the same thermometer readings (assuming identical thermometers) then the two objects are said to be in **thermal equilibrium**. That is, two objects are in thermal equilibrium if they have the same temperature. Observing the tendency of systems in contact to reach thermal equilibrium suggests that the hotter system is transferring thermal energy to the colder one until they both become warm.

The concept of thermal equilibrium is important in understanding temperature measurements. For example, as you likely know from common experience, it takes some time for a thermometer reading to stabilize. If you place a glass bulb thermometer under your tongue, it does not immediately measure your correct body temperature. This is (at least in part) because it takes some time for a thermometer to reach thermal equilibrium with another object like your body. When a thermometer comes to thermal equilibrium with an object that is not heating up or cooling down, the thermometer reading will reach a constant value. Only then do we have an accurate measurement of the object’s temperature.

Thermal equilibrium is important in the measurement of temperature in another way. Consider three objects: object *A*, object *B* and object *T*. (Object *T* may be a thermometer, but it doesn’t need to be.) Object *A* and object *B* are placed in separate, well-insulated environments as shown in Fig. 19-5. We measure the temperatures of the three objects, two at a time. Suppose we find that object *A* and object *T* are in thermal equilibrium. We then compare the temperatures of object *B* and object *T* and

find that they are in thermal equilibrium with each other as well (at the same thermometer reading as object A). Are object A and object B then necessarily in thermal equilibrium too? Experimentation provides the answer, which is referred to as the **zeroth law of thermodynamics**:

If bodies A and B are each in thermal equilibrium with a third body T , then they are in thermal equilibrium with each other.

If we choose object T to be a thermometer, we see that we use the zeroth law constantly in science laboratories. It is the basis of our acceptance of the use of thermometers to compare temperatures. For example, if we want to know whether the liquids in two different students' beakers are at the same temperature, we can measure the two temperatures separately with a single thermometer and compare them. Often when measuring temperature, the thermometer starts at room temperature and its temperature must rise or fall when it is placed in contact with body A or body B . Again, we must be careful not to have the thermometer system be so large that either body loses or gains enough thermal energy to change its temperature noticeably.

19-4 Heating, Cooling, and Temperature

Is just measuring the initial and final temperature of an object that is changing temperature a good way to learn about how objects heat or cool? In order to answer this question, let us consider several examples of how water cools:

1. A small cup of very hot water is put in a room that is being maintained at a comfortable air temperature of 20°C . The water will cool down until it reaches thermal equilibrium with the surrounding air.
2. We place a large bucket of hot water in the same room, it will also cool down, but it will take longer than the cup of water does to cool.
3. We first place a small cup of hot water in a sealed thermos bottle and then place the bottle in the room, the water will still reach thermal equilibrium with the room but it will take much longer to cool down to room temperature than it did before.
4. We put a cup containing water at 30°C in a very cold freezer. We find the water freezes and becomes ice. During the freezing process we keep the water-ice mixture well-stirred and measure its temperature as a function of time. As shown in Fig. 19-6, once the mixture of ice and water are cooled to 0°C , the mixture undergoes no change in temperature until all the ice is frozen.

The examples above are evidence that our ability to analyze thermal interactions is significantly limited if we rely solely on initial and final temperature measurements. Hence, we are motivated to invent a new, broader concept that we can use in discussing thermal interactions—even in cases where temperature changes are not the significant feature. The name of the process we will introduce is “heating,” which we can use to describe the interaction between a hotter body and colder body, *even if no temperature change occurs*. For example, if you surround ice water with air or water which has a higher temperature, the ice will melt. Or, heating cold water takes longer if it is insulated from its environment than if it is not. Observations such as those above form the basis of our understanding of the *process* called heating.

In order to gain some additional insight into the process of heating, consider two more observations.

FIGURE 19-5 (a) Body T (perhaps a thermometer) and body A are in thermal equilibrium. (Body S is a thermally insulating screen.) (b) Body T and body B are also in thermal equilibrium. (c) If (a) and (b) are true, the zeroth law of thermodynamics states that body A and body B are also in thermal equilibrium.

FIGURE 19-6 A temperature vs. time graph recorded by a data acquisition system shows what happens to a cup of water after it is placed in a cold freezer. When the water temperature decreases to 0°C ice begins to form. While ice is forming the temperature does not change. Once all the water is changed to ice the temperature starts decreasing again.

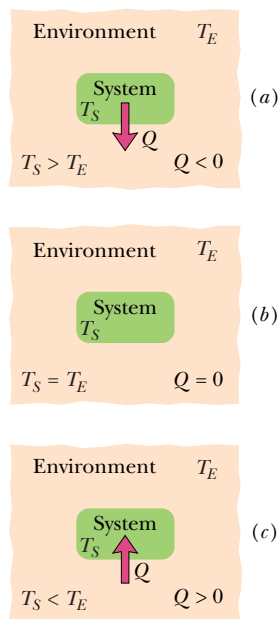

FIGURE 19-7 ■ If the temperature of a system exceeds that of its environment as in (a), an amount of thermal energy Q is transferred by the system to the environment until thermal equilibrium as shown in part (b) is established. (c) If the temperature of the system is below that of the environment, thermal energy is absorbed by the system until thermal equilibrium is established.

FIGURE 19-8 ■ In the United States we have not adopted the international system of units when referring to food energy, so the **food calorie** (denoted Cal rather than cal) is used in diet books and in all government-regulated food labels is actually a kilocalorie. Most other countries use *joules* (the accepted SI unit for energy) on food labels. The can in the photo above was purchased in Australia.

1. A container of water is placed on a burner to raise its temperature. It takes fuel (an energy source) for this process to occur.
2. If we start with two containers of water, one large and one small, at the same temperature and place them over identical burners, it takes a longer time (and so more fuel) to elevate the temperature of the larger amount of water to the same final value as the smaller.

Both of these observations are direct indications that there is energy involved in heating, just as we assumed in Chapter 10 when discussing energy conservation. Furthermore, the idea that the heating process is a *transfer of energy* from a hotter object to a colder object is consistent with all the other observations we have discussed in this chapter. Hence, we are led then to this important statement:

Heating is the transfer of energy from a system with a higher temperature to one with lower temperature that is in contact with it that occurs simply because a temperature difference exists between the systems.

The net amount of transferred thermal energy as the result of microscopic energy exchanges between systems (or parts of a system) is denoted by the letter Q . The thermal energy transferred between systems is often called “heat.” Because the term *heat* is sometimes used casually to mean the total thermal energy in a system, people often confuse heat with internal energy when describing thermal interactions. For this reason we try to avoid passive terms like *heat* or *stored heat* when describing thermal interactions. Since the phrase “heating a system” suggests an active process we will use terms like “heating,” “cooling,” or “thermal energy transfer” to refer to the additional energy that is added to (or subtracted from) a system through microscopic energy exchanges.

The amount of transferred thermal energy Q is taken to be *positive* when it is transferred *to a system* (then we say that thermal energy is absorbed). The transferred thermal energy Q is *negative* when it is transferred *from the system* (we then say that thermal energy is released or lost by the system).

This transfer of energy is shown in Fig. 19-7. In the situation of Fig. 19-7a, in which the temperature of the system T_S is greater than the temperature of the environment T_E ($T_S > T_E$), energy is transferred from the system to the environment, so Q is negative. In Fig. 19-7b, in which $T_S = T_E$, no thermal energy transfer takes place, Q is zero, and energy is neither released nor absorbed. In Fig. 19-7c, in which $T_S < T_E$, the transfer is to the system from the environment, so Q is positive.

It took scientists a while to realize that “heating” was associated with the transfer of energy from one system to another. Hence, thermal energy ended up with its own unit. Since heating was initially considered strictly in terms of temperature change, the **calorie** (cal) was defined as the amount of energy that would raise the temperature of 1 g of water from 14.5°C to 15.5°C. In the British system, the corresponding unit of thermal energy was the **British thermal unit** (Btu), defined as the amount of energy that would raise the temperature of 1 lb of water from 63°F to 64°F.

In 1948, the scientific community decided that since heating (like work) is an energy transfer process, the SI unit for thermal energy transferred (or “heat added”) should be the one we use for all other energy—namely, the **joule**. Joules are used instead of calories in most countries, as seen on the can of soda from Australia in Fig. 19-8. The calorie is now defined to be 4.1860 J (exactly), with no reference to the heating of water. (The “calorie” used in nutrition, sometimes called the Calorie with a capital C or Cal for short, is really a kilocalorie or 1000 calories.) The relations among the various thermal energy units are

$$1 \text{ cal} = 3.969 \times 10^{-3} \text{ Btu} = 4.1860 \text{ J} = 0.001 \text{ Cal (or food calorie)}. \quad (19-3)$$

Mechanisms for Transfer of Thermal Energy

We have discussed heating, which is the transfer of energy between a system and its environment that takes place simply because a temperature difference exists between them, but we have not yet described how that transfer takes place. We will briefly describe the three heating mechanisms here and return to discuss them more fully at the end of this chapter.

If you leave the end of a metal poker in a fire for enough time, its handle will get hot. There are large vibrations of the atoms and electrons of the metal at the fire end of the poker because of the high temperature of their environment. These increased vibrational amplitudes, and thus the associated energy, are passed along the poker, from atom to atom, during collisions between adjacent atoms. In this way, a region of increasing temperature extends itself along the poker to the handle. It is important to note though that there has been no flow of matter—only energy that is transmitted along the poker. This type of heating process is called (thermal) **conduction**.

Conduction is, by definition, a transfer mechanism that requires direct contact between two objects at different temperatures. Consider our poker to be a series of systems that can have different temperatures. If there is not direct contact between the colder object and hotter object (one atom and the next in our poker example), there cannot be a transfer of thermal energy by conduction. As we mentioned above, *conduction does not involve any mass transfer*. However, in some real situations it is sometimes impossible to avoid the transfer of material from one object to the other during heating. In such cases, the process is no longer one of “pure” conduction.

When you open a low and a high window in a heated house, you can feel cold outside air rushing into the room through the low window and warm room air rushing outside through the high window. This is because the cold air is more dense than the warm air so it displaces the warm air at the bottom of the room. The warm air rises as a result of buoyant forces and flows out the top window. The room gets colder because of the exchange of cold and warm air. In this situation, thermal energy is being transported by the flow of matter (air currents in this case). The transfer by the exchange of hotter and cooler fluids is known as **convection**.

Examples of heating by convection are everywhere. This is how air circulation helps spread the warmth through a room when a radiator or heater gets hot. It is why *all* the water in a tea kettle gets hot (as opposed to only the water in contact with the hot kettle surface) when the kettle is placed on a hot stove. Convection is part of many other natural processes. Atmospheric convection plays a fundamental role in determining global climate patterns and daily weather variations. Glider pilots and birds alike seek rising thermals (convection currents of warm air) that keep them aloft. Huge energy transfers take place within the oceans by the same process. Finally, energy is transported to the surface of the sun from the nuclear furnace at its core by enormous cells of convection, in which hot gas rises to the surface along the cell core and cooler gas around the core descends below the surface. In all examples of heating by convection, gravitational forces play a vital role. Without gravitational forces, hotter materials would not rise above cooler materials. Hence, there is no heating by convection on a space station.

When you sit in the sun you can feel your skin getting warmer. If you put a shield between you and the sun, the sensation of warmth immediately disappears. How is this energy transfer taking place? We know that the light from the sun has to pass through over a hundred million kilometers of almost empty space. So, this thermal energy transfer can't be attributed to either convection or conduction. Solar energy transfer is attributed to a third transfer process—the absorption of **electromagnetic radiation**. Although visible light is one kind of electromagnetic radiation, the sun and a hot fire that can also warm you emit both visible light and invisible infrared radiation that has a longer characteristic wavelength than light. (See Chapter 34 for more details on electromagnetic waves.) No medium is required for energy transfer via

electromagnetic radiation. Thermal energy transferred by infrared electromagnetic waves is often called **thermal radiation** or **radiant energy**.

READING EXERCISE 19-2: Explain the function of insulation in homes. ■

FIGURE 19-9 ■ (a) A computer-based data collection system with a digital temperature sensor can be used to monitor the temperature rise in a liquid while thermal energy is transferred to it at a constant rate by an immersion heater. The liquid in this photo is motor oil. (b) If thermal energy is transferred to two different liquids that have the same mass, the temperature does not usually rise at the same rate. So we define a different specific heat for each liquid. For example, a small immersion heater shown in Fig. 19-9a “heats up” 175 g of motor oil faster than 175 g of water. Data were taken once each second for 70 seconds with a computer-based data collection system.

19-5 Thermal Energy Transfer to Solids and Liquids

If we start with two containers of water, one large and one small, at the same temperature and place them to heat over identical burners, it takes a longer time (and so more fuel and thus more thermal energy) to elevate the temperature of the larger amount of water to the same final value as the smaller. It takes almost twice as much energy to heat a cup of water as it does to heat a cup of motor oil to the same temperature. This is shown in Fig. 19-9a and b. A common electric immersion heater is placed in a container of motor oil and plugged in. It puts out a bit less than 200 W of power at a constant rate. Since energy is power \times time the total amount of thermal energy transferred to the oil is directly proportional to the time the heater has been on. The graph in Fig. 19-9b shows that after 70 seconds, the change in water temperature, $T_f - T_i$, is about 15°C while the oil temperature has risen about 30°C. We can say the “water holds its heat” twice as well as motor oil. It would be more correct to say that water absorbs the thermal energy transferred to it without showing as much temperature change.

If we look at heating and cooling curves for a large number of different objects and different substances (see Fig. 19-9b for an example), we find that the relationship between thermal energy transfer and temperature is linear (as long as the material doesn’t melt, freeze, or vaporize). However, the scaling factor (proportionality constant) changes from material to material. The **heat capacity** C of an object is the name that we give to the proportionality constant between the thermal energy transferred Q and the resulting temperature change ΔT of the object; that is,

$$Q = C \Delta T = C(T_f - T_i), \quad (19-4)$$

in which T_i and T_f are the initial and final temperatures of the object. Heat capacity C has the unit of energy per degree Celsius. The heat capacity C of, say, a marble slab used in a bun warmer might be 179 cal/°C.

The word “capacity” in this context is really misleading in that it suggests analogy with the capacity of a bucket to hold water. Since heat is not a substance, *that analogy is misleading*, and you should not think of the object as “containing” thermal energy or being limited in its ability to absorb thermal energy. Thermal energy transfer can proceed without limit as long as the necessary temperature difference between the object and its surroundings is maintained. The object may, of course, melt or vaporize during the process.

Specific Heat

Two objects made of the same material—say, marble—will have heat capacities proportional to their masses. It is therefore convenient to define a “heat capacity per unit mass” or **specific heat** c that refers not to an object but to a unit mass of the material of which the object is made. Equation 19-4 then becomes

$$Q = cm \Delta T = cm(T_f - T_i), \quad (19-5)$$

where $C = mc$.

Through experiment we would find that although the heat capacity of a particular marble slab might be 179 cal/C° , the specific heat of the marble (in that slab or in any other marble object) is $0.21 \text{ cal/g} \cdot \text{C}^\circ$.

From the way the calorie and the British thermal unit were initially defined, measurements show that the specific heat of water is

$$c = 1 \text{ cal/g} \cdot \text{C}^\circ = 1 \text{ Btu/lb} \cdot \text{F}^\circ = 4190 \text{ J/kg} \cdot \text{C}^\circ. \quad (19-6)$$

Table 19-2 shows the specific heats of some substances at room temperature. Note that the value for water is relatively high. The specific heat of any substance actually depends somewhat on temperature, but the values in Table 19-2 apply reasonably well in a range of temperatures near room temperature.

TABLE 19-2
Specific Heats of Some Substances at Room Temperature and Constant Pressure

Substance	Specific Heat		Molar Specific Heat
	$\frac{\text{cal}}{\text{g} \cdot \text{C}^\circ}$	$\frac{\text{J}}{\text{kg} \cdot \text{C}^\circ}$	$\frac{\text{J}}{\text{mol} \cdot \text{C}^\circ}$
<i>Elemental Solids</i>			
Lead	0.0305	128	26.5
Tungsten	0.0321	134	24.8
Silver	0.0564	236	25.5
Copper	0.0923	386	24.5
Aluminum	0.215	900	24.4
<i>Other Solids</i>			
Brass	0.092	380	
Granite	0.19	790	
Glass	0.20	840	
Ice (-10°C)	0.530	2220	
<i>Liquids</i>			
Mercury	0.033	140	
Ethyl alcohol	0.58	2430	
Seawater	0.93	3900	
Water	1.00	4190	

Molar Specific Heat

In many instances the most convenient unit for specifying the amount of a substance is the mole (mol), where

$$1 \text{ mol} = 6.02 \times 10^{23} \text{ basic units}$$

of *any* substance. Thus 1 mol of aluminum means 6.02×10^{23} atoms (the atom being the elementary unit), and 1 mol of aluminum oxide means 6.02×10^{23} molecules of the oxide (because the molecule is the basic unit of a compound).

When quantities are expressed in moles, specific heats must also involve moles (rather than a mass unit); they are then called **molar specific heats**. Table 19-2 shows the values for some elemental solids (each consisting of a single element) at room temperature.

Specific Heats at Constant Pressure and Constant Volume

In determining and then using the specific heat of any substance, we need to know the conditions under which thermal energy is transferred. For solids and liquids, we usually assume that the sample is under constant pressure (usually atmospheric) during the

transfer. It is also conceivable that the sample is held at constant volume while the thermal energy is absorbed. This means that thermal expansion of the sample is prevented by applying external pressure. For solids and liquids, this is very hard to arrange experimentally but the effect can be calculated, and it turns out that the specific heats under constant pressure and constant volume for any solid or liquid differ usually by no more than a few percent. Gases, as you will see, have quite different values for their specific heats under constant-pressure conditions and under constant-volume conditions.

Heats of Transformation

Recall our example above of the ice (solid water). “Solid” is a description of the water that we will call its **phase**. There are, in general, three phases of matter: solid, liquid, and vapor. As a *solid*, the molecules of a sample are locked into a fairly rigid structure by their mutual attraction. As a *liquid*, the molecules have more energy and move about more. They may form brief clusters, but the sample does not have a rigid structure and can flow or settle into a container. As a *gas* or *vapor*, the molecules have even more energy, are free of one another, and can fill up the full volume of a container. To fully describe a material for thermodynamic purposes we must specify not only the phase (solid, liquid, or vapor) but also the temperature, pressure, and volume. The phase of a material along with the temperature, pressure, and volume of the material specify the **state** of the material.

As we all know, we find that ice melts when exposed to a warm room and becomes liquid water. The melting is called a **change of phase**. When thermal energy is absorbed or lost by a solid, liquid, or vapor, the temperature of the sample does not necessarily change. Instead, the sample may change from one phase to another. Through experiments we have found that while a material is undergoing a change in phase additional transfers of thermal energy do not change the temperature of the material. We saw one example of this in Fig. 19-6.

To *melt* a solid means to change it from the solid phase to the liquid phase. The process requires energy because the molecules of the solid must be freed from their rigid structure. Melting an ice cube to form liquid water is a common example. To *freeze* a liquid to form a solid is the reverse of melting and requires that energy be removed from the liquid, so that the molecules can settle into a rigid structure. To *vaporize* a liquid means to change it from the liquid phase to the vapor or gas phase. This process, like melting, requires energy because the molecules must be freed from their clusters. Boiling liquid water transforms it to water vapor (or steam—a gas of individual water molecules) is a common example. *Condensing* a gas to form a liquid is the reverse of vaporizing; it requires that energy be removed from the gas, so that the molecules can cluster instead of flying away from one another.

The amount of energy per unit mass that must be transferred as thermal energy when a sample completely undergoes a phase change is called the heat of transformation L . Thus, when a sample of mass m completely undergoes a phase change, the total energy transferred is

$$Q = Lm. \quad (19-7)$$

When the phase change is from liquid to gas (then the sample must absorb thermal energy) or from gas to liquid (then the sample must release thermal energy), the thermal energy required for this transformation is called the **heat of vaporization** L_V .^{*} For water at its normal boiling or condensation temperature,

$$L_V = 539 \text{ cal/g} = 40.7 \text{ kJ/mol} = 2256 \text{ kJ/kg} \quad (\text{water} \rightarrow \text{steam}). \quad (19-8)$$

^{*}Chemists often denote entropy as ΔH and call it enthalpy of vaporization.

When the phase change is from solid to liquid (then the sample must absorb thermal energy) or from liquid to solid (then the sample must release thermal energy), the heat of transformation is called the **heat of fusion** L_F . For water at its normal freezing or melting temperature,

$$L_F = 79.5 \text{ cal/g} = 6.01 \text{ kJ/mol} = 333 \text{ kJ/kg} \quad (\text{ice} \rightarrow \text{water}). \quad (19-9)$$

Table 19-3 shows the heat of transformation for some substances.

TABLE 19-3
Some Heats of Transformation

Substance	Melting		Boiling	
	Melting Point (°C)	Heat of Fusion L_F (kJ/kg)	Boiling Point (°C)	Heat of Vaporization L_V (kJ/kg)
Hydrogen	-259.2	58.0	-252.9	455
Oxygen	-218.4	13.9	-183.0	213
Mercury	-39.2	11.4	356.9	296
Water	-0.1	333	99.9	2256
Lead	327.9	23.2	1743.9	858
Silver	961.9	105	2049.9	2336
Copper	1082.9	207	2594.9	4730

Heating and Internal Energy

Consider melting a 0°C block of ice so that it melts and then becomes hot water. This system undergoes *both* a phase change and a temperature increase. What happens to the system's hidden internal energy that we mentioned in the introduction? Heating via thermal energy transfer increases its internal energy in two ways:

1. We change the system's microscopic configuration by allowing its atoms and molecules to move further away from each other (without a temperature change).
2. We increase its microscopic kinetic energy (or thermal energy) by increasing the motions of its atoms and molecules (which can be measured as a rise in temperature).

READING EXERCISE 19-3: If an amount of thermal energy Q is transferred to object A , it will cause each gram of A to rise in temperature by 3°C. If the same amount of energy is transferred to object B , then the temperature of each gram of B will rise by 4°C. If object A and B have the same mass, which one has the greater specific heat? ■

READING EXERCISE 19-4: Notice in Table 19-3 that water has a very large heat of vaporization. What is the significance of this to a firefighter who finds that the water sprayed on a very hot fire is converted to steam? Suppose that 1 g of steam comes in contact with 1 g of a firefighter's flesh and condenses. Assuming that flesh has the same heat capacity as water, what would be the temperature rise in 1 g of the firefighter's flesh? ■

TOUCHSTONE EXAMPLE 19-1: Melting Ice

(a) How much thermal energy must be absorbed by ice of mass $m = 720 \text{ g}$ at -10°C to take it to a liquid state at 15°C ?

SOLUTION ■ The first **Key Idea** is that the heating process is accomplished in three steps.

Step 1. The **Key Idea** here is that the ice cannot melt at a temperature below the freezing point—so initially, any thermal energy transferred to the ice can only increase the temperature of the ice. The energy Q_1 needed to increase that temperature from the initial value $T_i = -10^\circ\text{C}$ to a final value $T_f = 0^\circ\text{C}$ (so that the ice can then

melt) is given by Eq. 19-5 ($Q = cm \Delta T$). Using the specific heat of ice c_{ice} in Table 19-2 gives us

$$\begin{aligned} Q_1 &= c_{\text{ice}}m(T_f - T_i) \\ &= (2220 \text{ J/kg} \cdot ^\circ\text{C})(0.720 \text{ kg})[0^\circ\text{C} - (-10^\circ\text{C})] \\ &= 15\,984 \text{ J} = 15.98 \text{ kJ}. \end{aligned}$$

Step 2. The next **Key Idea** is that the temperature cannot increase from 0°C until all the ice melts—so any energy transferred to the ice due to heating now can only change ice to liquid water. The thermal energy Q_2 needed to melt all the ice is given by Eq. 19-7 ($Q = Lm$). Here L is the heat of fusion L_F , with the value given in Eq. 19-9 and Table 19-3. We find

$$Q_2 = L_F m = (333 \text{ kJ/kg})(0.720 \text{ kg}) = 239.8 \text{ kJ}.$$

Step 3. Now we have liquid water at 0°C . The next **Key Idea** is that the energy transferred to the liquid water during heating now can only increase the temperature of the liquid water. The Q_3 needed to increase the temperature of the water from the initial value $T_i = 0^\circ\text{C}$ to the final value $T_f = 15^\circ\text{C}$ is given by Eq. 19-5 (with the specific heat of liquid water c_{liq}):

$$\begin{aligned} Q_3 &= c_{\text{liq}}m(T_f - T_i) \\ &= (4190 \text{ J/kg} \cdot ^\circ\text{C})(0.720 \text{ kg})(15^\circ\text{C} - 0^\circ\text{C}) \\ &= 45\,252 \text{ J} \approx 45.25 \text{ kJ}. \end{aligned}$$

The total required thermal energy transfer Q^{tot} is the sum of the amounts required in the three steps:

$$\begin{aligned} Q^{\text{tot}} &= Q_1 + Q_2 + Q_3 \\ &= 15.98 \text{ kJ} + 239.8 \text{ kJ} + 45.25 \text{ kJ} \\ &\approx 300 \text{ kJ}. \end{aligned} \quad (\text{Answer})$$

Note that the energy transfer required to melt the ice is much greater than the energy transfer required to raise the temperature of either the ice or the liquid water.

(b) If we supply the ice with a total energy of only 210 kJ (as heat), what then are the final state and temperature of the water?

SOLUTION ■ From step 1, we know that 15.98 kJ is needed to raise the temperature of the ice to the melting point. The remaining energy required Q^{rem} is then $210 \text{ kJ} - 15.98 \text{ kJ}$, or about 194 kJ. From step 2, we can see that this amount of energy is insufficient to melt all the ice. Then this **Key Idea** becomes important: Because the melting of the ice is incomplete, we must end up with a mixture of ice and liquid; the temperature of the mixture must be the freezing point, 0°C .

We can find the mass m of ice that is melted by the available energy Q^{rem} by using Eq. 19-7 with L_F :

$$m = \frac{Q^{\text{rem}}}{L_F} = \frac{194 \text{ kJ}}{333 \text{ kJ/kg}} = 0.583 \text{ kg} \approx 580 \text{ g}.$$

Thus, the mass of the ice that remains is $720 \text{ g} - 580 \text{ g}$, or 140 g, and we have

$$580 \text{ g water and } 140 \text{ g ice at } 0^\circ\text{C}. \quad (\text{Answer})$$

TOUCHSTONE EXAMPLE 19-2: Copper Slug

A copper slug whose mass m_c is 75 g is heated in a laboratory oven to a temperature T of 312°C . The slug is then dropped into a glass beaker containing a mass $m_w = 220 \text{ g}$ of water. The heat capacity C_b of the beaker is 45 cal/K. The initial temperature T_i of the water and the beaker is 12°C . Assuming that the slug, beaker, and water are an isolated system and the water does not vaporize, find the final temperature T_f of the system at thermal equilibrium.

SOLUTION ■ One **Key Idea** here is that, with the system isolated, only transfers of thermal energy can occur. There are three such transfers, all as thermal energy. The slug loses energy, the water gains energy, and the beaker gains energy. Another **Key Idea** is that, because these transfers do not involve a phase change, the energy transfers can only change the temperatures. To relate the transfers to the temperature changes, we can use Eqs. 19-4 and 19-5 to write

$$\text{for the water: } Q_w = c_w m_w (T_f - T_i); \quad (19-10)$$

$$\text{for the beaker: } Q_b = C_b (T_f - T_i); \quad (19-11)$$

$$\text{for the copper: } Q_c = c_c m_c (T_f - T). \quad (19-12)$$

A third **Key Idea** is that, with the system thermally isolated, the total energy of the system cannot change. This means that the sum of these three thermal energy transfers is zero:

$$Q_w + Q_b + Q_c = 0. \quad (19-13)$$

Substituting Eqs. 19-10 through 19-12 into Eq. 19-13 yields

$$c_w m_w (T_f - T_i) + C_b (T_f - T_i) + c_c m_c (T_f - T) = 0. \quad (19-14)$$

Temperatures are contained in Eq. 19-14 only as differences. Thus, because the differences on the Celsius and Kelvin scales are identical, we can use either of those scales in this equation. Solving it for T_f , we obtain

$$T_f = \frac{c_c m_c T + C_b T_i + c_w m_w T_i}{c_w m_w + C_b + c_c m_c}.$$

Using Celsius temperatures and taking values for c_c and c_w from Table 19-2, we find the numerator to be

$$(0.0923 \text{ cal/g}\cdot^\circ\text{C})(75 \text{ g})(312^\circ\text{C}) + (45 \text{ cal/}^\circ\text{C})(12^\circ\text{C}) \\ + (1.00 \text{ cal/g}\cdot^\circ\text{C})(220 \text{ g})(12^\circ\text{C}) = 5339.8 \text{ cal,}$$

and the denominator to be

$$(1.00 \text{ cal/g}\cdot^\circ\text{C})(220 \text{ g}) + 45 \text{ cal/}^\circ\text{C} + (0.0923 \text{ cal/g}\cdot^\circ\text{C})(75 \text{ g}) \\ = 271.9 \text{ cal/}^\circ\text{C.}$$

We then have

$$T_f = \frac{5339.8 \text{ cal}}{271.9 \text{ cal/}^\circ\text{C}} = 19.6^\circ\text{C} \approx 20^\circ\text{C.}$$

From the given data you can show that

$$Q_w \approx 1670 \text{ cal,} \quad Q_b \approx 342 \text{ cal,} \quad Q_c \approx -2020 \text{ cal.}$$

Apart from rounding errors, the algebraic sum of these three thermal energy transfers is indeed zero, as Eq. 19-13 requires.

19-6 Thermal Energy and Work

Here we look in some detail at how internal energy can be transferred into or out of both as thermal energy and as macroscopic physical work (involving the displacement of the system in the presence of net forces). Let us take as our system a gas confined to a cylinder with a movable piston, as in Fig. 19-10. This is the kind of device that is used to drive a steam engine, the engine of an automobile, and many other tools—all of which convert thermal energy into work.

In our piston–cylinder system, the upward force on the piston due to the pressure of the confined gas is equal to the weight of lead shot loaded onto the top of the piston. The walls of the cylinder are made of insulating material that does not allow any transfer of thermal energy. The bottom of the cylinder, however, rests on a reservoir of thermal energy—a *thermal reservoir* (perhaps a hot plate) whose temperature T can be held constant.

The system (the gas) starts from an *initial state* i , described by a pressure P_i , a volume V_i , and a temperature T_i . You want to change the system to a final state f , described by a pressure P_f , a volume V_f , and a temperature T_f . The procedure by which you change the system from its initial state to its final state is called a *thermodynamic process*. During such a process, an amount of energy Q may be transferred into or out of the system from the thermal reservoir. Also, work can be done by the system to raise the loaded piston (positive work) or lower it (negative work). *We assume that all such changes occur slowly, so that all parts of the system are always in (approximate) thermal equilibrium.*

Suppose that you remove a few of the lead shot from the piston of Fig. 19-10, allowing the gas to push the piston and remaining shot upward through a differential displacement $d\vec{s}$ with an upward force \vec{F} . Since the displacement is tiny, we can assume that \vec{F} is constant during the displacement. Then \vec{F} has a magnitude that is equal to PA , where P is the pressure of the gas and A is the face area of the piston. The differential work dW done by the gas during the displacement is

$$dW = \vec{F} \cdot d\vec{s} = (PA)(|d\vec{s}|) = P(A|d\vec{s}|) \\ = PdV, \quad (19-15)$$

in which dV is the differential change in the volume of the gas due to the movement of the piston. When you have removed enough shot to allow the gas to change its volume from V_i to V_f , the total work done by the gas is

$$W = \int dW = \int_{V_i}^{V_f} P dV. \quad (19-16)$$

During the change in volume, the pressure and temperature of the gas may also change. To evaluate the integral in this expression directly, we need to know how pressure varies with volume for the actual process by which the system changes from state i to state f .

FIGURE 19-10 ■ Cross section of a system that confines a gas to a cylinder with a movable piston. (Its insulating lid is not shown.) Thermal energy Q can be transferred to or from the gas by regulating the temperature T of the adjustable thermal reservoir. Work W is done on the gas when the piston rises or falls.

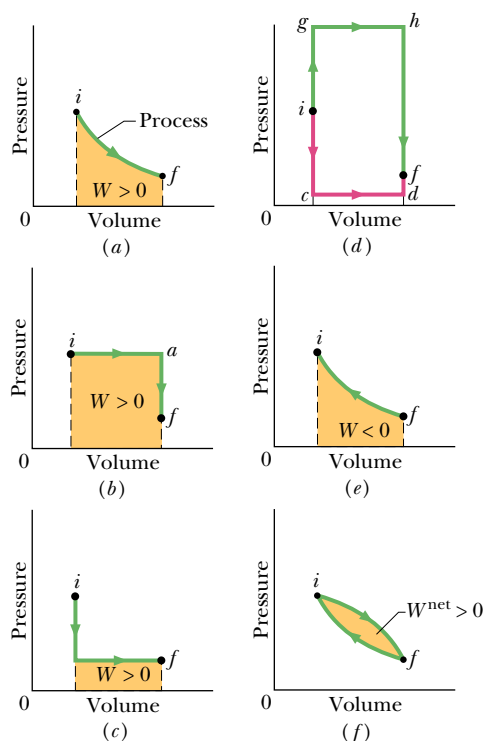

FIGURE 19-11 (a) The shaded area represents the work W done by a system as it goes from an initial state i to a final state f . Work W is positive because the system's volume increases. (b) W is still positive, but now greater. (c) W is still positive, but now smaller. (d) W can be even smaller (path $icdf$) or larger (path $ighf$). (e) Here the system goes from state i to state f , as the gas is compressed to less volume by an external force. The work W done by the system is now negative. (f) The net work W^{net} done by the system during a complete cycle is represented by the shaded area.

There are actually many ways to take the gas from state i to state f . One way is shown in Fig. 19-11a, which is a plot of the pressure of the gas versus its volume and is called a P - V diagram. In Fig. 19-11a, the curve indicates that the pressure decreases as the volume increases. The integral in Eq. 19-16 (and thus the work W done by the gas) is represented by the shaded area under the curve between points i and f . Regardless of exactly what we do to take the gas along the curve, that work by the gas or system is positive, due to the fact that the gas increases its volume by forcing the piston upward.

Another way to get from state i to state f is shown in Fig. 19-11b: the change takes place in two steps—the first from state i to state a and the second from state a to state f .

Step ia of this process is carried out at constant pressure, which means that you leave undisturbed the lead shot that ride on top of the piston in Fig. 19-10. You cause the volume to increase (from V_i to V_f) by slowly turning up the temperature control knob, raising the temperature of the gas to some higher value T_a . (Increasing the temperature increases the force from the gas on the piston, moving it upward.) During this step, positive work is done by the expanding gas (to lift the loaded piston) and thermal energy is absorbed by the system from the thermal reservoir (in response to the arbitrarily small temperature differences that you create as you turn up the system). The thermal energy transferred (Q) is positive because it is added to the system.

Step af of the process of Fig. 19-11b is carried out at constant volume, so you must wedge the piston, preventing it from moving. Then as you use a control knob to decrease the reservoir temperature, you find that the pressure drops from P_a to its final value P_f . During this step, thermal energy is lost by the system to the thermal reservoir.

For the overall process iaf , the work W , which is positive and is carried out only during step ia , is represented by the shaded area under the curve. Energy is transferred as thermal energy during both steps ia and af , with a net thermal energy transfer Q .

Figure 19-11c shows a process in which the previous two steps are carried out in reverse order. The work W in this case is smaller than for Fig. 19-11b, as is the net thermal energy absorbed. Figure 19-11d suggests that you can make the work done by the gas as small as you want (by following a path like $icdf$) or as large as you want (by following a path like $ighf$).

To sum up: A system can be taken from a given initial state to a given final state by an infinite number of processes. Thermal energy transfers may or may not be involved, and in general, the work W and the thermal energy transfer Q will have different values for different processes. We say that thermal energy and work are *path-dependent* quantities.

Figure 19-11e shows an example in which negative work is done by a system as some external force compresses the system, reducing its volume. The absolute value of the work done is still equal to the area beneath the P - V curve, but because the gas is compressed, the work done by the gas is negative.

Figure 19-11f shows a thermodynamic cycle in which the system is taken from some initial state i to some other state f and then back to i . The net work done by the system during the cycle is the sum of the positive work done during the expansion and the negative work done during the compression as shown by the shaded area inside the path. In Fig. 19-11f, the net work is positive because the area under the expansion curve (i to f) is greater than the area under the compression curve (f to i).

READING EXERCISE 19-5: The P - V diagram here shows six curved paths (connected by vertical paths) that can be followed by a gas. Which two of them should be part of a closed cycle if the net work done by the gas is to be at its maximum positive value?

19-7 The First Law of Thermodynamics

You have just seen that when a system changes from a given initial state to a given final state, both the work W done by the system and the thermal energy transferred to the system Q depend on the nature of the process.* Experimentally, however, we find a surprising thing. The quantity $Q - W$ is the same for all processes. It depends only on the initial and final states and does not depend at all on how the system gets from one to the other. All other combinations of Q and W , including Q alone, W alone, $Q + W$, and $Q - 2W$, are path dependent; only the quantity $Q - W$ is not.

So, we come to believe that the quantity $Q - W$ must represent a change in some intrinsic property of the system. Since we know that both heating and work are energy transfer processes, we assume that the quantity $Q - W$ results in a change in energy. But a change in the energy of what? As we pointed out in the introduction to this chapter, matter has hidden within it energy associated with the motions and configurations of the microscopic atoms and molecules of which it is composed. We call this energy associated with the microscopic kinetic and potential energies of the system the **internal energy** E^{int} . So, we can then write

$$\Delta E^{\text{int}} = E_f^{\text{int}} - E_i^{\text{int}} = Q - W \quad (\text{first law for } W = \text{work by system}) \quad (19-17)$$

where Q represents the thermal or heat energy transferred *to the system* and W represents the work done on the surroundings *by the system*. This expression represents a very important relationship and is called the **first law of thermodynamics**. If the thermodynamic system undergoes only a differential change, we can write the first law as†

$$dE^{\text{int}} = dQ - dW \quad (\text{first law}). \quad (19-18)$$

The internal energy E^{int} of a system increases if thermal energy Q is transferred to the system and decreases if thermal energy ($Q < 0$) is transferred from the system.

The internal energy E^{int} of a system decreases if it does an amount of work $W > 0$ on its surroundings and increases when it has an amount of work $W < 0$ done on it by the surroundings. (Work done on a system is negative. Work done by a system is positive.)

The first law of thermodynamics should remind you of issues we first raised in Chapter 10. However, in Chapter 10, we discussed energy conservation as it applies to isolated systems—that is, to systems in which no energy enters or leaves the system. The first law of thermodynamics is an extension of that principle to systems that are *not* isolated. In such cases, energy may be transferred into or out of the system as some combination of macroscopic physical work W done by a system and transfer of the microscopic thermal energy Q into a system. In our statement of the first law of thermodynamics above, we assume that there are no changes in the *macroscopic* kinetic energy or the potential energy of the system as a whole; that is, $\Delta K = \Delta U = 0$.

Before this chapter, the term *work* and the symbol W always meant the work done on a system. However, starting with Eq. 19-15 above and continuing through the next two chapters about thermodynamics, we focus on the work done *by* a system, such as the gas in Fig. 19-10. This confusing reversal of focus is left over from the 19th

*Recall that a system's state is specified by its pressure, volume, temperature, and phase.

†Here dQ and dW , unlike dE^{int} , are not true differentials; that is, there are no such functions as $Q(P, V)$ and $W(P, V)$ that depend only on the system state. Both dQ and dW are inexact differentials and often represented by the symbols $\bar{d}Q$ and $\bar{d}W$. Here we can treat them simply as infinitesimally small energy transfers.

century when scientists and engineers were most interested in how much physical work could be done *by* an engine on its surroundings.

The work done *on* a system is always the negative of the work done by the system, so if we rewrite $\Delta E^{\text{int}} = E_f^{\text{int}} - E_i^{\text{int}} = Q - W$ in terms of the work W^{on} done *on* the system, we have $\Delta E^{\text{int}} = Q + W^{\text{on}}$. This tells us the following: the internal energy of a system tends to increase if thermal energy is absorbed by the system or if positive work is done *on* the system. Conversely, the internal energy tends to decrease if thermal energy is lost by the system or if negative work is done *on* the system. This can be a bit confusing, so it is a good idea to spend a little time now to make sure that this distinction is clear.

READING EXERCISE 19-6: The figure here shows four paths on a P - V diagram along which a gas can be taken from state i to state f . Rank the paths according to (a) the change ΔE^{int} , (b) the work W done by the gas, and (c) the magnitude of the thermal energy Q transferred to the gas, greatest first.

19-8 Some Special Cases of the First Law of Thermodynamics

Here we look at four different thermodynamic processes, in each of which a certain restriction is imposed on the system. We then see what consequences follow when we apply the first law of thermodynamics to the process. The results are summarized in Table 19-4.

TABLE 19-4
The First Laws of Thermodynamics: Four Special Cases

The First Law: $\Delta E^{\text{int}} = Q - W$ (Eq. 19-17) ^a		
Process	Restriction	Consequence
Adiabatic	$Q = 0$	$\Delta E^{\text{int}} = -W$
Constant volume	$W = 0$	$\Delta E^{\text{int}} = Q$
Closed cycle	$\Delta E^{\text{int}} = 0$	$Q = W$
Free expansion	$Q = W = 0$	$\Delta E^{\text{int}} = 0$

^a $Q > 0$ represents thermal or heat energy added to the system; $W > 0$ represents work done by system.

- Adiabatic processes.** An adiabatic process is one in which *no transfer of thermal energy* occurs between the system and its environment. Adiabatic processes can occur if a system that is so well insulated that no thermal energy transfers can occur. A process can also be made adiabatic by having it occur so quickly that there is no time for the energy transfer. In either case, putting $Q = 0$ in the first law ($\Delta E^{\text{int}} = E_f^{\text{int}} - E_i^{\text{int}} = Q - W$) yields

$$\Delta E^{\text{int}} = -W \quad (\text{adiabatic process}). \quad (19-19)$$

This tells us that if the work done *by* the system on its surroundings is positive, the internal energy of the system decreases by an amount equal to the work it did. Conversely, if work is done *on* the system (that is, if W is negative), the internal energy of the system increases by that amount.

Figure 19-12 shows an idealized adiabatic process. Thermal energy cannot be transferred to or from a system because it is insulated from its surroundings. Thus, the only way energy can be transferred between the system and its environment is if work is either done by the system or on the system. If we remove shot from the piston and allow the gas to expand, work is done by the system (the gas) and thus is positive. Thus the internal energy of the gas must decrease. If, instead, we add shot and compress the gas, the work done by the system is negative and the internal energy of the gas increases.

2. **Constant-volume processes.** If the volume of a system (such as a gas in a container) is held constant, that system can do no work. Putting $W = 0$ in the first law ($\Delta E^{\text{int}} = \Delta E_f^{\text{int}} - E_i^{\text{int}} = Q - W$) yields

$$\Delta E^{\text{int}} = Q \quad (\text{constant-volume process}). \quad (19-20)$$

Thus, all the thermal energy transferred to a system (so that Q is positive), contributes to an increase in the system's internal energy. Conversely, if thermal energy is transferred from the system to its surroundings so that ΔQ is negative, the internal energy of the system must decrease.

3. **Cyclical processes.** There are processes in which, after certain interchanges of thermal energy and work, the system is restored to its initial state. Engines undergo this type of process. Since the system is restored to its initial state, no intrinsic property of the system—including its internal energy—can possibly change. Putting $\Delta E^{\text{int}} = 0$ in the first law ($\Delta E^{\text{int}} = E_f^{\text{int}} - E_i^{\text{int}} = Q - W$) yields

$$Q(\text{in}) = W(\text{by}) \quad (\text{cyclical process}). \quad (19-21)$$

Thus, the net work done by the system on its surroundings during the process must exactly equal the net amount of thermal energy transferred to the system. So the store of internal energy hidden in the system remains unchanged. Cyclical processes form a closed loop on a P - V plot, as shown in Fig. 19-11*f*.

4. **Free expansions.** These are adiabatic processes (that is, ones in which no transfer of thermal energy occurs between the system and its environment) and no work is done on or by the system. Thus, $Q = W = 0$ and the first law requires that

$$\Delta E^{\text{int}} = 0 \quad (\text{free expansion}). \quad (19-22)$$

Figure 19-13 shows how such an expansion can be carried out. A gas, which is in thermal equilibrium within itself, is initially confined by a closed stopcock to one half of an insulated double chamber; the other half is evacuated. The stopcock is opened, and the gas expands freely to fill both halves of the chamber. No thermal energy is transferred to or from the gas because of the insulation. No work is done by the gas because it rushes into a vacuum; the motion of the gas atoms or molecules is not opposed by any pressure.

FIGURE 19-13 ■ The initial stage of a free-expansion process. After the stopcock is opened, the gas fills both chambers and eventually reaches an equilibrium state.

A free expansion differs from all other processes we have considered because it cannot be done slowly and in a controlled way. As a result, at any given instant during the sudden expansion, the gas is not in thermal equilibrium and its

FIGURE 19-12 ■ An adiabatic expansion can be carried out by removing lead shot from the top of the piston. Adding lead shot reverses the process at any stage. (The insulating lid is not shown.)

pressure is not the same everywhere. Therefore, although we can plot the initial and final states on a P - V diagram, we cannot plot the expansion itself.

READING EXERCISE 19-7: For one complete cycle as shown in the P - V diagram here, (a) is the internal energy change ΔE^{int} of the gas positive, negative, or zero? and (b) what about the net thermal energy, Q , transferred to the gas?

TOUCHSTONE EXAMPLE 19-3: Boiling Water

FIGURE 19-14 ■ Water boiling at constant pressure. Thermal energy is transferred from the thermal reservoir until the liquid water has changed completely into steam. Work is done by the expanding gas as it lifts the loaded piston. The insulating lid is not shown.

Let 1.00 kg of liquid water at 100°C be converted to steam at 100°C by boiling at standard atmospheric pressure (which is 1.00 atm or 1.01×10^5 Pa) in the arrangement of Fig. 19-14. The volume of that water changes from an initial value of 1.00×10^{-3} m³ as a liquid to 1.671 m³ as steam.

(a) How much work is done by the system during this process?

SOLUTION ■ The **Key Idea** here is that the system must do positive work because the volume increases. In the general case we would calculate the work W done by integrating the pressure with respect to the volume (Eq. 19-16). However, here the pressure is constant at 1.01×10^5 Pa, so we can take P outside the integral. We then have

$$\begin{aligned} W &= \int_{V_i}^{V_f} P dV = P \int_{V_i}^{V_f} dV = P(V_f - V_i) \\ &= (1.01 \times 10^5 \text{ Pa})(1.671 \text{ m}^3 - 1.00 \times 10^{-3} \text{ m}^3) \quad (\text{Answer}) \\ &= 1.69 \times 10^5 \text{ J} = 169 \text{ kJ}. \end{aligned}$$

(b) How much thermal energy is transferred as heat during the process?

SOLUTION ■ The **Key Idea** here is that the thermal energy causes only a phase change and not a change in temperature, so it is given fully by Eq. 19-7 ($Q = Lm$). Because the change is from a liquid to a gaseous phase, L is the heat of vaporization L_V , with the value given in Eq. 19-8 and Table 19-3. We find

$$\begin{aligned} Q &= L_V m = (2256 \text{ kJ/kg})(1.00 \text{ kg}) \\ &= 2256 \text{ kJ} \approx 2260 \text{ kJ}. \quad (\text{Answer}) \end{aligned}$$

(c) What is the change in the system's internal energy during the process?

SOLUTION ■ The **Key Idea** here is that the change in the system's internal energy is related to the thermal energy transferred into the system and the work done on the surroundings which transfers out of the system) by the first law of thermodynamics (Eq. 19-17). Thus, we can write

$$\begin{aligned} \Delta E^{\text{int}} &= Q - W = 2256 \text{ kJ} - 169 \text{ kJ} \\ &\approx 2090 \text{ kJ} = 2.09 \text{ MJ}. \quad (\text{Answer}) \end{aligned}$$

This quantity is positive, indicating that the internal energy of the system has increased during the boiling process. This energy goes into separating the H₂O molecules, which strongly attract each other in the liquid state. We see that, when water is boiled, about 7.5% (= 169 kJ/2260 kJ) of the thermal energy added goes into the work of pushing back the atmosphere. The rest of the thermal energy added goes into the system's internal energy.

19-9 More on Temperature Measurement

In Section 1-4 we discussed the fact that there are only seven fundamental quantities in physics that serve as base units for the entire international system (or SI) of units. Temperature in kelvins is one of them. How is the kelvin unit defined? Why has a gas thermometer operating under constant volume become the standard thermometer? What are its fixed points? Why is it superior to the liquid thermometers we discussed in Section 19-2?

As we discussed in Section 19-2, there are several difficulties with defining temperature in terms of the height of a liquid column in a liquid thermometer. First, the

historical fixed points (such as freezing and boiling points at sea level, body temperature, and lowest ice/salt mixture temperature) are not reproducible to a high accuracy. Second, liquid thermometers are only usable in a narrow range of temperatures between the freezing and boiling points of the liquid. Third, no two liquids expand and contract in exactly the same way as their temperatures change.

These difficulties prompted a search for highly reproducible fixed points and a way to measure temperature that is independent of the behavior of any one particular substance. Gases are more promising substances for temperature measurements, since they are already “boiling” and have no upper limit except at the melting point of their container. Also, gases do not tend to liquefy until they reach very low temperatures. For example, air liquefies at about -200°C . Generally a gas volume (at constant pressure) or a gas pressure (at constant volume) can be measured between two fixed points. The scales can be determined in the same way as they are for liquids. The various gas scales have been found to agree among themselves better than liquid scales do. Other thermometers are based on changes of the electrical properties of materials or changes in the light given off by glowing substances and so on. Although we have dozens of thermometric scales based on the behaviors of various substances, none of them can be proven exactly true. Here we present some methods for identifying better fixed points and designing more accurate thermometers.

Defining Standard Fixed Points

Using a low-density gas instead of liquid to measure low temperatures gives very interesting results. As we suggested in Section 19-2, when thermal energy is extracted from a gas held at constant pressure, its temperature and volume drop. A simple apparatus showing these results for a limited range of temperatures is shown in Fig. 19-15.*

FIGURE 19-15 ■ Diagram of apparatus that can be used to measure volume changes as a function of the temperature of air or some other gas trapped at constant pressure. The pressure is a combination of atmospheric pressure plus the pressure exerted by the weight of the plunger of cross-sectional area A , so that $P = P^{\text{atm}} + mg/A$.

If you plot data for the volume of any low-density gas as a function of temperature, the graph is linear. By extrapolating the graph to zero volume, you can predict that the volume will go to zero at a temperature of approximately -273°C . In reality any gas will liquefy before its temperature gets that low. An alternative approach is to hold the volume of a gas constant and observe that its pressure will also approach zero at a temperature of about -273°C . A simple apparatus for doing this experiment is shown in Fig. 19-16.

FIGURE 19-16 ■ Diagram of apparatus that uses a computer data acquisition system to measure pressure changes as a function of the temperature of air or some other gas trapped at constant volume.

*The temperature sensor should be placed inside the flask in Fig. 19-15.

Actually the extrapolation to zero pressure gives a slightly different result depending on how much gas is placed in the flask that holds it to a constant volume. However, as we place smaller and smaller masses of gas in the flask and retake the data we find that the temperature at zero pressure converges to a lower limit of -273.16°C . Student data for this experiment using different apparatus are shown in Fig. 19-17.

FIGURE 19-17 ■ Data from a student experiment measuring the pressure of a fixed volume of gas at various temperatures. The experimental data are represented by the points in the graphs and the lines are fits to these data. The three data sets are for three different masses of gas (air) in a container. Regardless of the amount of gas, the pressure is a linear function of temperature that extrapolates to zero at approximately -280°C . (More precise measurements show that the zero point does depend slightly on the amount of gas, but has a well-defined limit of -273.16°C as the density of the gas goes to zero.)

Since vanishingly small samples of all gases appear to approach the same minimum temperature regardless of their chemical composition, this temperature seems to be a fundamental property of nature. We call this minimum temperature **absolute zero**. We define absolute zero as the temperature of a body when it has the minimum possible internal energy. *Because of the universality of this minimum temperature of -273.16°C it has become our standard low temperature fixed point.*

But what should we use if we want a second standard fixed point? We could, for example, select the freezing point or the boiling point of water. However, water's change of phase, for example from liquid to vapor (boiling), depends not just on temperature, but also on pressure. This introduces some technical difficulties and reduces our confidence in using boiling or freezing as fixed, reproducible thermal phenomena. As we suggested in Section 19-2 a state known as the triple point of water is a good candidate for a fixed point.

We have found through extensive experimentation that three phases—liquid water, solid ice, and water vapor (gaseous water)—can coexist, in thermal equilibrium, at one and only one set of values of pressure and temperature. Thus, this temperature is called the **triple point of water**. Since both the temperature and pressure are well defined at this point, *the triple point of water is often used as a standard high temperature fixed point in designing a thermometer.*

Figure 19-18 shows a triple-point cell, in which the triple point of water can be set up in a laboratory. For reasons that we will explain when introducing the thermodynamic temperature scale, the triple point of water has been assigned a value of 0.01°C .

FIGURE 19-18 ■ A triple-point cell, in which solid ice, liquid water, and water vapor coexist in thermal equilibrium. By international agreement, the temperature of this mixture has been defined to be 273.16 K . The bulb of a constant-volume gas thermometer is shown inserted into the well of the cell.

The Thermodynamic Temperature Scale

The accepted SI unit of temperature is the kelvin. The kelvin is named after Lord Kelvin who first proposed that there is a natural limit to how cold any object can get. If we assume that temperature is an indicator of the amount of internal energy in a system, then the natural limit occurs when $E^{\text{int}} = 0$. Kelvin proposed that when $E^{\text{int}} = 0$ then $T = 0$. This zero is known as **absolute zero**. It is defined by using absolute zero and the triple point of water as its two fixed points. In order to tie in with the popular Celsius scale, the thermodynamic scale was set to have the same “size” degree as the Celsius scale. This yields a rather odd definition. Basically the minimum possible temperature is defined as zero kelvin or 0 K, and the triple point of water is defined as exactly +273.16 K.

Since the triple point of water is 0.01°C, the conversion between a Celsius scale temperature and the thermodynamic scale temperature is very simple since one merely needs to add 273.15 to the Celsius temperature, T_C , to get the thermodynamic temperature T . In other words,

$$T = T_C + 273.15. \quad (19-23)$$

Figure 19-19 shows a wide range of temperatures in kelvin, either measured or conjectured. When expressing temperatures on the Fahrenheit or Celsius scales, we commonly say degrees Fahrenheit (°F) or degrees Celsius (°C), but thermodynamic temperatures are simply called “kelvin” (abbreviated K). Thus, we do not say “degrees kelvin” or write °K. Figure 19-20 compares the thermodynamic, Celsius, and Fahrenheit scales.

FIGURE 19-19 ■ Some temperatures on the thermodynamic scale. Temperature $T = 0$ corresponds to $10^{-\infty}$ and cannot be plotted on this thermodynamic scale.

FIGURE 19-20 ■ A comparison of the thermodynamic, Celsius, and Fahrenheit temperature scales.

When the universe began, some 10 to 20 billion years ago, its temperature was about 10^{39} K. As the universe expanded it cooled, and it has now reached an average temperature of about 3 K. We on Earth are a little warmer than that because we happen to live near a star. Without our sun, we too would be at 3 K (and we could not exist).

The Constant-Volume Gas Thermometer

Now that we have better fixed points we can use them as part of a standard thermometer that uses gas rather than a liquid as its medium. The standard thermometer, against which all other thermometers are calibrated, is based on the effect of temperature changes on the pressure of a gas occupying a fixed volume. Figure 19-21 shows such a **constant-volume gas thermometer**; it consists of a gas-filled bulb connected by a tube to a mercury manometer. By raising and lowering reservoir R , the mercury level on the left can always be brought to the zero of the scale to keep the gas volume constant (variations in the gas volume can affect temperature measurements).

The temperature of any body in thermal contact with the bulb (like the liquid in Fig. 19-21) is then defined to be

$$T = CP, \quad (19-24)$$

FIGURE 19-21 ■ A constant-volume gas thermometer, the gas-filled bulb on the left is immersed in a liquid whose temperature T is being measured. The mercury-filled bulb on the right is raised or lowered as P changes to keep the left-hand column of mercury at the zero point on the scale so the gas volume stays constant.

in which P is the pressure within the gas and C is a constant. From Eq. 15-10, the pressure P is

$$P = P^{\text{atm}} - \rho_{\text{Hg}}gh, \quad (19-25)$$

in which P^{atm} is the atmospheric pressure, ρ_{Hg} is the density of the mercury in the open-tube manometer (like that described in Section 15-5), and h is the measured difference between the mercury levels in the two arms of the tube.*

If we next put the bulb in a triple-point cell (Fig. 19-18), the temperature being measured is

$$T_3 = CP_3 \quad (19-26)$$

*For pressure units, we shall use units introduced in Section 15-3. The SI unit for pressure is the newton per square meter, which is called the pascal (Pa). The pascal is related to other common pressure units by

$$1.00 \text{ atm} = 1.01 \times 10^5 \text{ Pa} = 760 \text{ torr} \approx 14.7 \text{ lb/in.}^2$$

in which P_3 is the gas pressure now. Eliminating C between Eqs. 19-24 and 19-26 gives us the temperature as

$$T = T_3 \left(\frac{P}{P_3} \right) = (273.16 \text{ K}) \left(\frac{P}{P_3} \right) \quad (\text{provisional}). \quad (19-27)$$

We still have a problem with this thermometer. If we use it to measure a given temperature, we find that different gases in the bulb give slightly different results. However, as we use smaller and smaller masses of gas to fill the bulb, the readings converge nicely to a single temperature, no matter what gas we use.

Thus the recipe for measuring a temperature with a gas thermometer is

$$T = (273.16 \text{ K}) \left(\lim_{\text{gas} \rightarrow 0} \frac{P}{P_3} \right). \quad (19-28)$$

The recipe instructs us to measure an unknown temperature T as follows: Fill the thermometer bulb with an arbitrary amount of *any* gas (for example, nitrogen) and measure P_3 (using a triple-point cell) and P , the gas pressure at the temperature being measured. (Keep the gas volume the same.) Calculate the ratio P/P_3 . Then repeat both measurements with a smaller amount of gas in the bulb, and again calculate this ratio. Continue this way, using smaller and smaller amounts of gas, until you can extrapolate to the ratio P/P_3 that you would find if there were approximately no gas in the bulb. Calculate the temperature T by substituting that extrapolated ratio into Eq. 19-28. (The temperature is called the *ideal gas temperature*.)

19-10 Thermal Expansion

We already know that most materials expand when heated and contract when cooled. Indeed, we used this principle in our first definition of temperature. The design of thermometers and thermostats is often based on the differences in expansion between the components of a *bimetal strip* (Fig. 19-22). In aircraft manufacture, rivets and other fasteners are often cooled in dry ice before insertion and then allowed to expand to a tight fit. However, such **thermal expansion** is not always desirable, as Fig. 19-23 suggests. To prevent buckling, expansion slots must be placed in bridges to accommodate roadway expansion on hot days. Dental materials used for fillings must be matched in their thermal expansion properties to those of tooth enamel (otherwise consuming hot coffee or cold ice cream would be quite painful). Regardless of whether we might wish to exploit or avoid thermal expansion, this property has many important implications and we need to consider how it works in detail.

Linear Expansion

If the temperature of a metal rod of length L is raised by a small amount ΔT , its length is found to increase by an amount ΔL according to

$$\frac{\Delta L}{L} = \alpha \Delta T, \quad (19-29)$$

in which α is a constant called the coefficient of linear expansion. For small changes in temperature, the fractional length change ($\Delta L/L$) is proportional to the change in

FIGURE 19-22 (a) A bimetal strip, consisting of a strip of brass and a strip of steel welded together, at temperature T_0 . (b) The strip bends as shown at temperatures above this reference temperature. Below the reference temperature the strip bends the other way. Many thermostats operate on this principle, making and breaking an electrical contact as the temperature rises and falls.

FIGURE 19-23 Railroad tracks in Asbury Park, New Jersey, distorted because of thermal expansion on a very hot July day.

temperature. The coefficient α should be thought of as the ratio of how much the length changes per unit length given a certain change in temperature. It has the unit “per degree” or “per kelvin” and depends on the material. Although α varies somewhat with temperature, for most practical purposes it can be taken as constant for a particular material. Table 19-5 shows some coefficients of linear expansion. Note that the unit $^{\circ}\text{C}$ there could be replaced with the unit K.

TABLE 19-5
Some Coefficients of Linear Expansion^a

Substance α ($10^{-6}/^{\circ}\text{C}$)		Substance α ($10^{-6}/^{\circ}\text{C}$)	
Ice (at 0°C)	51	Steel	11
Lead	29	Glass (ordinary)	9
Aluminum	23	Glass (Pyrex)	3.2
Brass	19	Diamond	1.2
Copper	17	Invar ^b	0.7
Concrete	12	Fused quartz	0.5

^aRoom temperature values except for the listing for ice.

^bThis alloy was designed to have a low coefficient of expansion. The word is a shortened form of “invariable.”

The thermal expansion of a solid is like a (three-dimensional) photographic enlargement. Figure 19-24b shows the (exaggerated) expansion of a steel ruler after its temperature is increased from that of Fig. 19-24a. Equation 19-29 applies to every linear dimension of the ruler, including its edge, thickness, diagonals, and the diameters of the circle etched on it and the circular hole cut in it. If the disk cut from that hole originally fits snugly in the hole, it will continue to fit snugly if it undergoes the same temperature increase as the ruler.

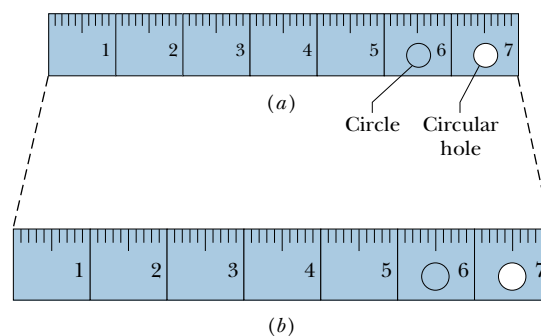

FIGURE 19-24 ■ The same steel ruler at two different temperatures. When the ruler expands, the scale, the numbers, the thickness, and the diameters of the circle and circular hole are all increased by the same factor. (The expansion has been exaggerated for clarity.)

Volume Expansion

If all dimensions of a solid expand with temperature, the volume of that solid must also expand. For liquids, volume expansion is the only meaningful expansion parameter. If the temperature of a solid or liquid whose volume is V is increased by a small amount ΔT , the increase in volume is found to be ΔV , where

$$\frac{\Delta V}{V} = \beta \Delta T \quad (19-30)$$

and β is the **coefficient of volume expansion** of the solid or liquid.

The coefficients of volume expansion β and linear expansion α for a solid are related. To see how, consider a rectangular solid of height h , width w , and length l . The volume of the rectangular solid is hwl . If the solid is heated, each dimension expands linearly so that the height becomes $h + \Delta h$, the width becomes $w + \Delta w$, and the length becomes $l + \Delta l$. Hence, the new volume is $(h + \Delta h)(w + \Delta w)(l + \Delta l)$. If we multiply this out, ignoring all terms with two or more deltas (Δ) because those terms will be very small, we get $hwl + hw \Delta l + h \Delta w l + \Delta h wl$. Since each dimension expands linearly, this means that our new volume is equal to $hwl + hwl(3\alpha \Delta T)$. Hence,

$$\beta = 3\alpha. \quad (19-31)$$

The most common liquid, water, does not behave like other liquids. Above about 4°C , water expands as the temperature rises, as we would expect. Between 0 and about 4°C , however, water *contracts* with increasing temperature. Thus, at about 4°C , the density of water passes through a maximum. At all other temperatures, the density of water is less than this maximum value.

This behavior of water is the reason why lakes freeze from the top down rather than from the bottom up. As water on the surface is cooled from, say, 10°C toward the freezing point, it becomes denser (“heavier”) than lower water and sinks to the bottom. Below 4°C , however, further cooling makes the water then on the surface *less* dense (“lighter”) than the lower water, so it stays on the surface until it freezes. Thus the surface freezes while the lower water is still liquid. If lakes froze from the bottom up, the ice so formed would tend not to melt completely during the summer, because it would be insulated by the water above. After a few years, many bodies of open water in the temperate zones of Earth would be frozen solid all year round—and aquatic life as we know it could not exist.

READING EXERCISE 19-8: The figure below shows four rectangular metal plates, with sides of L , $2L$, or $3L$. They are all made of the same material, and their temperature is to be increased by the same amount. Rank the plates according to the expected increase in (a) their vertical heights and (b) their areas, greatest first.

READING EXERCISE 19-9: Suppose that one of the plates shown above has a round hole cut out of its center. The temperature is increased. Does the hole in the center get larger, smaller, or remain unchanged in size? Explain your reasoning.

READING EXERCISE 19-10: Consider a cylindrical metal rod that stands on its base in a vertical orientation. The temperature increases uniformly. What happens to the pressure at the base of the rod? Does it increase, decrease, or remain unchanged? Explain your reasoning.

TOUCHSTONE EXAMPLE 19-4: Hot Day in Vegas

On a hot day in Las Vegas, an oil trucker loaded 37 000 L of diesel fuel. He encountered cold weather on the way to Payson, Utah, where the temperature was 23.0 K lower than in Las Vegas, and where he delivered his entire load. How many liters did he deliver? The coefficient of volume expansion for diesel fuel is $9.50 \times 10^{-4}/^\circ\text{C}$, and the coefficient of linear expansion for his steel truck tank is $11 \times 10^{-6}/^\circ\text{C}$.

SOLUTION ■ The **Key Idea** here is that the volume of the diesel fuel depends directly on the temperature. Thus, because the temperature decreased, the volume of the fuel did also. From Eq. 19-25, the volume change is

$$\begin{aligned}\Delta V &= V\beta \Delta T \\ &= (37\,000 \text{ L})(9.50 \times 10^{-4}/^\circ\text{C})(-23.0^\circ\text{C}) = -808 \text{ L}.\end{aligned}$$

Thus, the amount delivered was

$$\begin{aligned}V_{\text{del}} &= V + \Delta V = 37\,000 \text{ L} - 808 \text{ L} \\ &= 36\,192 \text{ L}.\end{aligned}\quad (\text{Answer})$$

Note that the thermal expansion of the steel tank has nothing to do with the problem. Question: Who paid for the “missing” diesel fuel?

19-11 More on Thermal Energy Transfer Mechanisms

In Section 19-4, during our initial discussion of the transfer of thermal energy between a system and its environment, we qualitatively discussed the three transfer mechanisms (conduction, convection, and radiation). In order to enhance our understanding of transfer mechanisms, we expand upon our discussion of conduction and radiation here.

Conduction

We all have a natural ability to sense hot and cold. But unfortunately, our “temperature sense” is in fact not always reliable. On a cold winter day, for example, why does an iron railing seem much colder to the touch than a wooden fence post when both are at the same temperature? Why are frying pans made out of metal while pot holders are made out of cloth and other fibers? The answer is that some materials are much more effective than others at transferring thermal energy via conduction.

Consider a slab of face area A and thickness L , whose faces are maintained at temperatures T_H and T_C by a hot reservoir and a cold reservoir, as in Fig. 19-25. Let Q be the energy that is transferred as thermal energy through the slab, from its hot face to its cold face, in a time interval Δt . Experiment shows that the thermal energy *conduction rate* P^{cond} (the power or thermal energy transferred per unit time—not a pressure) is

$$P^{\text{cond}} = \frac{Q}{\Delta t} = kA \frac{T_H - T_C}{L}, \quad (19-32)$$

in which k , called the *thermal conductivity*, is a constant that depends on the material of which the slab is made. That is, the thermal conductivity k is a *property* of the material. A material that readily transfers energy by conduction is a *good thermal conductor* and has a high value of k . Table 19-6 gives the thermal conductivities of some common metals, gases, and building materials.

Thermal Resistance to Conduction (*R*-Value)

If you are interested in insulating your house or in keeping cola cans cold on a picnic, you are more concerned with poor conductors of thermal energy than with good ones. For this reason, the concept of *thermal resistance* R has been introduced into engineering practice. The *R*-value of a slab of thickness L is defined as

$$R = \frac{L}{k}. \quad (19-33)$$

FIGURE 19-25 ■ Thermal conduction. Thermal energy Q is transferred from a reservoir at temperature T_H to a cooler reservoir at temperature T_C through a conducting slab of thickness L and thermal conductivity k .

The lower the thermal conductivity of the material of which a slab is made, the higher is the R -value of the slab, so something that has a high R -value is a *poor thermal conductor* and thus a *good thermal insulator*.

Note that R is a property attributed to a slab of a specified thickness, not to a material. That is, R is *not* a property of a material alone. The commonly used unit for R (which, in the United States at least, is almost never stated) is the square foot-fahrenheit degree-hour per British thermal unit ($\text{ft}^2 \cdot \text{F}^\circ \cdot \text{h}/\text{Btu}$).

Conduction Through a Composite Slab

Figure 19-26 shows a composite slab, consisting of two materials having different thicknesses L_1 and L_2 and different thermal conductivities k_1 and k_2 . The temperatures of the outer surfaces of the slab are T_H and T_C . Each face of the slab has area A . Let us derive an expression for the conduction rate through the slab under the assumption that the transfer is a *steady-state* process; that is, the temperatures everywhere in the slab and the rate of energy transfer do not change with time.

FIGURE 19-26 Thermal energy Q is transferred from a hot reservoir to a cold reservoir at a steady rate through a composite slab made up of two different materials with different thicknesses and different thermal conductivities. The steady-state temperature at the interface of the two materials is denoted T_X .

In the steady state, the conduction rates through the two materials must be equal. This is the same as saying that the energy transferred through one material in a certain time must be equal to that transferred through the other material in the same time. If this were not true, temperatures in the slab would be changing and we would not have a steady-state situation. Letting T_X be the temperature of the interface between the two materials, we can now use Eq. 19-33 to express the rate of thermal energy transfer as

$$P_{\text{cond}} = \frac{k_2 A (T_H - T_X)}{L_2} = \frac{k_1 A (T_X - T_C)}{L_1}. \quad (19-34)$$

Solving for T_X yields, after a little algebra,

$$T_X = \frac{k_1 L_2 T_C + k_2 L_1 T_H}{k_1 L_2 + k_2 L_1}. \quad (19-35)$$

Substituting this expression for T_X into either equality of Eq. 19-34 yields

$$P_{\text{cond}} = \frac{A(T_H - T_C)}{L_1/k_1 + L_2/k_2}. \quad (19-36)$$

We can extend Eq. 19-36 to apply to any number n of materials making up a slab:

$$P_{\text{cond}} = \frac{A(T_H - T_C)}{\sum_{i=1}^n (L_i/k_i)}. \quad (19-37)$$

The summation sign in the denominator tells us to add the values of L/k for all the materials.

TABLE 19-6
Some Thermal Conductivities^a

Substance	$k(\text{W}/\text{m} \cdot \text{K})$
<i>Metals</i>	
Stainless steel	14
Lead	35
Aluminum	235
Copper	401
Silver	428
<i>Gases</i>	
Air (dry)	0.026
Helium	0.15
Hydrogen	0.18
<i>Building Materials</i>	
Polyurethane foam	0.024
Rock wool	0.043
Fiberglass	0.048
White pine	0.11
Window glass	1.0

^aConductivities change somewhat with temperature. The given values are at room temperature.

Radiation

The rate P^{rad} at which an object emits energy via electromagnetic radiation depends on the object's surface area A and the temperature T of that area in kelvins and is given by

$$P^{\text{rad}} = \sigma \varepsilon A T^4. \quad (19-38)$$

Here $\sigma = 5.6703 \times 10^{-8} \text{ W/m}^2 \cdot \text{K}^4$ is called the *Stefan-Boltzmann constant* after Josef Stefan (who discovered Eq. 19-33 experimentally in 1879) and Ludwig Boltzmann (who derived it theoretically soon after). The symbol ε represents the *emissivity* of the object's surface, which has a value between 0 and 1, depending on the composition of the surface. A surface with the maximum emissivity of 1.0 is said to be a *blackbody radiator*, but such a surface is an ideal limit and does not occur in nature. Note again that the temperature in Eq. 19-38 must be in kelvins so that a temperature of absolute zero corresponds to no radiation. Note also that every object whose temperature is above 0 K—including you—emits thermal radiation. (See Fig. 19-27.)

FIGURE 19-27 ■ Thermogram of a house showing the distribution of heat over its surface. The color coding ranges from white to yellow for the warmest areas (greatest heat loss from windows, etc) through red to purple and green for the coolest areas (greatest insulation). This thermogram shows that the roof and windows (yellow) are poorly insulated, while the walls (red, purple, and green) are losing the least heat. Thermograms are often used to check houses for heat loss, so that they can be made more energy efficient through improved insulation.

The rate P^{abs} at which an object absorbs energy via thermal radiation from its environment, which we take to be at uniform temperature T_{env} (in kelvins), is

$$P^{\text{abs}} = \sigma \varepsilon A T_{\text{env}}^4. \quad (19-39)$$

The emissivity ε in Eq. 19-39 is the same as that in Eq. 19-38. An idealized blackbody radiator, with $\varepsilon = 1$, will absorb all the radiated energy it intercepts (rather than sending a portion back away from itself through reflection or scattering).

Because an object will radiate energy to the environment while it absorbs energy from the environment, the object's net rate P^{net} of energy exchange due to thermal radiation is

$$P^{\text{net}} = P^{\text{abs}} - P^{\text{rad}} = \sigma \varepsilon A (T_{\text{env}}^4 - T^4). \quad (19-40)$$

P^{net} is positive if net energy is being absorbed via radiation, and negative if it is being lost via radiation.

READING EXERCISE 19-11: The figure shows the face and interface temperatures of a composite slab consisting of four materials, of identical thicknesses, through which the thermal energy transfer is steady. Rank the materials according to their thermal conductivities, greatest first.

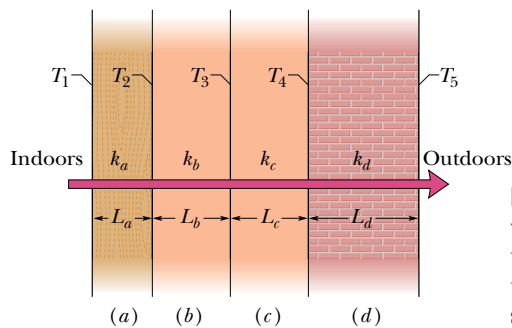

TOUCHSTONE EXAMPLE 19-5: Thermal Conduction

FIGURE 19-28 ■ A wall of four layers through which there is steady-state heat transfer.

Figure 19-28 shows the cross section of a wall made of white pine of thickness L_a and brick of thickness $L_d (= 2.0L_a)$, sandwiching two layers of unknown material with identical thicknesses and thermal conductivities. The thermal conductivity of the pine is k_a and that of the brick is $k_d (= 5.0k_a)$. The face area A of the wall is unknown. Thermal conduction through the wall has reached the steady state; the only known interface temperatures are $T_1 = 25^\circ\text{C}$, $T_2 = 20^\circ\text{C}$, and $T_5 = -10^\circ\text{C}$. What is interface temperature T_4 ?

SOLUTION ■ One **Key Idea** here is that temperature T_4 helps determine the rate P_a^{cond} at which energy is conducted through the pine, as given by Eq. 19-32. However, we lack enough data to solve Eq. 19-32 for T_4 . A second **Key Idea** is that because the conduction is steady, the conduction rate P_d^{cond} through the brick must equal the conduction rate P_a^{cond} through the pine. From Eq. 19-32 and Fig. 19-28, we can write

$$P_a^{\text{cond}} = k_a A \frac{T_1 - T_2}{L_a} \quad \text{and} \quad P_d^{\text{cond}} = k_d A \frac{T_4 - T_5}{L_d}.$$

Setting $P_a^{\text{cond}} = P_d^{\text{cond}}$ and solving for T_4 yield

$$T_4 = \frac{k_a L_d}{k_d L_a} (T_1 - T_2) + T_5.$$

Letting $L_d = 2.0L_a$ and $k_d = 5.0k_a$, and inserting the known temperatures, we find

$$\begin{aligned} T_4 &= \frac{k_a(2.0L_a)}{(5.0k_a)L_a} (25^\circ\text{C} - 20^\circ\text{C}) + (-10^\circ\text{C}) \\ &= -8.0^\circ\text{C}. \end{aligned} \quad (\text{Answer})$$

TOUCHSTONE EXAMPLE 19-6: Japanese Bees

FIGURE 19-29 ■ The bees were unharmed by their increased body temperature, which the hornet could not withstand.

When hundreds of Japanese bees form a compact ball around a giant hornet that attempts to invade their hive, they can quickly raise their body temperature from the normal 35°C to 47°C or 48°C . That higher temperature is lethal to the hornet but not to the bees (Fig. 19-29). Assume the following: 500 bees form a ball of radius $R = 2.0$ cm for a time $\Delta t = 20$ min, the primary loss of energy by the ball is by thermal radiation, the ball's surface has emissivity $\varepsilon = 0.80$, and the ball has a uniform temperature. On average, how much additional energy must each bee produce during the 20 min to maintain 47°C ?

SOLUTION ■ The **Key Idea** here is that, because the surface temperature of the bee ball increases after the ball forms, the rate at which energy is radiated by the ball also increases. Thus, the bees lose an additional amount of energy to thermal radiation. We can relate the surface temperature to the rate of radiation (energy per unit time) with Eq. 19-38 ($P^{\text{rad}} = \sigma \varepsilon A T^4$), in which A is the ball's surface area and T is the ball's surface temperature in kelvins. This rate is an energy per unit time; that is,

$$P^{\text{rad}} = \frac{\Delta E}{\Delta t}.$$

Thus, the amount of energy ΔE radiated in time t is $\Delta E = P^{\text{rad}} \Delta t$.

At the normal temperature $T_1 = 35^\circ\text{C}$, the radiation rate is P_1^{rad} and the amount of energy radiated in time Δt is $\Delta E_1 = P_1^{\text{rad}} \Delta t$. At the increased temperature $T_2 = 47^\circ\text{C}$, the (greater) radiation rate is P_2^{rad} and the (greater) amount of energy radiated in time Δt is $\Delta E_2 = P_2^{\text{rad}} \Delta t$. Thus, in maintaining the ball at T_2 for time Δt , the bees must (together) provide an additional amount of energy of $E = \Delta E_2 - \Delta E_1$.

We can now write

$$\begin{aligned} E &= \Delta E_2 - \Delta E_1 = P_2^{\text{rad}} \Delta t - P_1^{\text{rad}} \Delta t \\ &= (\sigma \varepsilon A T_2^4) \Delta t - (\sigma \varepsilon A T_1^4) \Delta t = \sigma \varepsilon A \Delta t (T_2^4 - T_1^4). \end{aligned} \quad (19-41)$$

The temperatures here *must* be in kelvins; thus, we write them as

$$T_2 = 47^\circ\text{C} + 273^\circ\text{C} = 320 \text{ K}$$

and

$$T_1 = 35^\circ\text{C} + 273^\circ\text{C} = 308 \text{ K}.$$

The surface area A of the ball is

$$A = 4\pi R^2 = (4\pi)(0.020 \text{ m})^2 = 5.027 \times 10^{-3} \text{ m}^2,$$

and the time Δt is 20 min = 1200 s. Substituting these and other known values into Eq. 19-41, we find

$$\begin{aligned} E &= (5.6703 \times 10^{-8} \text{ W/m}^2 \cdot \text{K}^4)(0.80)(5.027 \times 10^{-3} \text{ m}^2) \\ &\quad \times (1200 \text{ s})[(320 \text{ K})^4 - (308 \text{ K})^4] = 406.8 \text{ J}. \end{aligned}$$

Thus, with 500 bees in the ball, each bee must produce an additional energy of

$$\frac{E}{500} = \frac{406.8 \text{ J}}{500} = 0.81 \text{ J}. \quad (\text{Answer})$$

Problems

SEC. 19-2 ■ THERMOMETERS AND TEMPERATURE SCALES

1. Fahrenheit and Celsius At what temperature is the Fahrenheit scale reading equal to (a) twice that of the Celsius and (b) half that of the Celsius?

2. Oymyakon (a) In 1964, the temperature in the Siberian village of Oymyakon reached -71°C . What temperature is this on the Fahrenheit scale? (b) The highest officially recorded temperature in the continental United States was 134°F in Death Valley, California. What is this temperature on the Celsius scale?

SEC. 19-4 ■ HEATING, COOLING, AND TEMPERATURE

3. Hot and Cold It is an everyday observation that hot and cold objects cool down or warm up to the temperature of their surroundings. If the temperature difference ΔT between an object and its surroundings ($\Delta T = T_{\text{obj}} - T_{\text{sur}}$) is not too great, the rate of cooling or warming of the object is proportional, approximately, to this temperature difference; that is,

$$\frac{d(\Delta T)}{dt} = -A(\Delta T),$$

where A is a constant. (The minus sign appears because ΔT decreases with time if ΔT is positive and increases if ΔT is negative.) This is known as *Newton's law of cooling*. (a) On what factors does A depend? What are its dimensions? (b) If at some instant $t_1 = 0$ the temperature difference is ΔT_1 , show that it is

$$\Delta T = \Delta T_1 e^{-At_2}$$

at a later time t_2 .

4. House Heater The heater of a house breaks down one day when the outside temperature is 7.0°C . As a result, the inside temperature drops from 22°C to 18°C in 1.0 h. The owner fixes the heater and adds insulation to the house. Now she finds that, on a similar day, the house takes twice as long to drop from 22°C to 18°C when the heater is not operating. What is the ratio of the new value of constant A in Newton's law of cooling (see Problem 3) to the previous value?

SEC. 19-5 ■ THERMAL ENERGY TRANSFER TO SOLIDS AND LIQUIDS

5. A Certain Substance A certain substance has a mass per mole of 50 g/mol. When 314 J of thermal energy is transferred to a 30.0 g sample, the sample's temperature rises from 25.0°C to 45.0°C . What are (a) the specific heat and (b) the molar specific heat of this substance? (c) How many moles are present?

6. Diet Doctor A certain diet doctor encourages people to diet by drinking ice water. His theory is that the body must burn off enough fat to raise the temperature of the water from 0.00°C to the body temperature of 37.0°C . How many liters of ice water would have to be consumed to burn off 454 g (about 1 lb) of fat, assuming that this much fat burning requires 3500 Cal be transferred to the ice water? Why is it not advisable to follow this diet? (One liter = 10^3 cm^3 . The density of water is 1.00 g/cm^3 .)

7. Minimum Energy Calculate the minimum amount of energy, in joules required to completely melt 130 g of silver initially at 15.0°C .

8. How Much Unfrozen How much water remains unfrozen after 50.2 kJ of thermal energy is transferred from 260 g of liquid water initially at its freezing point?

9. Energetic Athlete An energetic athlete can use up all the energy from a diet of 4000 food calories/day where a food calorie = 1000 cal. If he were to use up this energy at a steady rate, how would his rate of energy use compare with the power of a 100 W bulb? (The power of 100 W is the rate at which the bulb converts electrical energy to thermal energy and the energy of visible light.)

10. Four Lightbulbs A room is lighted by four 100 W incandescent lightbulbs. (The power of 100 W is the rate at which a bulb converts electrical energy to thermal energy and the energy of visible light.) Assuming that 90% of the energy is converted to thermal energy, how much thermal energy is transferred to the room in 1.00 h?

11. Drilling a Hole A power of 0.400 hp is required for 2.00 min to drill a hole in a 1.60 lb copper block. (a) If the full power is the rate at which thermal energy is generated, how much is generated in Btu? (b) What is the rise in temperature of the copper if the copper absorbs 75.0% of this energy? (Use the energy conversion $1 \text{ ft} \cdot \text{lb} = 1.285 \times 10^{-3} \text{ Btu}$.)

12. How Much Butter How many grams of butter, which has a usable energy content of 6.0 Cal/g (= 6000 cal/g), would be equivalent to the change in gravitational potential energy of a 73.0 kg man who ascends from sea level to the top of Mt. Everest, at elevation 8.84 km? Assume that the average value of g is 9.80 m/s^2 .

13. Immersion Heater A small electric immersion heater is used to heat 100 g of water for a cup of instant coffee. The heater is labeled "200 watts," so it converts electrical energy to thermal energy that is transferred to the water at this rate. Calculate the time required to bring the water from 23°C to 100°C ignoring any thermal energy that transfers out of the cup.

14. Tub of Water One way to keep the contents of a garage from becoming too cold on a night when a severe subfreezing temperature is forecast is to put a tub of water in the garage. If the mass of the water is 125 kg and its initial temperature is 20°C , (a) how much thermal energy must the water transfer to its surroundings in order to freeze completely and (b) what is the lowest possible temperature of the water and its surroundings until that happens?

15. A Chef A chef, on finding his stove out of order, decides to boil the water for his wife's coffee by shaking it in a thermos flask. Suppose that he uses tap water at 15°C and that the water falls 30 cm each shake, the chef making 30 shakes each minute. Neglecting any transfer of thermal energy out of the flask, how long must he shake the flask for the water to reach 100°C ?

16. Copper Bowl A 150 g copper bowl contains 220 g of water, both at 20.0°C . A very hot 300 g copper cylinder is dropped into the water, causing the water to boil, with 5.00 g being converted to steam. The final temperature of the system is 100°C . Neglect energy transfers with the environment. (a) How much energy (in calories) is transferred to the water? (b) How much to the bowl? (d) What is the original temperature of the cylinder?

17. Ethyl Alcohol Ethyl alcohol has a boiling point of 78°C , a freezing point of -114°C , a heat of vaporization of 879 kJ/kg , a heat of fusion of 109 kJ/kg , and a specific heat of $2.43\text{ kJ/kg}\cdot^{\circ}\text{C}$. How much thermal energy must be transferred out of 0.510 kg of ethyl alcohol that is initially a gas at 78°C so that it becomes a solid at -114°C ?

18. Metric–Nonmetric *Nonmetric version:* How long does a $2.0 \times 10^5\text{ Btu/h}$ water heater take to raise the temperature of 40 gal of water from 70°F to 100°F ? *Metric version:* How long does a 59 kW water heater take to raise the temperature of 150 L of water from 21°C to 38°C ?

19. Buick A 1500 kg Buick moving at 90 km/h brakes to a stop, at a uniform rate and without skidding, over a distance of 80 m . At what average rate is mechanical energy transformed into thermal energy in the brake system?

20. Solar Water Heater In a solar water heater, radiant energy from the Sun is transferred to water that circulates through tubes in a rooftop collector. The solar radiation enters the collector through a transparent cover and warms the water in the tubes; this water is pumped into a holding tank. Assume that the efficiency of the overall system is 20% (that is, 80% of the incident solar energy is lost from the system). What collector area is necessary to raise the temperature of 200 L of water in the tank from 20°C to 40°C in 1.0 h when the intensity of incident sunlight is 700 W/m^2 ?

21. Steam What mass of steam at 100°C must be mixed with 150 g of ice at its melting point, in a thermally insulated container, to produce liquid water at 50°C ?

22. Iced Tea A person makes a quantity of iced tea by mixing 500 g of hot tea (essentially water) with an equal mass of ice at its melting point. If the initial hot tea is at a temperature of (a) 90°C and (b) 70°C , what are the temperature and mass of the remaining ice when the tea and ice reach a common temperature? Neglect energy transfers with the environment.

23. Ice Cubes (a) Two 50 g ice cubes are dropped into 200 g of water in a thermally insulated container. If the water is initially at 25°C , and the ice comes directly from a freezer at -15°C , what is the final temperature of the drink when the drink reaches thermal equilibrium? (b) What is the final temperature if only one ice cube is used?

24. Thermos of Coffee An insulated Thermos contains 130 cm^3 of hot coffee, at a temperature of 80.0°C . You put in a 12.0 g ice cube at its melting point to cool the coffee. By how many degrees has your coffee cooled once the ice has melted? Treat the coffee as though it were pure water and neglect energy transfers with the environment.

SEC. 19-8 ■ SOME SPECIAL CASES OF THE FIRST LAW OF THERMODYNAMICS

25. Gas Expands A sample of gas expands from 1.0 m^3 to 4.0 m^3 while its pressure decreases from 40 Pa to 10 Pa . How much work is done by the gas if its pressure changes with volume via each of the three paths shown in the P - V diagram in Fig. 19-30?

FIGURE 19-30 ■ Problem 25.

26. Work Done Consider that 200 J of work is done on a system and 70.0 cal of thermal energy is trans-

ferred out of the system. In the sense of the first law of thermodynamics, what are the values (including algebraic signs) of (a) W , (b) Q , and (c) ΔE^{int} ?

27. Closed Chamber Gas within a closed chamber undergoes the cycle shown in the P - V diagram of Fig. 19-31. Calculate the net thermal energy added to the system during one complete cycle.

FIGURE 19-31 ■ Problem 27.

28. Thermodynamic A thermodynamic system is taken from an initial state A to another state B and back again to A , via state C , as shown by path $ABCA$ in the P - V diagram of Fig. 19-31a. (a) Complete the table in Fig. 19-32b by filling in either $+$ or $-$ for the sign of each thermodynamic quantity associated with each step of the cycle. (b) Calculate the numerical value of the work done by the system for the complete cycle $ABCA$.

FIGURE 19-32 ■ Problem 28.

29. From i to f When a system is taken from state i to state f along path iaf in Fig. 19-33. $Q = 50\text{ cal}$ and $W = 20\text{ cal}$. Along path ibf , $Q = 36\text{ cal}$. (a) What is W along path ibf ? (b) If $W = -13\text{ cal}$ for the return path fi , what is Q for this path? (c) Take $E_i^{\text{int}} = 10\text{ cal}$. What is E_f^{int} ? (d) If $E_b^{\text{int}} = 22\text{ cal}$, what are the values of Q for path ib and path bf ?

FIGURE 19-33 ■ Problem 29.

30. Gas Within Gas within a chamber passes through the cycle shown in Fig. 19-34. Determine the thermal energy transferred by the system during process CA if the thermal energy added Q_{AB} ,

during process AB is 20.0 J, no thermal energy is transferred during process BC , and the net work done during the cycle is 15.0 J.

FIGURE 19-34 ■ Problem 30.

SEC. 19-9 ■ MORE ON TEMPERATURE MEASUREMENT

31. Gas Thermometer A particular gas thermometer is constructed of two gas-containing bulbs, each of which is put into a water bath, as shown in Fig. 19-35. The pressure difference between the two bulbs is measured by a mercury manometer as shown. Appropriate reservoirs, not shown in the diagram, maintain constant gas volume in the two bulbs. There is no difference in pressure when both baths are at the triple point of water. The pressure difference is 120 torr when one bath is at the triple point and the other is at the boiling point of water. It is 90.0 torr when one bath is at the triple point and the other is at an unknown temperature to be measured. What is the unknown temperature?

FIGURE 19-35 ■ Problem 31.

32. A Gas at Boiling Suppose the temperature of a gas at the boiling point of water is 373.15 K. What then is the limiting value of the ratio of the pressure of the gas at that boiling point to its pressure at the triple point of water? (Assume the volume of the gas is the same at both temperatures.)

33. Pairs of Scales At what temperature do the following pairs of scales read the same, if ever: (a) Fahrenheit and Celsius (verify the listing in Table 19-1), (b) Fahrenheit and Kelvin, and (c) Celsius and Kelvin?

SEC. 19-10 ■ THERMAL EXPANSION

34. Aluminum Flagpole An aluminum flagpole is 33 m high. By how much does its length increase as the temperature increases by 15 °C?

35. Pyrex Glass The Pyrex glass mirror in the telescope at the Mt. Palomar Observatory has a diameter of 200 in. The temperature ranges from -10°C to 50°C on Mt. Palomar. In micrometers, what is the maximum change in the diameter of the mirror, assuming that the glass can freely expand and contract?

36. Aluminum Alloy An aluminum-alloy rod has a length of 10.000 cm at 20.000°C and a length of 10.015 cm at the boiling point

of water. (a) What is the length of the rod at the freezing point of water? (b) What is the temperature if the length of the rod is 10.009 cm?

37. Circular Hole A circular hole in an aluminum plate is 2.725 cm in diameter at 0.000°C . What is its diameter when the temperature of the plate is raised to 100.0°C ?

38. Lead Ball What is the volume of a lead ball at 30°C if the ball's volume at 60°C is 50 cm^3 ?

39. Change in Volume Find the change in volume of an aluminum sphere with an initial radius of 10 cm when the sphere is heated from 0.0°C to 100°C .

40. Area Rectangular The area A of a rectangular plate is ab . Its coefficient of linear expansion is α . After a temperature rise ΔT , side a is longer by Δa and side b is longer by Δb (Fig. 19-36). Show that if the small quantity $(\Delta a \Delta b)/ab$ is neglected, then $\Delta A = 2\alpha A \Delta T$.

FIGURE 19-36 ■ Problem 40.

41. Aluminum Cup An aluminum cup of 100 cm^3 capacity is completely filled with glycerin at 22°C . How much glycerin, if any, will spill out of the cup if the temperature of both the cup and glycerin is increased to 28°C ? (The coefficient of volume expansion of glycerin is $5.1 \times 10^{-4}/^{\circ}\text{C}$.)

42. Rod At 20°C , a rod is exactly 20.05 cm long on a steel ruler. Both the rod and the ruler are placed in an oven at 270°C , where the rod now measures 20.11 cm on the same ruler. What is the coefficient of thermal expansion for the material of which the rod is made?

43. Steel Rod A steel rod is 3.000 cm in diameter at 25°C . A brass ring has an interior diameter of 2.992 cm at 25°C . At what common temperature will the ring just slide onto the rod?

44. Metal Cylinder When the temperature of a metal cylinder is raised from 0.0°C to 100°C , its length increases by 0.23%. (a) Find the percent change in density. (b) What is the metal? Use Table 19-5.

45. Barometer Show that when the temperature of a liquid in a barometer changes by ΔT and the pressure is constant, the liquid's height h changes by $\Delta h = \beta h \Delta T$, where β is the coefficient of volume expansion. Neglect the expansion of the glass tube.

46. Copper Coin When the temperature of a copper coin is raised by 100°C , its diameter increases by 0.18%. To two significant figures, give the percent increase in (a) the area of a face, (b) the thickness, (c) the volume, and (d) the mass of the coin. (e) Calculate the coefficient of linear expansion of the coin.

47. Pendulum Clock A pendulum clock with a pendulum made of brass is designed to keep accurate time at 20°C . If the clock operates at 0.0°C , what is the magnitude of its error, in seconds per hour, and does the clock run fast or slow?

48. Radioactive Source In a certain experiment, a small radioactive source must move at selected, extremely slow speeds. This

motion is accomplished by fastening the source to one end of an aluminum rod and heating the central section of the rod in a controlled way. If the effective heated section of the rod in Fig. 19-37 is 2.00 cm, at what constant rate must the temperature of the rod be changed if the source is to move at a constant speed of 100 nm/s?

FIGURE 19-37 ■ Problem 48.

49. Temperature Rise As a result of a temperature rise of 32°C , a bar with a crack at its center buckles upward (Fig. 19-38). If the fixed distance L_0 is 3.77 m and the coefficient of linear expansion of the bar is $25 \times 10^{-6}/^\circ\text{C}$, find the rise x of the center.

FIGURE 19-38 ■ Problem 49.

50. Copper Ring A 20.0 g copper ring has a diameter of 2.54000 cm at its temperature of 0.000°C . An aluminum sphere has a diameter of 2.54508 cm at its temperature of 100.0°C . The sphere is placed on top of the ring (Fig. 19-39), and the two are allowed to come to thermal equilibrium, with no thermal energy transferred to the surroundings. The sphere just passes through the ring at the equilibrium temperature. What is the mass of the sphere?

FIGURE 19-39 ■ Problem 50.

SEC. 19-11 ■ MORE ON THERMAL ENERGY TRANSFER MECHANISMS

51. Single-Family Dwelling The ceiling of a single-family dwelling in a cold climate should have an R -value of 30. To give such insulation, how thick would a layer of (a) polyurethane foam and (b) silver have to be?

52. North America The average rate at which energy is conducted outward through the ground surface in North America is 54.0 mW/m^2 , and the average thermal conductivity of the near-surface rocks is $2.50 \text{ W/m} \cdot \text{K}$. Assuming a surface temperature of 10.0°C , find the temperature at a depth of 35.0 km (near the base of the crust). Ignore the thermal energy transferred from the radioactive elements.

53. Slab Consider the slab shown in Fig. 19-25. Suppose that $L = 25.0 \text{ cm}$, $A = 90.0 \text{ cm}^2$, and the material is copper. If $T_H = 125^\circ\text{C}$, $T_C = 10.0^\circ\text{C}$, and a steady state is reached, find the conduction rate through the slab.

54. Body Heat (a) Calculate the rate at which body heat is conducted through the clothing of a skier in a steady-state process, given the following data: the body surface area is 1.8 m^2 and the clothing is 1.0 cm thick; the skin surface temperature is 33°C and the outer surface of the clothing is at 1.0°C ; the thermal conductivity of the clothing is $0.040 \text{ W/m} \cdot \text{K}$. (b) How would the answer to (a) change if, after a fall, the skier's clothes became soaked with water of thermal conductivity $0.60 \text{ W/m} \cdot \text{K}$?

55. Copper Rod A cylindrical copper rod of length 1.2 m and cross-sectional area 4.8 cm^2 is insulated to prevent thermal energy from being transferred through its surface. The ends are maintained at a temperature difference of 100°C by having one end in a water-ice mixture and the other in boiling water and steam. (a) Find the rate at which thermal energy is conducted along the rod. (b) Find the rate at which ice melts at the cold end.

56. Without a Spacesuit If you were to walk briefly in space without a spacesuit while far from the Sun (as an astronaut does in the movie *2001*), you would feel the cold of space—while you radiated thermal energy, you would absorb almost none from your environment. (a) At what rate would you lose thermal energy? (b) How much thermal energy would you lose in 30 s? Assume that your emissivity is 0.90, and estimate other data needed in the calculations.

57. Rectangular Rods Two identical rectangular rods of metal are welded end to end as shown in Fig. 19-40a, and 10 J of thermal energy is conducted (in a steady-state process) through the rods in 2.0 min. How long would it take for 10 J to be conducted through the rods if they were welded together as shown in Fig. 19-40b?

FIGURE 19-40 ■ Problem 57.

58. Four Squares Four square pieces of insulation of two different materials, all with the same thickness and area A , are available to cover an opening of area $2A$. This can be done in either of the two ways shown in Fig. 19-41. Which arrangement, (a) or (b), gives the lower thermal energy flow if $k_2 \neq k_1$?

FIGURE 19-41 ■ Problem 58.

59. Glass Window (a) What is the rate of thermal energy transfer in watts per square meter through a glass window 3.0 mm thick if

the outside temperature is -20°F and the inside temperature is $+72^{\circ}\text{F}$? (b) A storm window having the same thickness of glass is installed parallel to the first window, with an air gap of 7.5 cm between the two windows. What now is the rate of energy loss if conduction is the only important energy-transfer mechanism?

60. A Sphere A sphere of radius 0.500 m, temperature 27.0°C , and emissivity 0.850 is located in an environment of temperature 77.0°C . At what rate does the sphere (a) emit and (b) absorb thermal radiation? (c) What is the sphere's net rate of energy exchange?

61. Tank of Water A tank of water has been outdoors in cold weather, and a slab of ice 5.0 cm thick has formed on its surface (Fig. 19-42). The air above the ice is at -10°C .

FIGURE 19-42 ■ Problem 61.

Calculate the rate of formation of ice (in centimeters per hour) on the ice slab. Take the thermal conductivity and density of ice to be $0.0040 \text{ cal/s} \cdot \text{cm} \cdot \text{C}^{\circ}$ and 0.92 g/cm^3 . Assume that energy is not transferred through the walls or bottom of the tank.

62. A Wall Figure 19-43 shows (in cross section) a wall that consists of four layers. The thermal conductivities are $k_1 = 0.060 \text{ W/m} \cdot \text{K}$, $k_3 = 0.040 \text{ W/m} \cdot \text{K}$, and $k_4 = 0.12 \text{ W/m} \cdot \text{K}$ (k_2 is not known). The layer thicknesses are $L_1 = 1.5 \text{ cm}$, $L_3 = 2.8 \text{ cm}$, and $L_4 = 3.5 \text{ cm}$ (L_2 is not known). Energy transfer through the wall is steady. What is the temperature of the interface indicated?

FIGURE 19-43 ■ Problem 62.

Additional Problems

63. 300 F Club You can join the semi-secret “300 F” club at the Amundsen–Scott South Pole Station only when the outside temperature is below -70°C . On such a day, you first bask in a hot sauna and then run outside wearing only your shoes. (This is, of course, extremely dangerous, but the rite is effectively a protest against the constant danger of the winter cold at the south pole.)

Assume that when you step out of the sauna, your skin temperature is 102°F and the walls, ceiling, and floor of the sauna room have a temperature of 30°C . Estimate your surface area, and take your skin emissivity to be 0.80. (a) What is the approximate net rate P^{net} at which you lose energy via thermal radiation transfer to the room? Next, assume that when you are outside half your surface area transfers thermal radiation to the sky at a temperature of -25°C and the other half transfers thermal radiation to the snow and ground at a temperature of -80°C . What is the approximate net rate at which you lose energy via thermal radiation exchanges with (b) the sky and (c) the snow and ground?

64. Shallow Pond Ice has formed on a shallow pond and a steady state has been reached, with the air above the ice at -5.0°C and the bottom of the pond at 4.0°C . If the total depth of ice + water is 1.4 m, how thick is the ice? (Assume that the thermal conductivities of ice and water are 0.40 and $0.12 \text{ cal/m} \cdot \text{C}^{\circ} \cdot \text{s}$, respectively.)

65. Emperor Penguins Emperor penguins, those large penguins that resemble stuffy English butlers, breed and hatch their young even during severe Antarctic winters. Once an egg is laid, the father balances the egg on his feet to prevent the egg from freezing. He must do this for the full incubation period of 105 to 115 days, during which he cannot eat because his food is in the water. He can survive this long without food only if he can reduce his loss of internal food energy significantly. If he is alone, he loses that energy too quickly to stay warm, and eventually abandons the egg in order to eat. To

protect themselves and each other from the cold so as to reduce the loss of internal energy, penguin fathers huddle closely together, in groups of perhaps several thousand. In addition to providing other benefits, the huddling reduces the rate at which the penguins thermally radiate energy to their surroundings.

Assume that a penguin father is a circular cylinder with top surface area a , height h , surface temperature T , and emissivity ε . (a) Find an expression for the rate P_i at which an individual father would radiate energy to the environment from his top surface and his side surface were he alone with his egg.

If N identical fathers were well apart from one another, the total rate of energy loss via radiation would be NP_i . Suppose, instead, that they huddle closely to form a *huddled cylinder* with top surface area Na and height h . (b) Find an expression for the rate P_h at which energy is radiated by the top surface and the side surface of the huddled cylinder.

(c) Assuming $a = 0.34 \text{ m}^2$ and $h = 1.1 \text{ m}$ and using the expressions you obtained for P_i and P_h , graph the ratio P_h/NP_i versus N_h . Of course, the penguins know nothing about algebra or graphing, but their instinctive huddling reduces this ratio so that more of their eggs survive to the hatching stage. From the graphs (as you will see, you probably need more than one version), approximate how many penguins must huddle so that P_h/NP_i is reduced to (d) 0.5, (e) 0.4, (f) 0.3, (g) 0.2, and (h) 0.15. (i) For the assumed data, what is the lower limiting value for P_h/NP_i ?

66. The Penny and the Jelly Donut You see a penny lying on the ground. A penny won't buy much these days, so you think: “If I bend down to pick it up I will do work. To do that work I will have to burn some energy. It probably costs me more to buy the fuel (food) to provide that energy than I would gain by picking up the penny. It's not cost effective.” You pass it by. Is the argument correct? Estimate

the energy cost for picking up a penny. You may find the following information useful: A jelly donut contains about 250 Calories (1 Calorie = 1 Kcal).

67. Considering Changes For each of the situations described below, the object considered is undergoing some changes. Among the possible changes you should consider are: (Q) The object is absorbing or giving off thermal energy. (T) The object's temperature is changing. (E^{int}) The object's internal energy is changing. (W) The object is doing mechanical work or having work done on it. For each of the situations described below, identify which of the four changes are taking place and write as many of the letters Q, T, E^{int} , W, (or none) as are appropriate. (a) A cylinder with a piston on top contains a compressed gas and is sitting on a thermal reservoir (a large iron block). After everything has come to thermal equilibrium, the piston is moved upward somewhat (very slowly). The object to be considered is the gas in the cylinder. (b) Consider the same cylinder as in part (a), but it is wrapped in styrofoam, a very good thermal insulator, instead of sitting on a thermal reservoir. The piston is pressed downward (again, very slowly), compressing the gas. The object to be considered is the

gas in the cylinder. (c) An ice cube that is sitting in the open air and is melting.

68. KE and Temperature Converting kinetic energy into thermal energy produces small rises in temperature. This was in part responsible for the difficulty in discovering the law of conservation of energy. It also implies that hot objects contain a lot of energy. (This latter comment is largely responsible for the industrial revolution in the 19th century.) To get some feel for these numbers, assume all mechanical energy is converted to thermal energy and carry out three estimates:

(a) A steel ball is dropped from a height of 3 m onto a concrete floor. It bounces a large number of times but eventually comes to rest. Estimate the ball's rise in temperature.

(b) Suppose the steel ball you used in part (a) is at room temperature. If you converted all its thermal energy to translational kinetic energy, how fast would it be moving? (Give your answer in units of miles per hour. Also, ignore the fact that you would have to create momentum.)

(c) Suppose a nickel-iron meteor falls to Earth from deep space. Estimate how much its temperature would rise on impact.

20

The Kinetic Theory of Gases

When a container of cold champagne, soda pop, or any other carbonated drink is opened, a slight fog forms around the opening and some of the liquid sprays outward. (In the photograph, the fog is the white cloud that surrounds the stopper, and the spray has formed streaks within the cloud.)

What causes the fog?

The answer is in this chapter.

20-1 Molecules and Thermal Gas Behavior

In our studies of mechanics and thermodynamics we have found a number of strange and interesting results. In mechanics, we saw that moving objects tend to run down and come to a stop. We attributed this to the inevitable presence of friction and drag forces. Without these nonconservative forces mechanical energy would be conserved and perpetual motion would be possible. In thermodynamics, we discovered that ordinary objects, by virtue of their temperature, contain huge quantities of internal energy. This is where the “lost” energy resulting from friction forces is hidden. In this chapter, we will learn about some ways that matter can store internal energy. What you are about to learn may be counterintuitive. Instead of finding that the “natural state” of a system is to lose energy, you will find considerable evidence that the “natural state” of a system is quite the opposite. It is one in which its fundamental parts (atoms and molecules) are traveling every which way—in a state of perpetual motion.

Classical thermodynamics—the subject of the previous chapter—has nothing to say about atoms or molecules. Its laws are concerned only with such macroscopic variables as pressure, volume, and temperature. In this chapter we begin an exploration of the atomic and molecular basis of thermodynamics. As is usual in the development of new theories in physics, we start with a simple model. The fact that gases are fluid and compressible is evidence that their molecules are quite small relative to the average spacing between them. If so, we expect that gas molecules are relatively free and independent of one another. For this reason, we believe that the thermal behavior of gases will be easier to understand than that of liquids and solids. Thus, we begin an exploration of the atomic and molecular basis of thermodynamics by developing the kinetic theory of gases—a simplified model of gas behavior based on the laws of classical mechanics.

We start with a discussion of how the ideal gas law characterizes the macroscopic behavior of simple gases. This macroscopic law relates the amount of gas and its pressure, temperature, and volume to each other. Next we consider how kinetic theory, which provides us with a molecular (or microscopic) model of gas behavior, can be used to explain observed macroscopic relationships between gas pressure, volume, and temperature. We then move on to using kinetic theory as an underlying model of the characteristics of an ideal gas. The basic ideas of kinetic theory are that: (1) an ideal gas at a given temperature consists of a collection of tiny particles (atoms or molecules) that are in perpetual motion—colliding with each other and the walls of their container; and (2) the hidden internal energy of an ideal gas is directly proportional to the kinetic energy of its particles.

20-2 The Macroscopic Behavior of Gases

Any gas can be described by its macroscopic variables volume V , pressure P , and temperature T . Simple experiments were performed on low density gases in the 17th and 18th centuries to relate these variables. Robert Boyle (b. 1627) determined that at a constant temperature the product of pressure and volume remains constant. (See Fig. 20-1.)

FIGURE 20-1 ■ A contemporary setup for determining the relationship between gas pressure and volume using an inexpensive medical syringe and an electronic pressure sensor attached to a computer data acquisition system. The volume is changed when the plunger is pushed or pulled. When temperature is held constant, P and V turn out to be inversely proportional to each other so that PV is constant.

French scientists Jacques Charles (b. 1746) and Joseph Gay-Lussac (b. 1778) found that as the Kelvin temperature of a fixed volume of gas is raised its pressure increases proportionally. (See Fig. 19-16.) Similarly, Charles, who was a hot-air balloonist, discovered that for a constant pressure (such as atmospheric pressure) the volume of a gas is proportional to its temperature. (See Fig. 19-15.) By combining the results of all three of these experiments we must conclude that there is a proportionality between PV and T :

$$PV \propto T.$$

The Molecular Form of the Ideal Gas Law

If we can find a constant of proportionality between PV and T for a relatively low density gas, then we will have formulated a gas law. An examination of the student-generated P vs. T data shown in Fig. 19-17 indicates that the constant of proportionality between the product PV and the variable T (determined by the slopes) of the graphs decreases as the mass of gas confined to the same volume decreases. Similar experiments have shown that the slope of a P vs. T graph will change if the same volume and mass of a different kind of gas is used. This suggests that the constant of proportionality we are looking for must be a function of *both* the mass and type of gas. It was puzzling to early investigators that the slopes of their P vs. T and V vs. T graphs were not just proportional to the mass of the different gases used in the experiments.

The key to finding a constant of proportionality that embodies both gas type and mass was a hypothesis developed in the early 19th century by the Italian scientist Amadeo Avogadro (1776–1856). In 1811, Avogadro proposed that equal volumes of any kind of gas at the same pressure would have the same number of molecules and occupy the same volume. Eventually it was discovered that the constant of proportionality needed for the fledgling gas law was one that is directly proportional to the number of molecules of a gas rather than its mass, so that

$$PV = Nk_B T \quad (\text{molecular ideal gas law}), \quad (20-1)$$

where N is the number of molecules of confined gas and k_B is a proportionality constant needed to shift from kelvins to joules, the SI units for the product PV . The experimentally determined value of k_B is known historically as the Boltzmann constant. Its measured value is

$$k_B = 1.38 \times 10^{-23} \text{ J/K} \quad (\text{Boltzmann constant}). \quad (20-2)$$

It turns out that common gases such as O_2 , N_2 , and Ar behave like ideal gases at relatively low pressure (< 10 atm) when their temperatures are well above their boiling points. For example, air near room temperature and 1 atm of pressure behaves like an ideal gas.

Avogadro's Number and the Mole

The problem with the molecular form of the ideal gas law we just presented is that it is hard to count molecules. It is much easier to measure the mass of a sample of gas or its volume at a standard pressure. In this subsection we will define two new quantities—*mole* and *molar mass*. Although these quantities are related to the number of molecules in a gas, they can be measured macroscopically, so it is useful to reformulate the ideal gas law in terms of moles.

Let's start our reformulation of the ideal gas law with definitions of mole and molar mass. In Section 1-7, we presented the SI definition of the *atomic mass unit* in

terms of the mass of a carbon-12 atom. In particular, carbon-12 is assigned an atomic mass of exactly 12 u. Here the atomic mass unit u represents grams per mole (g/mol). In a related fashion, the SI definition of the *mole* (or *mol* for short) relates the number of particles in a substance to its macroscopic mass.

A **mole** is defined as the amount of any substance that contains the same number of atoms or molecules as there are in *exactly* 12 g of carbon-12.

The results of many different types of experiments, including x-ray diffraction studies in crystals, have revealed that there are a very large number of atoms in 12 g of carbon-12. The number of atoms is known as Avogadro's number and is denoted as N_A .

$$N_A = 6.022137 \times 10^{23} \text{ mol}^{-1} \quad (\text{Avogadro's number}). \quad (20-3)$$

Here the symbol mol^{-1} represents the inverse mole or “per mole.” Usually we round off the value to three significant figures so that $N_A = 6.02 \times 10^{23} \text{ mol}^{-1}$.

The number of moles n contained in a sample of any substance is equal to the ratio of the number of atoms or molecules N in the sample to the number of atoms or molecules N_A in 1 mole of the same substance:

$$n = \frac{N}{N_A}. \quad (20-4)$$

(Caution: The three symbols in this equation can easily be confused with one another, so you should sort them with their meanings now, before you end in “N-confusion.”)

We can easily calculate the mass of one mole of atoms or molecules in any sample, defined as the **molar mass** (denoted as M), by looking in a table of atomic or molecular masses.

Note that if we refer to Appendix F to find the molar mass, M , in grams of a sample of matter, we can determine the number of moles in the sample by determining its mass M_{sam} and using the equation

$$n = \frac{M_{\text{sam}}}{M}. \quad (20-5)$$

For atoms, the molar mass is just the atomic mass so that molar mass also has the unit g/mol, which is often denoted as u.

It is puzzling to note that the atomic mass of carbon that is listed in Appendix F is given as 12.01115 u rather than 12.00000 u. This is because a natural sample of carbon does not consist of only carbon-12. Instead it contains a relatively small percentage of carbon-13, which has an extra neutron in its nucleus. Nevertheless, by definition, a mole of pure carbon-12 and a mole of a naturally occurring mixture of carbon-12 and carbon-13 both contain Avogadro's number of atoms.

The Molar Form of the Ideal Gas Law

We can rewrite the molecular ideal gas law expressed in Eq. 20-1 in an alternative form by using Eq. 20-4, so that

$$PV = Nk_B T = nN_A k_B T.$$

Since both Avogadro's number and the Boltzmann constant are constants, we can replace their product with a new constant R , which is called the **universal gas constant** because it has the same value for all ideal gases—namely,

$$R = N_A k_B = 6.02 \times 10^{23} \text{ mol}^{-1} (1.38 \times 10^{-23} \text{ J/K}) = 8.31 \text{ J/mol} \cdot \text{K}. \quad (20-6)$$

This allows us to write

$$nR = Nk_B. \quad (20-7)$$

Substituting this into Eq. 20-1 gives a second expression for the **ideal gas law**:

$$PV = nRT \quad (\text{molar ideal gas law}), \quad (20-8)$$

in which P is the absolute (not gauge) pressure, V is the volume, n is the number of moles of gas present, and T is the temperature in Kelvin. Provided the gas density is low, the ideal gas law as represented in either Eq. 20-1 or Eq. 20-8 holds for any single gas or for any mixture of different gases. (For a mixture, n is the total number of moles in the mixture.)

Note the difference between the two expressions for the ideal gas law—Eq. 20-8 involves the number of moles n and Eq. 20-1 involves the number of atoms N . That is, the Boltzmann constant k_B tells us about individual atomic particles, whereas the gas constant R tells us about moles of particles. Recall that moles are defined via macroscopic measurements that are easily done in the lab—such as 1 mol of carbon has a mass of 12 g. As a result, R is easily measured in the lab. On the other hand, since k_B is about individual atoms, to get to it from a lab measurement we have to count the number of molecules in a mole. This is a decidedly nontrivial task.

You may well ask, “What is an *ideal gas* and what is so ‘ideal’ about it?” The answer lies in the simplicity of the law (Eqs. 20-1 and 20-8) that describes the macroscopic properties of a gas. Using this law—as you will see—we can deduce many properties of the ideal gas in a simple way. There is no such thing in nature as a truly ideal gas. But *all* gases approach the ideal state at low enough densities—that is, under conditions in which their molecules are far enough apart that they do not interact with one another as much as they do with the walls of their containers. Thus, the two equivalent ideal gas equations allow us to gain useful insights into the behavior of most real gases at low densities.

TOUCHSTONE EXAMPLE 20-1: Final Pressure

A cylinder contains 12 L of oxygen at 20°C and 15 atm. The temperature is raised to 35°C, and the volume is reduced to 8.5 L. What is the final pressure of the gas in atmospheres? Assume that the gas is ideal.

SOLUTION ■ The **Key Idea** here is that, because the gas is ideal, its pressure, volume, temperature, and number of moles are related by the ideal gas law, both in the initial state i and in the final state f (after the changes). Thus, from Eq. 20-8 we can write $P_i V_i = nRT_i$ and $P_f V_f = nRT_f$. Dividing the second equation by the first equation and solving for P_f yields

$$P_f = \frac{P_i T_f V_i}{T_i V_f}. \quad (20-9)$$

Note here that if we converted the given initial and final volumes from liters to SI units of cubic meters, the multiplying conversion

factors would cancel out of Eq. 20-9. The same would be true for conversion factors that convert the pressures from atmospheres to the more accepted SI unit of pascals. However, to convert the given temperatures to kelvins requires the addition of an amount that would not cancel and thus must be included. Hence, we must write

$$T_i = (273 + 20) \text{ K} = 293 \text{ K}$$

and

$$T_f = (273 + 35) \text{ K} = 308 \text{ K}.$$

Inserting the given data into Eq. 20-9 then yields

$$P_f = \frac{(15 \text{ atm})(308 \text{ K})(12 \text{ L})}{(293 \text{ K})(8.5 \text{ L})} = 22 \text{ atm}. \quad (\text{Answer})$$

20-3 Work Done by Ideal Gases

Heat engines are devices that can absorb thermal energy and do useful work on their surroundings. As you will see in the next chapter, air, which is typically used as a working medium in heat engines, behaves like an ideal gas in some circumstances. For this reason engineers are interested in knowing how to calculate the work done by ideal gases. Before we turn our attention to how the action of molecules that make up an ideal gas can be used to explain the ideal gas law, we first consider how to calculate the work done by ideal gases under various conditions. We restrict ourselves to expansions that occur slowly enough that the gas is very close to thermal equilibrium throughout its volume.

Work Done by an Ideal Gas at Constant Temperature

Suppose we put an ideal gas in a piston–cylinder arrangement like those in Chapter 19. Suppose also that we allow the gas to expand from an initial volume V_i to a final volume V_f while we keep the temperature T of the gas constant. Such a process, at *constant temperature*, is called an **isothermal expansion** (and the reverse is called an **isothermal compression**).

On a P - V diagram, an *isotherm* is a curve that connects points that have the same temperature. Thus, it is a graph of pressure versus volume for a gas whose temperature T is held constant. For n moles of an ideal gas, it is a graph of the equation

$$P = nRT \frac{1}{V} = (\text{a constant}) \frac{1}{V}. \quad (20-10)$$

Figure 20-2 shows three isotherms, each corresponding to a different (constant) value of T . (Note that the values of T for the isotherms increase upward to the right.) Superimposed on the middle isotherm is the path followed by a gas during an isothermal expansion from state i to state f at a constant temperature of 310 K.

To find the work done by an ideal gas during an isothermal expansion, we start with Eq. 19-16,

$$W = \int_{V_i}^{V_f} P dV. \quad (20-11)$$

This is a general expression for the work done during any change in volume of any gas. For an ideal gas, we can use Eq. 20-8 to substitute for P , obtaining

$$W = \int_{V_i}^{V_f} \frac{nRT}{V} dV. \quad (20-12)$$

Because we are considering an isothermal expansion, T is constant and we can move it in front of the integral sign to write

$$W = nRT \int_{V_i}^{V_f} \frac{dV}{V} = nRT [\ln V]_{V_i}^{V_f}. \quad (20-13)$$

By evaluating the expression in brackets at the limits and then using the relationship $\ln a - \ln b = \ln (a/b)$, we find that

$$W = nRT \ln \frac{V_f}{V_i} = Nk_B \ln \frac{V_f}{V_i} \quad (\text{ideal gas, isothermal process}). \quad (20-14)$$

Recall that the symbol \ln specifies a *natural* logarithm, which has base e .

FIGURE 20-2 ■ Three isotherms on a P - V diagram. The path shown along the middle isotherm represents an isothermal expansion of a gas from an initial state i to a final state f . The path from f to i along the isotherm would represent the reverse process, an isothermal compression.

As we often do in science and engineering we have derived a mathematical relationship. Before using this relationship it's a good idea to check our equation to see whether it makes sense. Unless a gas is undergoing a free expansion into a vacuum, we know that an expanding gas does work on its surroundings. If the gas contracts we expect that the surroundings have done work on the gas instead. Is this what Eq. 20-14 tells us? For an expansion, V_f is greater than V_i , so the ratio V_f/V_i in Eq. 20-14 is greater than unity. The natural logarithm of a quantity greater than unity is positive, and so the work W done by an ideal gas during an isothermal expansion is positive, as we expect. For a compression, V_f is less than V_i , so the ratio of volumes in Eq. 20-14 is less than unity. The natural logarithm in that equation—hence the work W —is negative, again as we expect.

Work Done at Constant Volume and at Constant Pressure

Equation 20-14 does not give the work W done by an ideal gas during *every* thermodynamic process. Instead, it gives the work only for a process in which the temperature is held constant. If the temperature varies, then the symbol T in Eq. 20-12 cannot be moved in front of the integral symbol as in Eq. 20-13, and thus we do not end up with Eq. 20-14.

However, we can go back to Eq. 20-11 to find the work W done by an ideal gas (or any other gas) during two more processes—a constant-volume process and a constant-pressure process. If the volume of the gas is constant, then Eq. 20-11 yields

$$W = 0 \quad (\text{constant-volume process}). \quad (20-15)$$

If, instead, the volume changes while the pressure P of the gas is held constant, then Eq. 20-11 becomes

$$W = P(V_f - V_i) = P\Delta V \quad (\text{constant-pressure process}). \quad (20-16)$$

READING EXERCISE 20-1: An ideal gas has an initial pressure of 3 pressure units and an initial volume of 4 volume units. The table gives the final pressure and volume of the gas (in those same units) in five processes. Which processes start and end on the same isotherm?

	<i>a</i>	<i>b</i>	<i>c</i>	<i>d</i>	<i>e</i>
<i>P</i>	12	6	5	4	1
<i>V</i>	1	2	7	3	12

TOUCHSTONE EXAMPLE 20-2: Work Done by Expansion

One mole of oxygen (assume it to be an ideal gas) expands at a constant temperature T of 310 K from an initial volume V_i of 12 L to a final volume V_f of 19 L. How much work is done by the gas during the expansion?

SOLUTION ■ The **Key Idea** is this: Generally we find the work by integrating the gas pressure with respect to the gas volume, using Eq. 20-11. However, because the gas here is ideal and the expansion is isothermal, that integration leads to Eq. 20-14. Therefore, we can write

$$\begin{aligned} W &= nRT \ln \frac{V_f}{V_i} \\ &= (1 \text{ mol})(8.31 \text{ J/mol} \cdot \text{K})(310 \text{ K}) \ln \left(\frac{19 \text{ L}}{12 \text{ L}} \right) \\ &= 1180 \text{ J}. \end{aligned} \quad (\text{Answer})$$

The expansion is graphed in the P - V diagram of Fig. 20-3. The work done by the gas during the expansion is represented by the area beneath the curve between i and f .

You can show that if the expansion is now reversed, with the gas undergoing an isothermal compression from 19 L to 12 L, the work done by the gas will be -1180 J. Thus, an external force would have to do 1180 J of work on the gas to compress it.

FIGURE 20-3 ■ The shaded area represents the work done by 1 mol of oxygen in expanding from V_i to V_f at a constant temperature T of 310 K.

20-4 Pressure, Temperature, and Molecular Kinetic Energy

In terms of our everyday experiences, molecules and atoms are invisible. Only in the past 40 years or so have scientists been able to “see” molecules using electron microscopes and field ion microscopes. But long before atoms and molecules could be “seen,” 19th-century scientists such as James Clerk Maxwell and Ludwig Boltzmann in Europe and Josiah Willard Gibbs in the United States constructed models that made the description and prediction of the *macroscopic* (visible to the naked eye) behavior of thermodynamic systems possible. Their models were based on the yet unseen *microscopic* atoms and molecules.

Is it possible to describe the behavior of an ideal gas that obeys the first law of thermodynamics microscopically as a collection of moving molecules? To answer this question, let’s observe the pressure exerted by a hypothetical molecule undergoing perfectly elastic collisions with the walls of a cubical box. By using the laws of mechanics we can derive a mathematical expression for the pressure exerted by just one of the molecules as a function of the volume of the box. Next we can extend our “ideal gas” so it is a low-density collection of molecules all having the same mass. By low density we mean that the volume occupied by the molecules is negligible compared to the volume of their container. This means that the molecules are far enough apart on the average that attractive interactions between molecules are also negligible. For this reason an ideal gas has internal energy related to its configuration. If we then define temperature as being related to the average kinetic energy of the molecules in an ideal gas, we can show that kinetic theory is a powerful construct for explaining both the ideal gas law and the first law of thermodynamics.

We start developing our idealized kinetic theory model by considering N molecules of an ideal gas that are confined in a cubical box of volume V , as in Fig. 20-4. The walls of the box are held at temperature T . How is the pressure P exerted by the gas on the walls related to the speeds of the molecules? Remember from our discussions of fluids in Chapter 15 that pressure is a scalar defined as the ratio of the magnitude of force (exerted normal to a surface) and the area of the surface. In the example at hand, a gas confined to a box, the pressure results from the motion of molecules in all directions resulting in elastic collisions between gas molecules and the walls of the box. We ignore (for the time being) collisions of the molecules with one another and consider only elastic collisions with the walls.

Figure 20-4 shows a typical gas molecule, of mass m and velocity \vec{v} , which is about to collide with the shaded wall. Because we assume that any collision of a molecule

FIGURE 20-4 ■ We assume a cubical box of edge L contains N ideal gas molecules (not shown) that move around perpetually without losing energy. One of the molecules of mass m and velocity \vec{v} is shown heading for a collision with the shaded wall of area L^2 . The normal to the shaded wall points in the positive x direction.

with a wall is elastic, when this molecule collides with the shaded wall, the only component of its velocity that is changed by the collision is its x -component. That x -component has the same magnitude after collision but its sign is reversed. This means that the only change in the particle's momentum is along the x axis, so

$$(\Delta p_x)_{\text{molecule}} = p_{fx} - p_{ix} = (-m|v_x|) - (+m|v_x|) = -2m|v_x|.$$

But the law of conservation of momentum tells us that the momentum change $(\Delta p_x)_{\text{wall}}$ that the wall experiences after a molecule collides with it is $+2m|v_x|$. Remember that in this book \vec{p} , p_x , p_y , and p_z denote momentum vectors or vector components and capital P represents pressure. *Be careful not to confuse them.*

The molecule of Fig. 20-4 will hit the shaded wall repeatedly. The time Δt between collisions is the time the molecule takes to travel to the opposite wall and back again (a distance of $2L$) at speed $|v_x|$. Thus, Δt is equal to $2L/|v_x|$. (Note that this result holds even if the molecule bounces off any of the other walls along the way, because those walls are parallel to x and so cannot change $|v_x|$.) Therefore, the average rate at which momentum is delivered to the shaded wall by this single molecule is

$$\frac{(\Delta p_x)_{\text{wall}}}{\Delta t} = \frac{+2m|v_x|}{2L/|v_x|} = \frac{mv_x^2}{L}.$$

From Newton's Second Law ($\vec{F} = d\vec{p}/dt$), the rate at which momentum is delivered to the wall is the force acting on that wall. To find the total force, we must add up the contributions of all of the N molecules that strike the wall during a short time interval Δt . We will allow for the possibility that all the molecules have different velocities. Then we can divide the magnitude of the total force acting normal to the shaded wall $|F_x|$ by the area of the wall (L^2) to determine the pressure P on that wall. Thus,

$$\begin{aligned} P &= \frac{|F_x|}{L^2} = \frac{mv_{x1}^2/L + mv_{x2}^2/L + \cdots + mv_{xN}^2/L}{L^2} \\ &= \left(\frac{m}{L^3}\right)(v_{x1}^2 + v_{x2}^2 + \cdots + v_{xN}^2). \end{aligned} \quad (20-17)$$

Since by definition $\langle v_x^2 \rangle = (v_{x1}^2 + v_{x2}^2 + \cdots + v_{xN}^2)/N$ we can replace the sum of squares of the velocities in the second parentheses of Eq. 20-17 by $N\langle v_x^2 \rangle$, where $\langle v_x^2 \rangle$ is the average value of the square of the x -components of all the speeds. Equation 20-17 for the pressure on the container wall then reduces to

$$P = \frac{Nm}{L^3} \langle v_x^2 \rangle = \frac{Nm}{V} \langle v_x^2 \rangle, \quad (20-18)$$

since the volume V of the cubical box is just L^3 .

It is reasonable to assume that molecules are moving at random in three dimensions rather than just in the x direction that we considered initially, so that $\langle v_x^2 \rangle = \langle v_y^2 \rangle = \langle v_z^2 \rangle$ and

$$\langle v^2 \rangle = \langle v_x^2 + v_y^2 + v_z^2 \rangle = \langle v_x^2 \rangle + \langle v_y^2 \rangle + \langle v_z^2 \rangle = 3\langle v_x^2 \rangle,$$

or $\langle v_x^2 \rangle = \langle v^2 \rangle / 3$.

Thus, we can rewrite the expression above as

$$P = \frac{Nm\langle v^2 \rangle}{3V}. \quad (20-19)$$

The square root of $\langle v^2 \rangle$ is a kind of average speed, called the **root-mean-square speed** of the molecules and symbolized by v^{rms} . Its name describes it rather well: You *square* each speed, you find the *mean* (that is, the average) of all these squared speeds, and then you take the square *root* of that mean. With $\sqrt{\langle v^2 \rangle} = v^{\text{rms}}$, we can then write Eq. 20-19 as

$$P = \frac{Nm(v^{\text{rms}})^2}{3V}. \quad (20-20)$$

Equation 20-20 is very much in the spirit of kinetic theory. It tells us how the pressure of the gas (a purely macroscopic quantity) depends on the speed of the molecules (a purely microscopic quantity). We can turn Eq. 20-20 around and use it to calculate v^{rms} as

$$v^{\text{rms}} = \sqrt{\frac{3PV}{Nm}}.$$

Combining this with the molecular form of the ideal gas law in Eq. 20-1 ($PV = Nk_B T$) gives us

$$v^{\text{rms}} = \sqrt{\frac{3k_B T}{m}} \quad (\text{ideal gas}), \quad (20-21)$$

where m is the mass of a single molecule in kilograms.

Table 20-1 shows some rms speeds calculated from Eq. 20-21. The speeds are surprisingly high. For hydrogen molecules at room temperature (300 K), the rms speed is 1920 m/s or 4300 mi/h—faster than a speeding bullet! Remember too that the rms speed is only a kind of average speed; some molecules move much faster than this, and some much slower.

TABLE 20-1
Some Molecular Speeds at Room Temperature ($T = 300 \text{ K}$)^a

Gas	Molar Mass $M = mN_A$ (10^{-3} kg/mol)	v^{rms} (m/s)
Hydrogen (H_2)	2.02	1920
Helium (He)	4.0	1370
Water vapor (H_2O)	18.0	645
Nitrogen (N_2)	28.0	517
Oxygen (O_2)	32.0	483
Carbon dioxide (CO_2)	44.0	412
Sulfur dioxide (SO_2)	64.1	342

^aFor convenience, we often set room temperature at 300 K even though (at 27°C or 81°F) that represents a fairly warm room.

The speed of sound in a gas is closely related to the rms speed of the molecules of that gas. In a sound wave, the disturbance is passed on from molecule to molecule by means of collisions. The wave cannot move any faster than the “average” speed of the molecules. In fact, the speed of sound must be somewhat less than this “average” molecular speed because not all molecules are moving in exactly the same direction as the wave. As examples, at room temperature, the rms speeds of hydrogen and nitrogen molecules are 1920 m/s and 517 m/s, respectively. The speeds of sound in these two gases at this temperature are 1350 m/s and 350 m/s, respectively.

Translational Kinetic Energy

Let's again consider a single molecule of an ideal gas as it moves around in the box of Fig. 20-4, but we now assume that its speed changes when it collides with other molecules. Its translational kinetic energy at any instant is $\frac{1}{2}mv^2$. Its *average* translational kinetic energy over the time that we watch it is

$$\langle K \rangle = \frac{1}{2}\langle mv^2 \rangle = \frac{1}{2}m\langle v^2 \rangle = \frac{1}{2}m(v^{\text{rms}})^2, \quad (20-22)$$

in which we make the assumption that the average speed of the molecule during our observation is the same as the average speed of all the molecules at any given instant. (Provided the total energy of the gas is not changing and we observe our molecule for long enough, this assumption is appropriate.) Substituting for v^{rms} from Eq. 20-21 leads to

$$\langle K \rangle = \left(\frac{1}{2}m\right) \frac{3k_B T}{m}$$

so that

$$\langle K \rangle = \frac{3}{2}k_B T \quad (\text{one ideal gas molecule}). \quad (20-23)$$

This equation tells us something unexpected:

At a given temperature T , all ideal gas molecules—no matter what their mass—have the same average translational kinetic energy—namely, $(\frac{3}{2})k_B T$. When we measure the temperature of a gas, we are also measuring the average translational kinetic energy of its molecules.

READING EXERCISE 20-2: What happens to the average translational kinetic energy of each molecule in a gas when its temperature in kelvin: (a) doubles and (b) is reduced to zero? ■

READING EXERCISE 20-3: A gas mixture consists of molecules of types 1, 2, and 3, with molecular masses $m_1 > m_2 > m_3$. Rank the three types according to (a) average kinetic energy and (b) rms speed, greatest first. ■

FIGURE 20-5 ■ A molecule traveling through a gas, colliding with other gas molecules in its path. Although the other molecules are shown as stationary, we believe they are also moving in a similar fashion.

20-5 Mean Free Path

In considering the motion of molecules, a question often arises: If molecules move so fast (hundreds of meters per second), why does it take as long as a minute or so before you can smell perfume when someone opens a bottle across a room (only a few meters away)? To answer this question, we continue to examine the motion of molecules in an ideal gas. Figure 20-5 shows the path of a typical molecule as it moves through the gas, changing both speed and direction abruptly as it collides elastically with other molecules. Between collisions, our typical molecule moves in a straight line at constant speed. Although the figure shows all the other molecules as stationary, they too are moving similarly.

One useful parameter to describe this random motion is the **mean free path** λ of the molecules. As its name implies, λ is the average distance traversed by a molecule between collisions. We expect λ to vary inversely with N/V , the number of molecules per unit volume (or “number density” of molecules). The larger N/V is, the more collisions there should be and the smaller the mean free path. We also expect λ to vary inversely with the size of the molecules, say, with their diameter d . (If the molecules were points, as we have assumed them to be, they would never collide and the mean

free path would be infinite.) Thus, the larger the molecules are, the smaller the mean free path. We can even predict that λ should vary (inversely) as the *square* of the molecular diameter because the cross section of a molecule—not its diameter—determines its effective target area.

The expression for the mean free path does, in fact, turn out to be

$$\lambda = \frac{1}{\sqrt{2}\pi d^2 N/V} \quad (\text{ideal gas mean free path}). \quad (20-24)$$

To justify Eq. 20-24, we focus attention on a single molecule and assume—as Fig. 20-5 suggests—that our molecule is traveling with a constant speed v and that all the other molecules are at rest. Later, we shall relax this assumption.

We assume further that the molecules are spheres of diameter d . A collision will then take place if the centers of the molecules come within a distance d of each other, as in Fig. 20-6a. Another, more helpful way to look at the situation is to consider our single molecule to have a *radius* of d and all the other molecules to be *points*, as in Fig. 20-6b. This does not change our criterion for a collision.

As our single molecule zigzags through the gas, it sweeps out a short cylinder of cross-sectional area πd^2 between successive collisions. If we watch this molecule for a time interval Δt , it moves a distance $v\Delta t$, where v is its assumed speed. Thus, if we align all the short cylinders swept out in Δt , we form a composite cylinder (Fig. 20-7) of length $v\Delta t$ and volume $(\pi d^2)(v\Delta t)$. The number of collisions that occur in time Δt is then equal to the number of (point) molecules that lie within this cylinder.

Since N/V is the number of molecules per unit volume, the number of molecules in the cylinder is N/V times the volume of the cylinder, or $(N/V)(\pi d^2 v\Delta t)$. This is also the number of collisions in time Δt . The mean free path is the length of the path (and of the cylinder) divided by this number:

$$\begin{aligned} \lambda &= \frac{\text{length of path}}{\text{number of collisions}} \approx \frac{v\Delta t}{\pi d^2 v\Delta t N/V} \\ &= \frac{1}{\pi d^2 N/V}. \end{aligned} \quad (20-25)$$

This equation is only approximate because it is based on the assumption that all the molecules except one are at rest. In fact, *all* the molecules are moving; when this is taken properly into account, Eq. 20-24 results. Note that it differs from the (approximate) Eq. 20-25 only by a factor of $1/\sqrt{2}$.

We can even get a glimpse of what is “approximate” about Eq. 20-25. The v in the numerator and that in the denominator are—strictly—not the same. The v in the numerator is $\langle v \rangle$, the mean speed of the molecule *relative to the container*. The v in the denominator is $\langle v^{\text{rel}} \rangle$, the mean speed of our single molecule *relative to the other molecules*, which are moving. It is this latter average speed that determines the number of collisions. A detailed calculation, taking into account the actual speed distribution of the molecules, gives $\langle v^{\text{rel}} \rangle = \sqrt{2} \langle v \rangle$ and thus the factor $\sqrt{2}$.

The mean free path of air molecules at sea level is about $0.1 \mu\text{m}$. At an altitude of 100 km, the density of air has dropped to such an extent that the mean free path rises to about 16 cm. At 300 km, the mean free path is about 20 km. A problem faced by those who would study the physics and chemistry of the upper atmosphere in the laboratory is the unavailability of containers large enough to hold gas samples that simulate upper atmospheric conditions. Yet studies of the concentrations of freon, carbon dioxide, and ozone in the upper atmosphere are of vital public concern.

Recall the question that began this section: If molecules move so fast, why does it take as long as a minute or so before you can smell perfume when someone opens a bottle across a room? We now know part of the answer. In still air, each perfume molecule moves away from the bottle only very slowly because its repeated collisions with other molecules prevent it from moving directly across the room to you.

FIGURE 20-6 (a) A collision occurs when the centers of two molecules come within a distance d of each other, d being the molecular diameter. (b) An equivalent but more convenient representation is to think of the moving molecule of interest as having a *radius* d and all other molecules as being *points*. The condition for a collision is unchanged.

FIGURE 20-7 In time Δt the moving molecule effectively sweeps out a cylinder of length $v\Delta t$ and radius d .

TOUCHSTONE EXAMPLE 20-3: Mean Free Path

(a) What is the mean free path λ for oxygen molecules at temperature $T = 300$ K and pressure $P = 1.00$ atm? Assume that the molecular diameter is $d = 290$ pm and the gas is ideal.

SOLUTION ■ The **Key Idea** here is that each oxygen molecule moves among other *moving* oxygen molecules in a zigzag path due to the resulting collisions. Thus, we use Eq. 20-24 for the mean free path, for which we need the number of molecules per unit volume, N/V . Because we assume the gas is ideal, we can use the ideal gas law of Eq. 20-1 ($PV = Nk_B T$) to write $N/V = P/k_B T$. Substituting this into Eq. 20-24, we find

$$\begin{aligned}\lambda &= \frac{1}{\sqrt{2}\pi d^2 N/V} = \frac{k_B T}{\sqrt{2}\pi d^2 P} \\ &= \frac{(1.38 \times 10^{-23} \text{ J/K})(300 \text{ K})}{\sqrt{2}\pi(2.9 \times 10^{-10} \text{ m})^2 (1.01 \times 10^5 \text{ Pa})} \quad (\text{Answer}) \\ &= 1.1 \times 10^{-7} \text{ m}.\end{aligned}$$

This is about 380 molecular diameters.

(b) Assume the average speed of the oxygen molecules is $\langle v \rangle = 450$ m/s. What is the average time interval Δt between successive

collisions for any given molecule? At what rate does the molecule collide; that is, what is the frequency f of its collisions?

SOLUTION ■ To find the time interval Δt between collisions, we use this **Key Idea**: Between collisions, the molecule travels, on average, the mean free path λ at average speed $\langle v \rangle$. Thus, the average time between collisions is

$$\begin{aligned}\langle \Delta t \rangle &= \frac{(\text{distance})}{(\text{average speed})} = \frac{\lambda}{\langle v \rangle} = \frac{1.1 \times 10^{-7} \text{ m}}{450 \text{ m/s}} \quad (\text{Answer}) \\ &= 2.44 \times 10^{-10} \text{ s} \approx 0.24 \text{ ns}.\end{aligned}$$

This tells us that, on average, any given oxygen molecule has less than a nanosecond between collisions.

To find the frequency f of the collisions, we use this **Key Idea**: The average rate or frequency at which the collisions occur is the inverse of the average time $\langle \Delta t \rangle$ between collisions. Thus,

$$f = \frac{1}{2.44 \times 10^{-10} \text{ s}} = 4.1 \times 10^9 \text{ s}^{-1}. \quad (\text{Answer})$$

This tells us that, on average, any given oxygen molecule makes about 4 billion collisions per second.

20-6 The Distribution of Molecular Speeds

The root-mean-square speed v^{rms} gives us a general idea of molecular speeds in a gas at a given temperature. We often want to know more. For example, what fraction of the molecules have speeds greater than the rms value? Greater than twice the rms value? To answer such questions, we need to know how the possible values of speed are distributed among the molecules. Figure 20-8a shows this distribution for oxygen molecules at room temperature ($T = 300$ K); Fig. 20-8b compares it with the distribution at $T = 80$ K.

FIGURE 20-8 ■ (a) The Maxwell speed distribution for oxygen molecules at $T = 300$ K. The three characteristic speeds are marked. (b) The curves for 300 K and 80 K. Note that the molecules move more slowly at the lower temperature. Because these are probability distributions, the area under each curve has a numerical value of unity.

In 1852, Scottish physicist James Clerk Maxwell first solved the problem of finding the speed distribution of gas molecules. His result, known as **Maxwell's speed distribution law**, is

$$f(v) = 4\pi \left(\frac{m}{2\pi k_B T} \right)^{3/2} v^2 e^{-mv^2/2k_B T}. \quad (20-26)$$

Here v is the molecular speed, T is the gas temperature, m is the mass of a single gas molecule, and k_B is Boltzmann's constant. It is this equation that is plotted in Fig. 20-8a, b. The quantity $f(v)$ in Eq. 20-26 and Fig. 20-8 is a *probability distribution function*: For any speed v , the product $f(v)dv$ (a dimensionless quantity) is the fraction of molecules whose speeds lie in the interval of width dv centered on speed v .

As Fig. 20-8a shows, this fraction is equal to the area of a strip with height $f(v)$ and width dv . The total area under the distribution curve corresponds to the fraction of the molecules whose speeds lie between zero and infinity. All molecules fall into this category, so the value of this total area is unity; that is,

$$\int_0^{\infty} f(v) dv = 1. \quad (20-27)$$

The fraction of molecules with speeds in an interval of, say, v_1 to v_2 is then

$$\text{fraction} = \int_{v_1}^{v_2} f(v) dv. \quad (20-28)$$

Average, RMS, and Most Probable Speeds

In principle, we can find the **average speed** $\langle v \rangle$ of the molecules in a gas with the following procedure: We *weight* each value of v in the distribution; that is, we multiply it by the fraction $f(v)dv$ of molecules with speeds in a differential interval dv centered on v . Then we add up all these values of $vf(v)dv$. The result is $\langle v \rangle$. In practice, we do all this by evaluating

$$\langle v \rangle = \int_0^{\infty} v f(v) dv. \quad (20-29)$$

Substituting for $f(v)$ from Eq. 20-26 and using definite integral 20 from the list of integrals in Appendix E, we find

$$\langle v \rangle = \sqrt{\frac{8k_B T}{\pi m}} \quad (\text{average speed}). \quad (20-30)$$

Similarly, we can find the average of the square of the speeds $\langle v^2 \rangle$ with

$$\langle v^2 \rangle = \int_0^{\infty} v^2 f(v) dv. \quad (20-31)$$

Substituting for $f(v)$ from Eq. 20-27 and using generic integral 16 from the list of integrals in Appendix E, we find

$$\langle v^2 \rangle = \frac{3k_B T}{m}. \quad (20-32)$$

The square root of $\langle v^2 \rangle$ is the **root-mean-square speed** v^{rms} . Thus,

$$v^{\text{rms}} = \sqrt{\frac{3k_B T}{m}} \quad (\text{rms speed}), \quad (20-33)$$

which agrees with Eq. 20-21.

The **most probable speed** v^{prob} is the speed at which $f(v)$ is maximum (see Fig. 20-8a). To calculate v^{prob} , we set $df/dv = 0$ (the slope of the curve in Fig. 20-8a is zero at the maximum of the curve) and then solve for v . Doing so, we find

$$v^{\text{prob}} = \sqrt{\frac{2k_B T}{m}} \quad (\text{most probable speed}). \quad (20-34)$$

What is the relationship between the most probable speed, the average speed, and the rms speed of a molecule? The relationship is fixed.

The most probable speed v^{prob} is always less than the average speed $\langle v \rangle$ which in turn is less than the rms speed v^{rms} . More specifically, $v^{\text{prob}} = 0.82 v^{\text{rms}}$ and $\langle v \rangle = 0.92 v^{\text{rms}}$.

This is consistent with the idea that a molecule is more likely to have speed v^{prob} than any other speed, but some molecules will have speeds that are many times v^{prob} . These molecules lie in the *high-speed tail* of a distribution curve like that in Fig. 20-8a. We should be thankful for these few, higher speed molecules because they make possible both rain and sunshine (without which we could not exist). We next see why.

Rain: The speed distribution of water molecules in, say, a pond at summertime temperatures can be represented by a curve similar to that of Fig. 20-8a. Most of the molecules do not have nearly enough kinetic energy to escape from the water through its surface. However, small numbers of very fast molecules with speeds far out in the tail of the curve can do so. It is these water molecules that evaporate, making clouds and rain a possibility.

As the fast water molecules leave the surface, carrying energy with them, the temperature of the remaining water is maintained by thermal energy transfer from the surroundings. Other fast molecules—produced in particularly favorable collisions—quickly take the place of those that have left, and the speed distribution is maintained.

Sunshine: Let the distribution curve of Fig. 20-8a now refer to protons in the core of the Sun. The Sun's energy is supplied by a nuclear fusion process that starts with the merging of two protons. However, protons repel each other because of their electrical charges, and protons of average speed do not have enough kinetic energy to overcome the repulsion and get close enough to merge. Very fast protons with speeds in the tail of the distribution curve can do so, however, and thus the Sun can shine.

20-7 The Molar Specific Heats of an Ideal Gas

Up to now, we have taken the specific heat of a substance as a quantity to be measured. But now, with the kinetic theory of gases, we know something about the structure of matter and where its energy is stored. With this additional information, we can actually calculate and make predictions about what we expect the specific heats of different kinds of gases to be. If we compare our predictions based on kinetic theory to experimental measurements, we get some good agreement and also some surprises. The surprises are among the first hints that the laws of matter at the atomic level are not just Newton's laws scaled down. In other words, we begin to notice that atoms aren't just little billiard balls but something different from any macroscopic object with which we have experience.

To explore this idea, we derive here (from molecular considerations) an expression for the internal energy E^{int} of an ideal gas. In other words, we find an expression

for the energy associated with the random motions of the atoms or molecules in the gas. We shall then use that expression to derive the molar specific heats of an ideal gas.

Internal Energy E^{int}

Let us first assume that our ideal gas is a *monatomic gas* (which has individual atoms rather than molecules), such as helium, neon, or argon. Let us also assume that the internal energy E^{int} of our ideal gas is simply the sum of the translational kinetic energies of its atoms.

The average translational kinetic energy of a single atom depends only on the gas temperature and is given by Eq. 20-23 as $\langle K \rangle = \frac{3}{2}k_B T$. A sample of n moles of such a gas contains nN_A atoms. The internal energy E^{int} of the sample is then

$$E^{\text{int}} = (nN_A)\langle K \rangle = (nN_A)\left(\frac{3}{2}k_B T\right). \quad (20-35)$$

Using Eq. 20-6 ($k_B = R/N_A$), we can rewrite this as

$$E^{\text{int}} = \frac{3}{2}Nk_B T = \frac{3}{2}nRT \quad (\text{monatomic ideal gas}). \quad (20-36)$$

Thus,

The internal energy E^{int} of an ideal gas is a function of the gas temperature *only*; it does not depend on any other variable.

With Eq. 20-36 in hand, we are now able to derive an expression for the molar specific heat of an ideal gas. Actually, we shall derive two expressions. One is for the case in which the volume of the gas remains constant as thermal energy is transferred to or from it. The other is for the case in which the pressure of the gas remains constant as thermal energy is transferred to or from it. The symbols for these two molar specific heats are C_V and C_P , respectively. (By convention, the capital letter C is used in both cases, even though C_V and C_P represent types of specific heat and not heat capacities.)

Molar Specific Heat at Constant Volume

Figure 20-9a shows n moles of an ideal gas at pressure P and temperature T , confined to a cylinder of fixed volume V . This *initial state* i of the gas is marked on the P - V diagram of Fig. 20-9b. Suppose that you add a small amount of thermal energy Q to the gas by slowly turning up the temperature of the thermal reservoir. The gas temperature rises a small amount to $T + \Delta T$, and its pressure rises to $P + \Delta P$, bringing the gas to *final state* f .

In such experiments, we would find that the thermal energy transferred Q is related to the temperature change ΔT by

$$Q = nC_V \Delta T \quad (\text{constant volume}), \quad (20-37)$$

where C_V is a constant called the **molar specific at constant volume**. Substituting this expression for Q into the first law of thermodynamics as given by Eq. 19-17 ($\Delta E^{\text{int}} = Q - W$) yields

$$\Delta E^{\text{int}} = nC_V \Delta T - W. \quad (20-38)$$

FIGURE 20-9 (a) The temperature of an ideal gas is raised from T to $T + \Delta T$ in a constant-volume process. Thermal energy is added, but no work is done. (b) The process on a P - V diagram. (The system's insulated lid is not shown.)

With the volume held constant, the gas cannot expand and thus cannot do any work. Therefore, $W = 0$, and Eq. 20-38 gives us

$$C_V = \frac{\Delta E^{\text{int}}}{n \Delta T}. \quad (20-39)$$

From Eq. 20-36 we know that $E^{\text{int}} = \frac{3}{2}nRT$, so the change in internal energy must be

$$\Delta E^{\text{int}} = \frac{3}{2}nR \Delta T. \quad (20-40)$$

Substituting this result into Eq. 20-39 yields

$$C_V = \frac{3}{2}R = 12.5 \text{ J/mol} \cdot \text{K} \quad (\text{monatomic gas}). \quad (20-41)$$

As Table 20-2 shows, this prediction that $C_V = \frac{3}{2}R$ based on ideal gas kinetic theory agrees very well with experiment for the real monatomic gases (the case that we have assumed). The experimental values of C_V for *diatomic gases* and *polyatomic gases* (which have molecules with more than two atoms) are greater than the predicted value of $\frac{3}{2}R$. Reasons for this will be discussed in Section 20-8.

TABLE 20-2
Molar Specific Heats

Molecule	Example	C_V (J/mol · K)
Monatomic (1 atom)	Ideal	$\frac{3}{2}R = 12.5$
	Real	He
	Real	Ar
Diatomic (2 atoms)	Ideal	$\frac{5}{2}R = 20.8^*$
	Real	N ₂
	Real	O ₂
Polyatomic (> 2 atoms)	Ideal	$3R = 24.9^*$
	Real	NH ₄
	Real	CO ₂

*The presentation of the $\frac{5}{2}R$ and $3R$ will be explained in the next section.

We can now generalize Eq. 20-36 for the internal energy of any ideal gas by substituting C_V for $\frac{3}{2}R$; we get

$$E^{\text{int}} = nC_V T \quad (\text{any ideal gas}). \quad (20-42)$$

This equation applies not only to an ideal monatomic gas but also to diatomic and polyatomic ideal gases, provided the experimentally determined value of C_V is used. Just as with Eq. 20-37, we see that the internal energy of a gas depends on the temperature of the gas but not on its pressure or density.

When an ideal gas that is confined to a container undergoes a temperature change ΔT , then from either Eq. 20-39 or Eq. 20-42 we can write the resulting change in its internal energy as

$$\Delta E^{\text{int}} = nC_V \Delta T \quad (\text{any ideal gas, any process}). \quad (20-43)$$

This equation tells us:

A change in the internal energy E^{int} of a confined ideal gas depends on the change in the gas temperature only; it does *not* depend on what type of process produces the change in the temperature.

As examples, consider the three paths between the two isotherms in the P - V diagram of Fig. 20-10. Path 1 represents a constant-volume process. Path 2 represents a constant-pressure process (that we are about to examine). Path 3 represents a process in which no thermal energy is exchanged with the system's environment (we discuss this in Section 20-11). Although the values of Q and work W associated with these three paths differ, as do P_f and V_f , the values of ΔE^{int} associated with the three paths are identical and are all given by Eq. 20-43, because they all involve the same temperature change ΔT . Therefore, no matter what path is actually taken between T and $T + \Delta T$, we can *always* use path 1 and Eq. 20-43 to compute ΔE^{int} easily.

Molar Specific Heat at Constant Pressure

We now assume that the temperature of the ideal gas is increased by the same small amount ΔT as previously, but that the necessary thermal energy (Q) is added with the gas under constant pressure. An experiment for doing this is shown in Fig. 20-11a; the P - V diagram for the process is plotted in Fig. 20-11b. From such experiments we find that the transferred thermal energy Q is related to the temperature change ΔT by

$$Q = nC_p \Delta T \quad (\text{constant pressure}), \quad (20-44)$$

where C_p is a constant called the **molar specific heat at constant pressure**. This C_p is *greater* than the molar specific heat at constant volume C_v , because energy must now be supplied not only to raise the temperature of the gas but also for the gas to do work—that is, to lift the weighted piston of Fig. 20-11a.

FIGURE 20-11 (a) The temperature of an ideal gas is raised from T to $T + \Delta T$ in a constant-pressure process. Thermal energy is added and work is done in lifting the loaded piston. (b) The process on a P - V diagram. The work $P\Delta V$ is given by the shaded area.

To relate molar specific heats C_p and C_v , we start with the first law of thermodynamics (Eq. 19-17):

$$\Delta E^{\text{int}} = Q - W. \quad (20-45)$$

We next replace each term in Eq. 20-45. For ΔE^{int} , we substitute from Eq. 20-43. For Q , we substitute from Eq. 20-44. To replace W , we first note that since the pressure remains

FIGURE 20-10 Three paths representing three different processes that take an ideal gas from an initial state i at temperature T to some final state f at temperature $T + \Delta T$. The change ΔE^{int} in the internal energy of the gas is the same for these three processes and for any others that result in the same change of temperature.

constant, Eq. 20-16 tells us that $W = P\Delta V$. Then we note that, using the ideal gas equation ($PV = nRT$), we can write

$$W = P\Delta V = nR\Delta T. \quad (20-46)$$

Making these substitutions in Eq. 20-45, we find

$$nC_V\Delta T = nC_P\Delta T - nR\Delta T$$

and then dividing through by $n\Delta T$,

$$C_V = C_P - R,$$

so

$$C_P = C_V + R \quad (\text{any ideal gas}). \quad (20-47)$$

This relationship between C_P and C_V predicted by kinetic theory agrees well with experiment, not only for monatomic gases but for gases in general, as long as their density is low enough so that we may treat them as ideal. As we discuss in Section 19-5, there is very little difference between C_P and C_V for liquids and solids because of their relative incompressibility.

READING EXERCISE 20-4: The figure here shows five paths traversed by a gas on a P - V diagram. Rank the paths according to the change in internal energy of the gas, greatest first.

■

TOUCHSTONE EXAMPLE 20-4: Helium Bubble

A bubble of 5.00 mol of helium is submerged at a certain depth in liquid water when the water (and thus the helium) undergoes a temperature increase ΔT of 20.0 C° at constant pressure. As a result, the bubble expands. The helium is monatomic and ideal.

(a) How much thermal energy is added to the helium during the increase and expansion?

SOLUTION ■ One **Key Idea** here is that the thermal energy transferred Q is related to the temperature change ΔT by the molar

specific heat of the gas. Because the pressure P is held constant during the addition of energy, we use the molar specific heat at constant pressure C_P and Eq. 20-44,

$$Q = nC_P\Delta T, \quad (20-48)$$

to find Q . To evaluate C_P we go to Eq. 20-47, which tells us that for any ideal gas, $C_P = C_V + R$. Then from Eq. 20-41, we know that for any *monatomic* gas (like helium), $C_V = \frac{3}{2}R$. Thus, Eq. 20-48 gives us

$$\begin{aligned}
 Q &= n(C_V + R) \Delta T = n\left(\frac{3}{2}R + R\right) \Delta T = n\left(\frac{5}{2}R\right) \Delta T \\
 &= (5.00 \text{ mol})(2.5)(8.31 \text{ J/mol} \cdot \text{K})(20.0 \text{ C}^\circ) \quad (\text{Answer}) \\
 &= 2077.5 \text{ J} \approx 2080 \text{ J}.
 \end{aligned}$$

(b) What is the change ΔE^{int} in the internal energy of the helium during the temperature increase?

SOLUTION ■ Because the bubble expands, this is not a constant-volume process. However, the helium is nonetheless confined (to the bubble). Thus, a **Key Idea** here is that the change ΔE^{int} is the same as *would occur* in a constant-volume process with the same temperature change ΔT . We can easily find the constant-volume change ΔE^{int} with Eq. 20-43:

$$\begin{aligned}
 \Delta E^{\text{int}} &= nC_V \Delta T = n\left(\frac{3}{2}R\right) \Delta T \\
 &= (5.00 \text{ mol})(1.5)(8.31 \text{ J/mol} \cdot \text{K})(20.0 \text{ C}^\circ) \quad (\text{Answer}) \\
 &= 1246.5 \text{ J} \approx 1250 \text{ J}.
 \end{aligned}$$

(c) How much work W is done by the helium as it expands against the pressure of the surrounding water during the temperature increase?

SOLUTION ■ One **Key Idea** here is that the work done by *any* gas expanding against the pressure from its environment is

given by Eq. 20-11, which tells us to integrate $P dV$. When the pressure is constant (as here), we can simplify that to $W = P \Delta V$. When the gas is *ideal* (as here), we can use the ideal gas law (Eq. 20-8) to write $P \Delta V = nR \Delta T$. We end up with

$$\begin{aligned}
 W &= nR \Delta T \\
 &= (5.00 \text{ mol})(8.31 \text{ J/mol} \cdot \text{K})(20.0 \text{ C}^\circ) \quad (\text{Answer}) \\
 &= 831 \text{ J}.
 \end{aligned}$$

Because we happen to know Q and ΔE^{int} , we can work this problem another way. The **Key Idea** now is that we can account for the energy changes of the gas with the first law of thermodynamics, writing

$$\begin{aligned}
 W &= Q - \Delta E^{\text{int}} = 2077.5 \text{ J} - 1246.5 \text{ J} \quad (\text{Answer}) \\
 &= 831 \text{ J}.
 \end{aligned}$$

Note that during the temperature increase, only a portion (1250 J) of the thermal energy (2080 J) that is transferred to the helium goes to increasing the internal energy of the helium and thus the temperature of the helium. The rest (831 J) is transferred out of the helium as work that the helium does during the expansion. If the water were frozen, it would not allow that expansion. Then the same temperature increase of 20.0 C° would require only 1250 J of energy, because no work would be done by the helium.

20-8 Degrees of Freedom and Molar Specific Heats

As Table 20-2 shows, the prediction that $C_V = \frac{3}{2}R$ agrees with experiment for monatomic gases. But it fails for diatomic and polyatomic gases. Let us try to explain the discrepancy by considering the possibility that molecules with more than one atom can store internal energy in forms other than *translational* kinetic energy.

Figure 20-12 shows common models of helium (a *monatomic* molecule, containing a single atom), oxygen (a *diatomic* molecule, containing two atoms), and methane (a *polyatomic* molecule). From such models, we would assume that all three types of molecules can have translational motions (say, moving left–right and up–down) and rotational motions (spinning about an axis like a top). However, due to their highly symmetric nature, rotational motions in a monatomic molecule need special consideration. We will return to this point shortly. In addition, we would assume that the diatomic and polyatomic molecules can have oscillatory motions, with the atoms oscillating slightly toward and away from one another, as if attached to opposite ends of a spring.

FIGURE 20-12 ■ Models of molecules as used in kinetic theory: (a) helium, a typical monatomic molecule; (b) oxygen, a typical diatomic molecule; and (c) methane, a typical polyatomic molecule. The spheres represent atoms, and the lines between them represent bonds. Two rotation axes are shown for the oxygen molecule.

To keep account of the various ways in which energy can be stored in a gas, James Clerk Maxwell introduced the theorem of the **equipartition of energy**:

Every kind of molecule has a certain number f of **degrees of freedom**, which are independent ways in which the molecule can store energy. Each such degree of freedom has associated with it—on average—an energy of $\frac{1}{2}k_B T$ per molecule (or $\frac{1}{2}RT$ per mole).

Let us apply the theorem to the translational and rotational motions of the molecules in Fig. 20-12. (We discuss oscillatory motion in the next section.) For the translational motion, superimpose an xyz coordinate system on any gas. The molecules will, in general, have velocity components along all three axes. Thus, gas molecules of all types have three degrees of translational freedom (three ways to move in translation) and, on average, an associated energy of $3(\frac{1}{2}k_B T)$ per molecule.

For the rotational motion, imagine the origin of our xyz coordinate system at the center of each molecule in Fig. 20-12. In a gas, each molecule should be able to rotate with an angular velocity component along each of the three axes, so each gas should have three degrees of rotational freedom and, on average, an additional energy of $3(\frac{1}{2}k_B T)$ per molecule. *However*, experiment shows this is true only for the polyatomic molecules.

A possible solution to this dilemma is that rotations about an axis of symmetry don't count as a degree of freedom. For example, as seen in Fig. 20-12, a single-atom molecule is symmetric about all three (mutually perpendicular) axes through the molecule. Hence, according to our proposed solution, these rotations are not additional degrees of freedom. A diatomic molecule is symmetric about only one axis (the axis through the center of both atoms). Accordingly, a diatomic molecule would have two rather than three degrees of freedom associated with rotation of the molecule.

It appears that modifying our theory in this manner brings us more in alignment with the experimental results. However, one should ask what reasoning (other than experimental evidence) supports this modification of the theory. One thing is clear. If a molecule were rotating about an axis of symmetry, it would be impossible to tell. Unlike a baseball (which has stitches or other marks) molecules have no characteristics that allow us to sense the rotation. Although classical physics gives us no real foundation for ignoring the motion simply because it is indistinguishable from no motion at all, this is what quantum theory would suggest.

So, according to our new model, a monatomic molecule has zero degrees of freedom associated with rotation because any rotation would be about an axis of symmetry. A diatomic molecule has two degrees of freedom associated with rotations about the two axes perpendicular to the line connecting the atoms (the axes are shown in Fig. 20-12*b*) but no degree of freedom for rotation about that line itself. Therefore, a diatomic molecule can have a rotational energy of only $2(\frac{1}{2}k_B T)$ per molecule. A polyatomic molecule has a full three degrees of freedom associated with rotational motion.

To extend our analysis of molar specific heats (C_P and C_V , in Section 20-7) to ideal diatomic and polyatomic gases, it is necessary to retrace the derivations of that analysis in detail. First, we replace Eq. 20-36 ($E^{\text{int}} = \frac{3}{2}nRT$) with $E^{\text{int}} = (f/2)nRT$, where f is the number of degrees of freedom listed in Table 20-3. Doing so leads to the prediction

$$C_V = \left(\frac{f}{2}\right)R = 4.16 f \text{ J/mol} \cdot \text{K}, \quad (20-49)$$

which agrees—as it must—with Eq. 20-41 for monatomic gases ($f = 3$). As Table 20-3 shows, this prediction also agrees with experiment for diatomic gases ($f = 5$), but it is too low for polyatomic gases. *Note*: The symbol f used here to denote degrees of

freedom should not be confused with $f(v)$ used to describe the velocity distribution function for molecules.

TABLE 20-3
Degrees of Freedom for Various Molecules

Molecule	Example	Degrees of Freedom			Predicted Molar Specific Heats	
		Translational	Rotational	Total (f)	C_V (Eq. 20-47)	$C_P = C_V + R$
Monatomic	He	3	0	3	$\frac{3}{2}R$	$\frac{5}{2}R$
Diatomic	O ₂	3	2	5	$\frac{5}{2}R$	$\frac{7}{2}R$
Polyatomic	CH ₄	3	3	6	$3R$	$4R$

TOUCHSTONE EXAMPLE 20-5: Internal Energy Change

A cabin of volume V is filled with air (which we consider to be an ideal diatomic gas) at an initial low temperature T_1 . After you light a wood stove, the air temperature increases to T_2 . What is the resulting change ΔE^{int} in the internal energy of the air in the cabin?

SOLUTION ■ As the air temperature increases, the air pressure P cannot change but must always be equal to the air pressure outside the room. The reason is that, because the room is not airtight, the air is not confined. As the temperature increases, air molecules leave through various openings and thus the number of moles n of air in the room decreases. Thus, one **Key Idea** here is that we *cannot* use Eq. 20-43 ($\Delta E^{\text{int}} = nC_V \Delta T$) to find ΔE^{int} , because it requires constant n .

A second **Key Idea** is that we *can* relate the internal energy E^{int} at any instant to n and the temperature T with Eq. 20-42 ($E^{\text{int}} = nC_V T$). From that equation we can then write

$$\Delta E^{\text{int}} = \Delta(nC_V T) = C_V \Delta(nT).$$

Next, using Eq. 20-8 ($PV = nRT$), we can replace nT with PV/R , obtaining

$$\Delta E^{\text{int}} = C_V \Delta \left(\frac{PV}{R} \right). \quad (20-50)$$

Now, because P , V , and R are all constants, Eq. 20-50 yields

$$\Delta E^{\text{int}} = 0, \quad (\text{Answer})$$

even though the temperature changes.

Why does the cabin feel more comfortable at the higher temperature? There are at least two factors involved: (1) You exchange electromagnetic radiation (thermal radiation) with surfaces inside the room, and (2) you exchange energy with air molecules that collide with you. When the room temperature is increased, (1) the amount of thermal radiation emitted by the surfaces and absorbed by you is increased, and (2) the amount of energy you gain through the collisions of air molecules with you is increased.

20-9 A Hint of Quantum Theory

We can improve the agreement of kinetic theory with experiment by including the oscillations of the atoms in a gas of diatomic or polyatomic molecules. For example, the two atoms in the O₂ molecule of Fig. 20-12*b* can oscillate toward and away from each other, with the interconnecting bond acting like a spring. However, experiment shows that such oscillations occur only at relatively high temperatures of the gas—the motion is “turned on” only when the gas molecules have relatively large energies. Rotational motion is also subject to such “turning on,” but at a lower temperature.

Figure 20-13 is of help in seeing this turning on of rotational motion and oscillatory motion. The ratio C_V/R for diatomic hydrogen gas (H₂) is plotted there against temperature, with the temperature scale logarithmic to cover several orders of magnitude. Below about 80 K, we find that $C_V/R = 1.5$. This result implies that only the three translational degrees of freedom of hydrogen are involved in the specific heat.

FIGURE 20-13 ■ A plot of C_V/R versus temperature for (diatomic) hydrogen gas. Because rotational and oscillatory motions begin at certain energies, only translation is possible at very low temperatures. As the temperature increases, rotational motion can begin. At still higher temperatures, oscillatory motion can begin.

As the temperature increases, the value of C_V/R gradually increases to 2.5, implying that two additional degrees of freedom have become involved. Quantum theory shows that these two degrees of freedom are associated with the rotational motion of the hydrogen molecules and that this motion requires a certain minimum amount of energy. At very low temperatures (below 80 K), the molecules do not have enough energy to rotate. As the temperature increases from 80 K, first a few molecules and then more and more obtain enough energy to rotate, and C_V/R increases, until all of them are rotating and $C_V/R = 2.5$.

Similarly, quantum theory shows that oscillatory motion of the molecules requires a certain (higher) minimum amount of energy. This minimum amount is not met until the molecules reach a temperature of about 1000 K, as shown in Fig. 20-13. As the temperature increases beyond 1000 K, the number of molecules with enough energy to oscillate increases, and C_V/R increases, until all of them are oscillating and $C_V/R = 3.5$. (In Fig. 20-13, the plotted curve stops at 3200 K because at that temperature, the atoms of a hydrogen molecule oscillate so much that they overwhelm their bond, and the molecule then *dissociates* into two separate atoms.)

The observed fact that rotational degrees of freedom are not excited until sufficiently high temperatures are reached implies that rotational kinetic energy is not a continuous function of angular velocity. Instead, a discrete, quantized energy level must be attained before rotation is excited. This discreteness of energy levels is a hallmark of quantum mechanical behavior. It is interesting to note that some of the issues discussed in this chapter are the first examples (with many more to come) that macroscopic properties of matter, which are easily measured in the laboratory, depend critically on (and provide strong evidence for) the quantum theory we will develop later.

The compatibility between microscopic theory and macroscopic observations when coupled with quantum theory and other phenomena in physics and chemistry provided additional support for the theory that matter is composed of atoms and molecules.

20-10 The Adiabatic Expansion of an Ideal Gas

We saw in Section 18-2 that sound waves are propagated through air and other gases as a series of compressions and expansions; these variations in the transmission medium take place so rapidly that there is no time for thermal energy to be transferred from one part of the medium to another. As we saw in Section 19-8, a process for which $Q = 0$ is an *adiabatic process*. We can ensure that $Q = 0$ either by carrying out the process very quickly (as in sound waves) or by doing it (at any rate) in a well-insulated container. Let us see what the kinetic theory has to say about adiabatic processes.

FIGURE 20-14 (a) The volume of an ideal gas is increased by removing weight from the piston. The process is adiabatic ($Q = 0$). (b) The process proceeds from i to f along an adiabat on a P - V diagram.

Figure 20-14a shows our usual insulated cylinder. Its insulating lid is not shown. It now contains an ideal gas and rests on an insulating stand. By removing mass from the piston, we can allow the gas to expand adiabatically (in a slow process rather than a free expansion). As the volume increases, both the pressure and the temperature drop. We shall prove next that the relation between the pressure and the volume during such an adiabatic process is

$$PV^\gamma = \text{a constant} \quad (\text{ideal gas adiabatic process}), \quad (20-51)$$

in which $\gamma = C_p/C_v$, the ratio of the molar specific heats for the gas. On a P - V diagram such as that in Fig. 20-14b, the process occurs along a line (called an *adiabat*) that has the equation $P = (\text{a constant})/V^\gamma$. Since the gas goes from an initial state i to a final state f , we can rewrite Eq. 20-51 as

$$P_i V_i^\gamma = P_f V_f^\gamma \quad (\text{ideal gas adiabatic process}). \quad (20-52)$$

We can also write an equation for an adiabatic process in terms of T and V . To do so, we use the ideal gas equation ($PV = nRT$) to eliminate P from Eq. 20-51, finding

$$\left(\frac{nRT}{V}\right) V^\gamma = \text{a constant}.$$

Because n and R are constants, we can rewrite this in the alternative form

$$TV^{\gamma-1} = \text{a constant} \quad (\text{ideal gas adiabatic process}). \quad (20-53)$$

in which the constant is different from that in Eq. 20-51. When the gas goes from an initial state i to a final state f , we can rewrite Eq. 20-53 as

$$T_i V_i^{\gamma-1} = T_f V_f^{\gamma-1} \quad (\text{adiabatic process}). \quad (20-54)$$

We can now answer the question that opens this chapter. At the top of an unopened carbonated drink, there is a gas of carbon dioxide and water vapor. Because the pressure of the gas is greater than atmospheric pressure, the gas expands out into the atmosphere when the container is opened. Thus, the gas increases its volume, but that means it must do work to push against the atmosphere. Because the expansion is

so rapid, it is adiabatic and the only source of energy for the work is the internal energy of the gas. Because the internal energy decreases, the temperature of the gas must also decrease, which can cause the water vapor in the gas to condense into tiny drops, forming the fog. (Note that Eq. 20-54 also tells us that the temperature must decrease during an adiabatic expansion: Since V_f is greater than V_i , then T_f must be less than T_i .)

Proof of Eq. 20-51

Suppose that you remove some shot from the piston of Fig. 20-14*a*, allowing the ideal gas to push the piston and the remaining shot upward and thus to increase the volume by a differential amount dV . Since the volume change is tiny, we may assume that the pressure P of the gas on the piston is constant during the change. This assumption allows us to say that the work dW done by the gas during the volume increase is equal to $P dV$. From Eq. 19-18, the first law of thermodynamics can then be written as

$$dE^{\text{int}} = Q - P dV. \quad (20-55)$$

Since the gas is thermally insulated (and thus the expansion is adiabatic), we substitute 0 for Q . Then we use Eq. 20-43 to substitute $nC_V dT$ for dE^{int} . With these substitutions, and after some rearranging, we have

$$n dT = -\left(\frac{P}{C_V}\right) dV. \quad (20-56)$$

Now using the ideal gas law ($PV = nRT$) and derivative rule 3 in Appendix E we have

$$P dV + V dP = nR dT. \quad (20-57)$$

Replacing R with its equal, $C_P - C_V$, in Eq. 20-57 yields

$$n dT = \frac{P dV + V dP}{C_P - C_V}. \quad (20-58)$$

Equating Eqs. 20-56 and 20-58 and rearranging them give

$$\frac{dP}{P} + \left(\frac{C_P}{C_V}\right) \frac{dV}{V} = 0.$$

Replacing the ratio of the molar specific heats with γ and integrating (see integral 5 in Appendix E) yield

$$\ln P + \gamma \ln V = \text{a constant.}$$

Rewriting the left side as $\ln PV^\gamma$ and then taking the antilog of both sides, we find

$$PV^\gamma = \text{a constant}, \quad (20-59)$$

which is what we set out to prove.

Free Expansions

Recall from Section 19-8 that a free expansion of a gas is an adiabatic process that involves no work done on or by the gas, and no change in the internal energy of the gas.

A free expansion is thus quite different from the type of adiabatic process described by Eqs. 20-51 through 20-59, in which work is done and the internal energy changes. Those equations then do *not* apply to a free expansion, even though such an expansion is adiabatic.

Also recall that in a free expansion, a gas is in equilibrium only at its initial and final points; thus, we can plot only those points, but not the expansion itself, on a P - V diagram. In addition, because $\Delta E^{\text{int}} = 0$, the temperature of the final state must be that of the initial state. Thus, the initial and final points on a P - V diagram must be on the same isotherm, and instead of Eq. 20-54 we have

$$T_i = T_f \quad (\text{free expansion}). \quad (20-60)$$

If we next assume that the gas is ideal (so that $PV = nRT$), because there is no change in temperature, there can be no change in the product PV . Thus, instead of Eq. 20-51 a free expansion involves the relation

$$P_i V_i = P_f V_f \quad (\text{free expansion}). \quad (20-61)$$

TOUCHSTONE EXAMPLE 20-6: Final Temperature

In Touchstone Example 20-2, 1 mol of oxygen (assumed to be an ideal gas) expands isothermally (at 310 K) from an initial volume of 12 L to a final volume of 19 L.

(a) What would be the final temperature if the gas had expanded adiabatically to this same final volume? Oxygen (O_2) is diatomic and here has rotation but not oscillation.

SOLUTION ■ The **Key Ideas** here are as follows:

1. When a gas expands against the pressure of its environment, it must do work.
2. When the process is adiabatic (no thermal energy is transferred as heat), then the energy required for the work can come only from the internal energy of the gas.
3. Because the internal energy decreases, the temperature T must also decrease.

We can relate the initial and final temperatures and volumes with Eq. 20-54:

$$T_i V_i^{\gamma-1} = T_f V_f^{\gamma-1}. \quad (20-62)$$

Because the molecules are diatomic and have rotation but not oscillation, we can take the molar specific heats from Table 20-3. Thus,

$$\gamma = \frac{C_P}{C_V} = \frac{\frac{7}{2}R}{\frac{5}{2}R} = 1.40.$$

Solving Eq. 20-62 for T_f and inserting known data then yield

$$\begin{aligned} T_f &= \frac{T_i V_i^{\gamma-1}}{V_f^{\gamma-1}} = \frac{(310 \text{ K})(12 \text{ L})^{1.40-1}}{(19 \text{ L})^{1.40-1}} \\ &= (310 \text{ K})\left(\frac{12}{19}\right)^{0.40} = 258 \text{ K}. \end{aligned} \quad (\text{Answer})$$

(b) What would be the final temperature and pressure if, instead, the gas had expanded freely to the new volume, from an initial pressure of 2.0 Pa?

SOLUTION ■ Here the **Key Idea** is that the temperature does not change in a free expansion:

$$T_f = T_i = 310 \text{ K}. \quad (\text{Answer})$$

We find the new pressure using Eq. 20-61, which gives us

$$P_f = P_i \frac{V_i}{V_f} = (2.0 \text{ Pa}) \frac{12 \text{ L}}{19 \text{ L}} = 1.3 \text{ Pa}. \quad (\text{Answer})$$

Problems

SEC. 20-2 ■ THE MACROSCOPIC BEHAVIOR OF GASES

1. Arsenic Find the mass in kilograms of 7.50×10^{24} atoms of arsenic, which has a molar mass of 74.9 g/mol.

2. Gold Gold has a molar mass of 197 g/mol. (a) How many moles of gold are in a 2.50 g sample of pure gold? (b) How many atoms are in the sample?

3. Water If the water molecules in 1.00 g of water were distributed uniformly over the surface of Earth, how many such molecules would there be on 1.00 cm² of the surface?

4. It Is Written A distinguished scientist has written: “There are enough molecules in the ink that makes one letter of this sentence to provide not only one for every inhabitant of Earth, but one for every creature if each star of our galaxy had a planet as populous as Earth.” Check this statement. Assume the ink sample (molar mass = 18 g/mol) to have a mass of 1 μg, the population of Earth to be 5×10^9 , and the number of stars in our galaxy to be 10^{11} .

5. Compute Compute (a) the number of moles and (b) the number of molecules in 1.00 cm³ of an ideal gas at a pressure of 100 Pa and a temperature of 220 K.

6. Best Vacuum The best laboratory vacuum has a pressure of about 1.00×10^{-18} atm, or 1.01×10^{-13} Pa. How many gas molecules are there per cubic centimeter in such a vacuum at 293 K?

7. Oxygen Gas Oxygen gas having a volume of 1000 cm³ at 40.0°C and 1.01×10^5 Pa expands until its volume is 1500 cm³ and its pressure is 1.06×10^5 Pa. Find (a) the number of moles of oxygen present and (b) the final temperature of the sample.

8. Tire An automobile tire has a volume of 1.64×10^{-2} m³ and contains air at a gauge pressure (pressure above atmospheric pressure) of 165 kPa when the temperature is 0.00°C. What is the gauge pressure of the air in the tires when its temperature rises to 27.0°C and its volume increases to 1.67×10^{-2} m³? Assume atmospheric pressure is 1.00×10^5 Pa.

9. A Quantity of Ideal Gas A quantity of ideal gas at 10.0°C and 100 kPa occupies a volume of 2.50 m³. (a) How many moles of the gas are present? (b) If the pressure is now raised to 300 kPa and the temperature is raised to 30.0°C, how much volume does the gas occupy? Assume no leaks.

SEC. 20-3 ■ WORK DONE BY IDEAL GASES

10. Work Done by External Agent Calculate the work done by an external agent during an isothermal compression of 1.00 mol of oxygen from a volume of 22.4 L at 0°C and 1.00 atm pressure to 16.8 L.

11. P , V , T Pressure P , volume V , and temperature T for a certain non-ideal material are related by

$$P = \frac{AT - BT^2}{V},$$

where A and B are constants. Find an expression for the work done by the material if the temperature changes from T_1 to T_2 while the pressure remains constant.

12. A Container Encloses A container encloses two ideal gases. Two moles of the first gas are present, with molar mass M_1 . The second gas has molar mass $M_2 = 3M_1$, and 0.5 mol of this gas is present. What fraction of the total pressure on the container wall is attributable to the second gas? (The kinetic theory explanation of pressure leads to the experimentally discovered law of partial pressures for a mixture of gases that do not react chemically: *The total pressure exerted by the mixture is equal to the sum of the pressures*

that the several gases would exert separately if each were to occupy the vessel alone.)

13. Air Initially Occupies Air that initially occupies 0.14 m³ at a gauge pressure of 103.0 kPa is expanded isothermally to a pressure of 101.3 kPa and then cooled at constant pressure until it reaches its initial volume. Compute the work done by the air. (Gauge pressure is the difference between the actual pressure and atmospheric pressure.)

14. A Sample A sample of an ideal gas is taken through the cyclic process $abca$ shown in Fig. 20-15; at point a , $T = 200$ K. (a) How many moles of gas are in the sample? What are (b) the temperature of the gas at point b , (c) the temperature of the gas at point c , and (d) the net thermal energy transferred to the gas during the cycle?

FIGURE 20-15 ■ Problem 14.

15. Air Bubble An air bubble of 20 cm³ volume is at the bottom of a lake 40 m deep where the temperature is 4.0°C. The bubble rises to the surface, which is at a temperature of 20°C. Take the temperature of the bubble’s air to be the same as that of the surrounding water. Just as the bubble reaches the surface, what is its volume?

16. Pipe of Length L A pipe of length $L = 25.0$ m that is open at one end contains air at atmospheric pressure. It is thrust vertically into a freshwater lake until the water rises halfway up in the pipe, as shown in Fig. 20-16. What is the depth h of the lower end of the pipe? Assume that the temperature is the same everywhere and does not change.

FIGURE 20-16 ■ Problem 16.

17. Container A Container A in Fig. 20-17 holds an ideal gas at a pressure of 5.0×10^5 Pa and a temperature of 300 K. It is connected by a thin tube (and a closed valve) to container B, with four times the volume of A. Container B holds the same ideal gas at a pressure of 1.0×10^5 Pa and a temperature of 400 K. The valve is opened to allow the pressures to equalize, but the temperature of each container is kept constant at its initial value. What then is the pressure in the two containers?

FIGURE 20-17 ■ Problem 17.

SEC. 20-4 ■ PRESSURE, TEMPERATURE, AND MOLECULAR KINETIC ENERGY

18. Helium Atoms Calculate the rms speed of helium atoms at 1000 K. See Appendix F for the molar mass of helium atoms.

19. Lowest Possible The lowest possible temperature in outer space is 2.7 K. What is the root-mean-square speed of hydrogen molecules at this temperature? (The molar mass of hydrogen molecules (H_2) is given in Table 20-1)

20. Speed of Argon Find the rms speed of argon atoms at 313 K. See Appendix F for the molar mass of argon atoms.

21. Sun's Atmosphere The temperature and pressure in the Sun's atmosphere are 2.00×10^6 K and 0.0300 Pa. Calculate the rms speed of free electrons (mass = 9.11×10^{-31} kg) there, assuming they are an ideal gas.

22. Nitrogen Molecule (a) Compute the root-mean-square speed of a nitrogen molecule at 20.0°C . The molar mass of nitrogen molecules (N_2) is given in Table 20-1. At what temperatures will the root-mean-square speed be (b) half that value and (c) twice that value?

23. Hydrogen Molecules A beam of hydrogen molecules (H_2) is directed toward a wall, at an angle of 55° with the normal to the wall. Each molecule in the beam has a speed of 1.0 km/s and a mass of 3.3×10^{-24} g. The beam strikes the wall over an area of 2.0 cm^2 , at the rate of 10^{23} molecules per second. What is the beam's pressure on the wall?

24. Density of Gas At 273 K and 1.00×10^{-2} atm, the density of a gas is $1.24 \times 10^{-5} \text{ g/cm}^3$. (a) Find v^{rms} for the gas molecules. (b) Find the molar mass of the gas and identify the gas. (*Hint:* The gas is listed in Table 20-1.)

25. Translational Kinetic Energy What is the average translational kinetic energy of nitrogen molecules at 1600 K?

26. Average Value Determine the average value of the translational kinetic energy of the molecules of an ideal gas at (a) 0.00°C and (b) 100°C . What is the translational kinetic energy per mole of an ideal gas at (c) 0.00°C and (d) 100°C ?

27. Evaporating Water Water standing in the open at 32.0°C evaporates because of the escape of some of the surface molecules. The heat of vaporization (539 cal/g) is approximately equal to ϵn , where ϵ is the average energy of the escaping molecules and n is the number of molecules per gram. (a) Find ϵ . (b) What is the ratio of ϵ to the average kinetic energy of H_2O molecules, assuming the latter is related to temperature in the same way as it is for gases?

28. Alternative Form Show that the ideal gas equation, Eq. 20-8, can be written in the alternative form $P = \rho RT/M$, where ρ is the mass density of the gas and M is the molar mass.

29. Avogadro's Law Avogadro's law states that under the same conditions of temperature and pressure, equal volumes of gas contain equal numbers of molecules. Is this law equivalent to the ideal gas law? Explain.

SEC. 20-5 ■ MEAN FREE PATH

30. Nitrogen Molecules The mean free path of nitrogen molecules at 0.0°C and 1.0 atm is 0.80×10^{-5} cm. At this temperature and pressure there are 2.7×10^{19} molecules/ cm^3 . What is the molecular diameter?

31. Earth's Surface At 2500 km above Earth's surface, the number density of the atmosphere is about 1 molecule/ cm^3 . (a) What mean free path is predicted by Eq. 20-24 and (b) what is its significance under these conditions? Assume a molecular diameter of 2.0×10^{-8} cm.

32. What Frequency At what frequency would the wavelength of sound in air be equal to the mean free path of oxygen molecules at 1.0 atm pressure and 0.00°C ? Take the diameter of an oxygen molecule to be 3.0×10^{-8} cm.

33. Mean Free Path of Jelly Beans Assuming that jelly beans in a bag could behave like ideal gas particles, what is the mean free path for 15 spherical jelly beans in a bag that is vigorously shaken? The volume of the bag is 1.0 L, and the diameter of a jelly bean is 1.0 cm. (Consider bean-bean collisions, not bean-bag collisions.)

34. Mean Free Path for Argon At 20°C and 750 torr pressure, the mean free paths for argon gas (Ar) and nitrogen gas (N_2) are $\lambda_{\text{Ar}} = 9.9 \times 10^{-6}$ cm and $\lambda_{\text{N}_2} = 27.5 \times 10^{-6}$ cm. (a) Find the ratio of the effective diameter of argon to that of nitrogen. What is the mean free path of argon at (b) 20°C and 150 torr, and (c) -40°C and 750 torr?

35. Particle Accelerator In a certain particle accelerator, protons travel around a circular path of diameter 23.0 m in an evacuated chamber, whose residual gas is at 295 K and 1.00×10^{-6} torr pressure. (a) Calculate the number of gas molecules per cubic centimeter at this pressure. (b) What is the mean free path of the gas molecules if the molecular diameter is 2.00×10^{-8} cm?

SEC. 20-6 ■ THE DISTRIBUTION OF MOLECULAR SPEEDS

36. Twenty-Two Particles Twenty-two particles have speeds as follows (N_i represents the number of particles that have speed v_i):

N_i	2	4	6	8	2
v_i (cm/s)	1.0	2.0	3.0	4.0	5.0

(a) Compute their average speed $\langle v \rangle$. (b) Compute their root-mean-square speed v^{rms} . (c) Of the five speeds shown, which is the most probable speed v^{prob} ?

37. Ten Molecules The speeds of 10 molecules are 2.0, 3.0, 4.0 . . . , 11 km/s. (a) What is their average speed? (b) What is their root-mean-square speed?

38. Ten Particles (a) Ten particles are moving with the following speeds: four at 200 m/s, two at 500 m/s, and four at 600 m/s. Calculate their average and root-mean-square speeds. Is $v^{\text{rms}} > \langle v \rangle$? (b) Make up your own speed distribution for the 10 particles and show that $v^{\text{rms}} \geq \langle v \rangle$ for your distribution. (c) Under what condition (if any) does $v^{\text{rms}} = \langle v \rangle$?

39. Compute Temperature (a) Compute the temperatures at which the rms speed for (a) molecular hydrogen and (b) molecular oxygen is equal to the speed of escape from Earth. (c) Do the same for the speed of escape from the Moon, assuming the local gravitational constant on its surface to be 0.16g. (d) The temperature high in Earth's upper atmosphere (in the thermosphere) is about 1000 K. Would you expect to find much hydrogen there? Much oxygen? Explain.

40. Most Probable Speed It is found that the most probable speed of molecules in a gas when it has (uniform) temperature T_2 is the

same as the rms speed of the molecules in this gas when it has (uniform) temperature T_1 . Calculate T_2/T_1 .

41. Hydrogen Molecule A molecule of hydrogen (diameter 1.0×10^{-8} cm), traveling with the rms speed, escapes from a furnace ($T = 4000$ K) into a chamber containing atoms of cold argon (diameter 3.0×10^{-8} cm) at a number density of 4.0×10^{19} atoms/cm³. (a) What is the speed of the hydrogen molecule? (b) If the H₂ molecule collides with an argon atom, what is the closest their centers can be, considering each as spherical? (c) What is the initial number of collisions per second experienced by the hydrogen molecule? (*Hint:* Assume that the cold argon atoms are stationary. Then the mean free path of the hydrogen molecule is given by Eq. 20-25, and not Eq. 20-24.)

42. Two Containers—Same Temperature Two containers are at the same temperature. The first contains gas with pressure P_1 , molecular mass m_1 , and root-mean-square speed v_1^{rms} . The second contains gas with pressure $2P_1$, molecular mass m_2 , and average speed $\langle v_2 \rangle = 2v_1^{\text{rms}}$. Find the mass ratio m_1/m_2 .

43. Hypothetical Speeds Figure 20-18 shows a hypothetical speed distribution for a sample of N gas particles (note that $f(v) = 0$ for $v > 2v_0$). (a) Express a in terms of N and v_0 . (b) How many of the particles have speeds between $1.5v_0$ and $2.0v_0$? (c) Express the average speed of the particles in terms of v_0 . (d) Find v^{rms} .

FIGURE 20-18 ■ Problem 43.

SEC. 20-7 ■ THE MOLAR SPECIFIC HEATS OF AN IDEAL GAS

44. Internal Energy What is the internal energy of 1.0 mol of an ideal monatomic gas at 273 K?

45. Isothermal Expansion One mole of an ideal gas undergoes an isothermal expansion. Find the thermal energy Q added to the gas in terms of the initial and final volumes and the temperature. (*Hint:* Use the first law of thermodynamics.)

46. Added as Heat When 20.9 J of thermal energy was added to a particular ideal gas, the volume of the gas changed from 50.0 cm³ to 100 cm³ while the pressure remained constant at 1.00 atm. (a) By how much did the internal energy of the gas change? If the quantity of gas present is 2.00×10^{-3} mol, find the molar specific heat of the gas at (b) constant pressure and (c) constant volume.

47. Three Nonreacting Gases A container holds a mixture of three nonreacting gases: n_1 moles of the first gas with molar specific heat at constant volume C_1 , and so on. Find the molar specific heat at constant volume of the mixture, in terms of the molar specific heats and quantities of the separate gases.

48. Ideal Diatomic Gas One mole of an ideal diatomic gas goes from a to c along the diagonal path in Fig. 20-19. During the transition, (a) what is the change in internal energy of the gas, and (b) how much thermal energy is added to the gas? (c) How much thermal energy is required if the gas goes from a to c along the indirect path abc ?

FIGURE 20-19 ■ Problem 48.

49. Gas Molecule The mass of a gas molecule can be computed from its specific heat at constant volume C_V . Take $C_V = 0.075$ cal/g · °C for argon and calculate (a) the mass of an argon atom and (b) the molar mass of argon.

SEC. 20-8 ■ DEGREES OF FREEDOM AND MOLAR SPECIFIC HEATS

50. Heating a Diatomic Gas We give 70 J of thermal energy to a diatomic gas, which then expands at constant pressure. The gas molecules rotate but do not oscillate. By how much does the internal energy of the gas increase?

51. One Mole of Oxygen One mole of oxygen (O₂) is heated at constant pressure starting at 0°C. How much energy Q must be added to the gas to double its volume? (The molecules rotate but do not oscillate.)

52. Oxygen Heating Suppose 12.0 g of oxygen (O₂) is heated at constant atmospheric pressure from 25.0°C to 125°C. (a) How many moles of oxygen are present? (See Table 20-1 for the molar mass.) (b) How much thermal energy is transferred to the oxygen? (The molecules rotate but do not oscillate.) (c) What fraction of the thermal energy absorbed by the oxygen is used to raise the internal energy of the oxygen?

53. Molecular Rotation Suppose 4.00 mol of an ideal diatomic gas, with molecular rotation but not oscillation, experienced a temperature increase of 60.0 K under constant-pressure conditions. (a) How much thermal energy was transferred to the gas? (b) How much did the internal energy of the gas increase? (c) How much work was done by the gas? (d) How much did the translational kinetic energy of the gas increase?

SEC. 20-10 ■ THE ADIABATIC EXPANSION OF AN IDEAL GAS

54. Liter of Gas (a) One liter of a gas with $\gamma = 1.3$ is at 273 K and 1.0 atm pressure. It is suddenly compressed adiabatically to half its original volume. Find its final pressure and temperature. (b) The gas is now cooled back to 273 K at constant pressure. What is its final volume?

55. A Certain Gas A certain gas occupies a volume of 4.3 L at a pressure of 1.2 atm and a temperature of 310 K. It is compressed adiabatically to a volume of 0.76 L. Determine (a) the final pressure and (b) the final temperature, assuming the gas to be an ideal gas for which $\gamma = 1.4$.

56. Adiabatic Process We know that for an adiabatic process $PV^\gamma = \text{a constant}$. Evaluate the constant for an adiabatic process involving exactly 2.0 mol of an ideal gas passing through the state

having exactly $P = 1.0$ atm and $T = 300$ K. Assume a diatomic gas whose molecules have rotation but not oscillation.

57. Let n Moles Let n moles of an ideal gas expand adiabatically from an initial temperature T_1 to a final temperature T_2 . Prove that the work done by the gas is $nC_V(T_1 - T_2)$, where C_V is the molar specific heat at constant volume. (*Hint:* Use the first law of thermodynamics.)

58. Bulk Modulus For adiabatic processes in an ideal gas, show that (a) the bulk modulus is given by

$$B = -V \frac{dP}{dV} = \gamma P,$$

and therefore (b) the speed of sound in the gas is

$$v_{\text{wave}} = \sqrt{\frac{\gamma P}{\rho}} = \sqrt{\frac{\gamma RT}{M}}.$$

See Eqs. 18-1 and 18-2. Here M is the molar mass and the total mass of the gas is $m = nM$.

59. Molar Specific Heats Air at 0.000°C and 1.00 atm pressure has a density of 1.29×10^{-3} g/cm³, and the speed of sound in air is 331 m/s at that temperature. Use those data to compute the ratio γ of the molar specific heats of air. (*Hint:* See Problem 58.)

60. Free Expansion (a) An ideal gas initially at pressure P_0 undergoes a free expansion until its volume is 3.00 times its initial volume. What then is its pressure? (b) The gas is next slowly and adiabatically compressed back to its original volume. The pressure after compression is $(3.00)^{1/3} P_0$. Is the gas monatomic, diatomic, or polyatomic? (c) How does the average kinetic energy per molecule in this final state compare with that in the initial state?

61. The Cycle One mole of an ideal monatomic gas traverses the cycle of Fig. 20-20. Process $1 \rightarrow 2$ occurs at constant volume, process $2 \rightarrow 3$ is adiabatic, and process $3 \rightarrow 1$ occurs at constant pressure. (a) Compute the thermal energy Q absorbed by the gas, the change in its internal energy ΔE^{int} , and the work done by the gas W , for each of the three processes and for the cycle as a whole. (b) The initial pressure at point 1 is 1.00 atm. Find the pressure and the volume at points 2 and 3. Use 1.00 atm = 1.013×10^5 Pa and $R = 8.314$ J/mol · K.

FIGURE 20-20 ■ Problem 61.

Additional Problems

62. Extensive vs. Intensive An intensive variable is one that can be defined locally within a system. Its magnitude does not depend on whether we select the whole system or a part of the system. An extensive variable is one that is defined for the system as a whole; its magnitude does depend on how much of the system we choose to select. Which of the following variables are intensive and which are extensive? Explain your reasoning in each case.

(a) density, (b) pressure, (c) volume, (d) temperature, (e) mass, (f) internal energy, (g) number of moles, and (h) molecular weight.

63. Changes in Gas Molecules An ideal gas is contained in an airtight box. Complete each of the following five statements below to show the quantitative change that will occur. For example, if you want to say that the volume, initially equal to V , quadruples, complete the statement with “ $4V$ ”.

(a) If the absolute temperature of the gas is halved, the average speed of a gas molecule, $\langle v \rangle$, becomes _____.

(b) If the average speed of a gas molecule doubles, the pressure, P , on a wall of the box becomes _____.

(c) If the absolute temperature of the gas is halved, the pressure, P , on a wall of the box becomes _____.

(d) If the absolute temperature of the gas is increased by 25%, the total internal energy of the gas, E^{int} , becomes _____.

(e) If the number of gas molecules inside the box is doubled, but the temperature is kept the same, the pressure, P , on a wall of the box becomes _____.

64. Scales in a Gas The actual diameter of an atom is about 1 angstrom (10^{-10} m). In order to develop some intuition for the molecular scale of a gas, assume that you are considering a liter of air

(mostly N_2 and O_2) at room temperature and a pressure of 10^5 Pa. (a) Calculate the number of molecules in the sample of gas. (b) Estimate the average spacing between the molecules. (c) Estimate the average speed of a molecule using the Maxwell-Boltzmann distribution. (d) Suppose that the gas were rescaled upward so that each atom was the size of a tennis ball (but we don’t change the time scale). What would be the average spacing between molecules and the average speed of the molecules in miles/hour?

65. Is the M-B Distribution Wrong? A good student makes the following observation. “If I try to accelerate a small sphere through air, it will be resisted by air drag. If I drop an object, it will eventually reach a terminal velocity where the air is resisting as much as gravity is trying to accelerate (Eq. 6-25). The smaller the ball, the slower is the terminal velocity. But you tell me the Maxwell distribution says that the molecules of air move very rapidly. I estimate that this is much faster than the molecule’s terminal velocity, so it can’t move that fast. The Maxwell distribution must be wrong.” (a) The Newton drag law for a sphere moving through air is calculated by a molecular model to be $D = \rho\pi R^2 v^2$, where D is the magnitude of the drag force, R is the radius of the sphere, ρ is the density of the air, and v is the velocity of the object through the air. Calculate the terminal velocity for a sphere the size and mass of an air molecule falling through a fluid the density of air ($\rho = 1$ kg/m³). (b) From your estimate in part (a), is this speed greater or less than the average speed the molecule should have given the M-B distribution? What is wrong with the student’s argument?

66. Avogadro’s Hypothesis Why does Avogadro’s hypothesis (that a given volume of gas at a given temperature and pressure has the same number of molecules no matter what kind of gas it is) not hold for liquids and solids?

67. Boiling Molecules When a molecule of a liquid approaches the surface, it experiences a force barrier that tries to keep it in the liquid. Thus it has to do work to escape and loses some of its kinetic energy when it leaves.

(a) Assume that a water molecule can evaporate from the liquid if it hits the surface from the inside with a kinetic energy greater than the thermal energy corresponding to the temperature of boiling wa-

ter, 100°C . Use this to estimate the numerical value of the work W required to remove a water molecule from the liquid.

(b) Even though the average speed of a molecule in water below the boiling point corresponds to a kinetic energy less than W , some molecules leave anyway and the water evaporates. Explain why this happens.

21

Entropy and the Second Law of Thermodynamics

An anonymous graffito on a wall of the Pecan Street Cafe in Austin, Texas, reads: “Time is God’s way of keeping things from happening all at once.” Time also has direction—some things happen in a certain sequence and could never happen on their own in a reverse sequence. As an example, an accidentally dropped egg splatters in a cup. The reverse process, a splattered egg re-forming into a whole egg and jumping up to an outstretched hand, will never happen on its own—but why not? Why can’t that process be reversed, like a videotape run backward?

What in the world gives direction to time?

The answer is in this chapter.

21-1 Some One-Way Processes

Suppose you come indoors on a very cold day and wrap your cold hands around a warm mug of cocoa. Then your hands get warmer and the mug gets cooler. However, it never happens the other way around. That is, your cold hands never get still colder while the warm mug gets still warmer.

If we assume that the rate of thermal energy transfer from the warm mug and your hands to the room is slow, the system consisting of your hands and the mug is approximately a *closed system*, one that is more or less isolated from (does not interact with) its environment. Here are some other one-way processes that we observe to occur in closed systems: (1) A crate sliding over a horizontal surface eventually stops—but you never see an initially stationary crate on a horizontal surface start to move all by itself. (2) If you drop a glob of putty, it falls to the floor—but an initially motionless glob of putty on the floor never leaps spontaneously into the air. (3) If you puncture a helium-filled balloon in a closed room, the helium gas spreads throughout the room—but the individual helium atoms will never migrate back out of the room and refill the balloon. We call such one-way processes **irreversible**, meaning that they cannot be reversed by means of only small changes in their environment.

Many chemical transformations are also irreversible. For example, when methane gas is burned, each methane molecule mixes with an oxygen molecule. Water vapor and carbon dioxide are given off as shown in the following chemical equation:

This combustion process is irreversible. We don't find water and carbon dioxide spontaneously reacting to produce methane and oxygen gas.

The one-way character of such thermodynamic processes is so pervasive that we take it for granted. If these processes were to occur spontaneously (on their own) in the “wrong” direction, we would be astonished beyond belief. *Yet none of these “wrong-way” events would violate the law of conservation of energy.* In the “cold hands-warm mug” example, energy would be conserved even for a “wrong-way” thermal energy transfer between hands and mug. Conservation of energy would be obeyed even if a stationary crate or a stationary glob of putty suddenly were to transfer internal energy to macroscopic kinetic energy and begin to move. Energy would still be conserved if the helium atoms released from a balloon were, on their own, to clump together again.

Changes in energy within a closed system do not determine the direction of irreversible processes. So, we conclude that the direction must be set by another property that we have not yet considered. We shall discuss this new property quite a bit in this chapter. It is called the *entropy* S of the system. Knowing the *change in entropy* ΔS of a system turns out to be a useful quantity in analyzing thermodynamic processes. It is defined in the next section, but here we can state the central property of entropy change (often called the *entropy postulate*):

If an irreversible process occurs in a *closed* system, the entropy S of the system always increases; it never decreases.

Entropy, unlike energy, does *not* obey a conservation law. The energy of a closed system is conserved. It always remains constant. For irreversible processes, the *entropy* of a closed system always increases. Because of this property, the change in entropy is sometimes called “the arrow of time.” For example, we associate the irreversible breaking of the egg in our opening photograph with the forward direction of time and also with an increase in entropy. The backward direction of time (a videotape run backward) would correspond to the broken egg re-forming into a whole egg and rising into the air. This backward process would result in an entropy decrease and so it never happens.

There are two equivalent ways to define the change in entropy of a system. The first is macroscopic. It is in terms of the system's temperature and any thermal energy transfers between the system and its surroundings. The second is macroscopic or statistical. It is defined by counting the ways in which the atoms or molecules that make up the system can be arranged. We use the first approach in the next section, and the second in Section 21-7.

READING EXERCISE 21-1: Consider the irreversible process of dropping a glob of putty on the floor. Describe what energy transformations are taking place that allow us to believe that energy is conserved. ■

READING EXERCISE 21-2: List additional everyday phenomena that illustrate irreversibility without violating energy conservation. ■

21-2 Change in Entropy

In this section, we will try to develop a definition for *change in entropy* by looking again at the macroscopic process that we described in Sections 19-8 and 20-10—namely, the free expansion of an ideal gas. Figure 21-1a shows the gas in its initial equilibrium state i , confined by a closed stopcock to the left half of a thermally insulated container. If we open the stopcock, the gas rushes to fill the entire container, eventually reaching the final equilibrium state f shown in Fig. 21-1b. Unless the number of gas molecules is small (which is very hard to accomplish), this is an *irreversible* process. Again, what we mean by irreversible is that it is extremely improbable that all the gas particles would return, by themselves, to the left half of the container.

The P - V plot of the process in Fig. 21-2 shows the pressure and volume of the gas in its initial state i and final state f . As we discuss in Section 19-1, the pressure and volume of the gas depend only on the state that the gas is in, and not on the process by which it arrived in that state. Therefore, pressure and volume are examples of *state properties*. **State properties** are properties that depend only on the state of the gas and not on how it reached that state. Other state properties are temperature and internal energy. We now assume that the gas has still another state property—its entropy. Furthermore, we define the **change in entropy** $S_f - S_i$ of a system during a process that takes the system from an initial state i to a final state f as

$$\Delta S = S_f - S_i \equiv \int_i^f \frac{dQ}{T} \quad (\text{change in entropy defined}). \quad (21-1)$$

Here Q is the *thermal energy transferred* to or from the system during a heating or cooling process, and T is the temperature of the system in kelvin. Thus, an entropy change depends not only on the thermal energy transferred Q , but also on the temperature at which the transfer takes place. Because T is always positive, the sign of ΔS is the same as that of Q (positive if thermal energy is transferred to the system and negative if thermal energy is transferred from the system). We see from this relation (Eq. 21-1) that the SI unit for entropy and entropy change is the joule per kelvin.

There is a problem, however, in applying Eq. 21-1 to the free expansion of Fig. 21-1. As the gas rushes to fill the entire container, the pressure, temperature, and volume of the gas fluctuate unpredictably. In other words, they do not have a sequence of well-defined equilibrium values during the intermediate stages of the change from initial equilibrium state i to final equilibrium state f . Thus, we cannot trace a pressure–volume path for the free expansion on the P - V plot of Fig. 21-2. More importantly, that means that we cannot find a relation between thermal energy transfer Q and temperature T that allows us to integrate as Eq. 21-1 requires.

FIGURE 21-1 ■ The free expansion of an ideal gas consisting of a large number of molecules. (a) The gas is confined to the left half of an insulated container by a closed stopcock. (b) When the stopcock is opened, the gas rushes to fill the entire container. This process is irreversible; that is, it is never observed to occur in reverse, with the gas spontaneously collecting itself in the left half of the container.

FIGURE 21-2 ■ A P - V diagram showing the initial state i and the final state f of the free expansion of Fig. 21-1. The intermediate states of the gas cannot be shown because they are not equilibrium states.

FIGURE 21-3 ■ The isothermal expansion of an ideal gas, done in a reversible way. The gas has the same initial state i and same final state f as in the irreversible process of Figs. 21-1 and 21-2.

FIGURE 21-4 ■ A P - V diagram for the reversible isothermal expansion of Fig. 21-3. The intermediate states, which are now equilibrium states, are shown.

However, if our assumption is correct and entropy is truly a state property, the difference in entropy between states i and f must depend *only on those states* and not at all on the way the system went from one state to the other. That means that we can replace the irreversible free expansion of Fig. 21-1 with a *reversible* process that connects states i and f . With a reversible process we can trace a pressure–volume path on a P - V plot, and we can find a relation between thermal energy transfer Q and temperature T that allows us to use Eq. 21-1 to obtain the entropy change.

We saw in Section 20-10 that the temperature of an ideal gas does not change during a free expansion. So, $T_i = T_f = T$. Thus, points i and f in Fig. 21-2 must be on the same isotherm. A convenient replacement process is then a reversible isothermal expansion from state i to state f , which actually proceeds *along* that isotherm. Furthermore, because T is constant throughout a reversible isothermal expansion, the integral of Eq. 21-1 is greatly simplified.

Figure 21-3 shows how to produce such a reversible isothermal expansion. We confine the gas to an insulated cylinder that rests on a thermal reservoir maintained at the temperature T . We begin by placing just enough lead shot on the movable piston so that the pressure and volume of the gas are those of the initial state i of Fig. 21-1a. We then remove shot slowly (piece by piece) until the pressure and volume of the gas are those of the final state f of Fig. 21-1b. The temperature of the gas does not change because the gas remains in thermal contact with the reservoir throughout the process.

The reversible isothermal expansion of Fig. 21-3 is physically quite different from the irreversible free expansion of Fig. 21-1. However, *both processes have the same initial state and the same final state. Thus, if entropy is a state property, these two processes must result in the same change in entropy.*

Because we removed the lead shot slowly, the intermediate states of the gas are equilibrium states, so we can plot them on a P - V diagram (Fig. 21-4). To apply Eq. 21-1 to the isothermal expansion, we take the constant temperature T outside the integral, obtaining

$$\Delta S = S_f - S_i = \frac{1}{T} \int_i^f dQ.$$

Because $\int dQ = Q$, where Q is the thermal energy transferred during the process, we have

$$\Delta S = S_f - S_i = \frac{Q}{T} \quad (\text{change in entropy, isothermal process}). \quad (21-2)$$

To keep the temperature T of the gas constant during the isothermal expansion of Fig. 21-3, the thermal energy transferred *from* the reservoir to the gas must have been Q . Thus, Q is positive and the entropy of the gas *increases* during the isothermal process and during the free expansion of Fig. 21-1.

To summarize:

Assuming entropy is a state property, we can find the entropy change for an irreversible process occurring in a *closed* system by replacing that process with any reversible process that connects the same initial and final states. We can then calculate the entropy change for this reversible process with Eq. 21-1. The change in entropy for an irreversible process connecting the same two states would be the same.

We can even use this approach if the temperature of the system is not quite constant. That is, if the temperature change ΔT of a system is small relative to the temperature (in kelvin) before and after the process, the entropy change can be approximated as

$$\Delta S = S_f - S_i \approx \frac{Q}{\langle T \rangle} \quad (21-3)$$

where $\langle T \rangle$ is the average kelvin temperature of the system during the process.

Entropy as a State Property

In the previous section, we assumed that entropy, like pressure, internal energy, and temperature, is a property of the state of a system and is independent of how that state is reached. The fact that entropy is indeed a state property (or *state function* as state properties are sometimes called) can really only be deduced by careful experiment. However, we will prove entropy is a state property for the special and important case of an ideal gas undergoing a reversible process. This proof will serve two purposes. First, it will verify (for at least this one case) that entropy is a state property (or state function) as we assumed in the section above. Second, it will allow us to develop an expression for the entropy change in an ideal gas as it goes from some initial state i to some final state f via a reversible process.

To make the process reversible, we must make changes slowly in a series of small steps, with the ideal gas in an equilibrium state at the end of each step. For each small step, the thermal energy transfer to or from the gas is dQ , the work done by or on the gas is dW , and the change in internal energy is dE^{int} . These are related by the first law of thermodynamics in differential form (Eq. 19-18):

$$dE^{\text{int}} = dQ - dW.$$

Because the steps are reversible, with the gas in equilibrium states, we can replace dW with $P dV$ (Eq. 19-15). Since we are dealing with an ideal gas, we can also replace dE^{int} with $nC_V dT$ (Eq. 20-43). Solving for the thermal energy transferred to or from the system in a single small step of the process dQ then leads to

$$dQ = P dV + nC_V dT.$$

We replace the pressure P in this equation with nRT/V (using the ideal gas law). Then we divide each term in the resulting equation by the temperature T , obtaining

$$\frac{dQ}{T} = nR \frac{dV}{V} + nC_V \frac{dT}{T}.$$

Now let us integrate each term of this equation between an arbitrary initial state i and an arbitrary final state f to get

$$\int_i^f \frac{dQ}{T} = \int_i^f nR \frac{dV}{V} + \int_i^f nC_V \frac{dT}{T}.$$

The quantity on the left is the entropy change $\Delta S (= S_f - S_i)$ as we defined it in Eq. 21-1. Substituting this and integrating the quantities on the right yields an expression for the entropy change in an ideal gas undergoing a reversible process:

$$\Delta S = S_f - S_i = nR \ln \frac{V_f}{V_i} + nC_V \ln \frac{T_f}{T_i}. \quad (21-4)$$

Note that we did not have to specify a particular reversible process when we integrated. Therefore, the integration must hold for all reversible processes that take the gas from state i to state f . Thus, we see that the change in entropy ΔS between the initial and final states of an ideal gas does depend only on properties of the initial state (V_i and T_i) and properties of the final states (V_f and T_f); ΔS does not depend on how the gas changes between the two equilibrium states. Therefore, in at least this one case, we know that entropy must be a state property. In the work that follows in this chapter, we will accept without further proof that entropy is in fact a state property for any system undergoing any process.

READING EXERCISE 21-3: Thermal energy is transferred to water on a stove. Rank the entropy changes of the water as its temperature rises (a) from 20°C to 30°C, (b) from 30°C to 35°C, and (c) from 80°C to 85°C, greatest first. ■

TOUCHSTONE EXAMPLE 21-1: Nitrogen

One mole of nitrogen gas is confined to the left side of the container of Fig. 21-1a. You open the stopcock and the volume of the gas doubles. What is the entropy change of the gas for this irreversible process? Treat the gas as ideal.

SOLUTION ■ We need two **Key Ideas** here. One is that we can determine the entropy change for the irreversible process by calculating it for a reversible process that provides the same change in volume. The other is that the temperature of the gas does not change in the free expansion. Thus, the reversible process should be an isothermal expansion—namely, the one of Figs. 21-3 and 21-4.

Since the internal energy of an ideal gas depends only on temperature, $\Delta E^{\text{int}} = 0$ here and so $Q = W$ from the first law. Combining this result with Eq. 20-14 gives

$$Q = W = nRT \ln\left(\frac{V_f}{V_i}\right),$$

in which n is the number of moles of gas present. From Eq. 21-2 the entropy change for this isothermal reversible process is

$$\Delta S^{\text{rev}} = \frac{Q}{T} = \frac{nRT \ln(V_f/V_i)}{T} = nR \ln \frac{V_f}{V_i}.$$

Substituting $n = 1.00$ mol and $V_f/V_i = 2$, we find

$$\begin{aligned} \Delta S^{\text{rev}} &= nR \ln \frac{V_f}{V_i} = (1.00 \text{ mol})(8.31 \text{ J/mol} \cdot \text{K})(\ln 2) \\ &= +5.76 \text{ J/K}. \end{aligned} \quad (\text{Answer})$$

Thus, the entropy change for the free expansion (and for all other processes that connect the initial and final states shown in Fig. 21-2) is

$$\Delta S^{\text{irrev}} = \Delta S^{\text{rev}} = +5.76 \text{ J/K}.$$

ΔS is positive, so the entropy increases, in accordance with the entropy postulate of Section 21-1.

TOUCHSTONE EXAMPLE 21-2: Copper Blocks

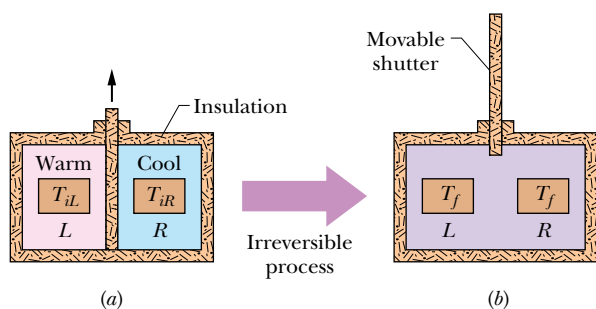

FIGURE 21-5 ■ (a) In the initial state, two copper blocks L and R , identical except for their temperatures, are in an insulating box and are separated by an insulating shutter. (b) When the shutter is removed, the blocks exchange thermal energy and come to a final state, both with the same temperature T_f . The process is irreversible.

Figure 21-5a shows two identical copper blocks of mass $m = 1.5$ kg: block L at temperature $T_{iL} = 60^\circ\text{C}$ and block R at temperature $T_{iR} = 20^\circ\text{C}$. The blocks are in a thermally insulated box and are separated by an insulating shutter. When we lift the shutter, the blocks eventually come to the equilibrium temperature $T_f = 40^\circ\text{C}$ (Fig. 21-5b). What is the net entropy change of the two-block system during this irreversible process? The specific heat of copper is $386 \text{ J/kg} \cdot \text{K}$.

SOLUTION ■ The **Key Idea** here is that to calculate the entropy change, we must find a reversible process that takes the system from the initial state of Fig. 21-5a to the final state of Fig. 21-5b. We can calculate the net entropy change ΔS^{rev} of the reversible process using Eq. 21-1, and then the entropy change for the irreversible process is equal to ΔS^{rev} . For such a reversible process we need a thermal reservoir whose temperature can be changed slowly (say, by turning a knob). We then take the blocks through the following two steps, illustrated in Fig. 21-6.

FIGURE 21-6 ■ The blocks of Fig. 21-5 can proceed from their initial state to their final state in a reversible way if we use a reservoir with a controllable temperature (a) to transfer thermal energy reversibly from block L and (b) to transfer thermal energy reversibly to block R .

Step 1. With the reservoir's temperature set at 60°C , put block L on the reservoir. (Since block and reservoir are at the same temperature, they are already in thermal equilibrium.) Then slowly lower the temperature of the reservoir and the block to 40°C . As the block's temperature changes by each increment dT during this process, thermal energy dQ is transferred *from* the block to the reservoir. Using Eq. 19-5, we can write this transferred energy as $dQ = mc dT$, where c is the specific heat of copper. According to Eq. 21-1, the entropy change ΔS_L of block L during the full temperature change from initial temperature T_{iL} ($= 60^\circ\text{C} = 333\text{ K}$) to final temperature T_f ($= 40^\circ\text{C} = 313\text{ K}$) is

$$\begin{aligned}\Delta S_L &= \int_i^f \frac{dQ}{T} = \int_{T_{iL}}^{T_f} \frac{mc dT}{T} = mc \int_{T_{iL}}^{T_f} \frac{dT}{T} \\ &= mc \ln \frac{T_f}{T_{iL}}.\end{aligned}$$

Inserting the given data yields

$$\begin{aligned}\Delta S_L &= (1.5\text{ kg})(386\text{ J}/[\text{kg}\cdot\text{K}]) \ln \frac{313\text{ K}}{333\text{ K}} \\ &= -35.86\text{ J/K}.\end{aligned}$$

Step 2: With the reservoir's temperature now set at 20°C , put block R on the reservoir. Then slowly raise the temperature of the reservoir and the block to 40°C . With the same reasoning used to find ΔS_L , you can show that the entropy change ΔS_R of block R during this process is

$$\begin{aligned}\Delta S_R &= (1.5\text{ kg})(386\text{ J}/[\text{kg}\cdot\text{K}]) \ln \frac{313\text{ K}}{293\text{ K}} \\ &= +38.23\text{ J/K}.\end{aligned}$$

The net entropy change ΔS^{rev} of the two-block system undergoing this two-step reversible process is then

$$\begin{aligned}\Delta S^{\text{rev}} &= \Delta S_L + \Delta S_R \\ &= -35.85\text{ J/K} + 38.23\text{ J/K} = 2.4\text{ J/K}.\end{aligned}$$

Thus, the net entropy change ΔS^{irrev} for the two-block system undergoing the actual irreversible process is $\Delta S^{\text{irrev}} = \Delta S^{\text{rev}} = 2.4\text{ J/K}$. This result is positive, in accordance with the entropy postulate of Section 21-1.

21-3 The Second Law of Thermodynamics

Here is a puzzle. We saw in Touchstone Example 21-1 that if we cause the reversible, isothermal process of Fig. 21-3 to proceed from (a) to (b) in that figure, the change in entropy of the gas—which we take as our system—is positive. However, because the process is reversible, we can just as easily make it proceed from (b) to (a), simply by slowly adding lead shot to the piston of Fig. 21-3b until the original volume of the gas is restored. In this reverse isothermal process, the gas must keep its temperature from increasing and so must transfer thermal energy to its surroundings to make up for the work done via the lead shot. Since this thermal energy transfer is *from* our system (the gas), Q is negative. So, from $\Delta S = S_f - S_i = Q/T$ (Eq. 21-2) we find that ΔS must be negative and hence the entropy of the gas must decrease.

Doesn't this decrease in the entropy of the gas violate the entropy postulate of Section 21-1, which states that entropy always increases? No, because that postulate holds only for *irreversible* processes occurring in *closed* systems. The procedure suggested here does not meet these requirements. The process is *not* irreversible and (because there is a heat transfer from the gas to the reservoir) the system—which is the gas alone—is not closed.

However, if we include the reservoir, along with the gas, as part of the system, then we do have a closed system. Let's check the change in entropy of the enlarged system *gas + reservoir* for the process that takes it from (b) to (a) in Fig. 21-3. During this reversible process, thermal energy is transferred from the gas to the reservoir—that is, from one part of the enlarged system to another. Let $|Q|$ represent the amount of energy transferred. With $\Delta S = S_f - S_i = Q/T$ (Eq. 21-2), we can then calculate separately the entropy changes for the gas (which loses $|Q|$ of thermal energy) and the reservoir (which gains $|Q|$ in thermal energy). We get

$$\Delta S_{\text{gas}} = -\frac{|Q|}{T}$$

and

$$\Delta S_{\text{res}} = +\frac{|Q|}{T}.$$

The entropy change of the closed system is the sum of these two quantities, *which* (since the process is isothermal) *is zero*.

With this result, we can modify the entropy postulate of Section 21-1 to include both reversible and irreversible processes:

If a process occurs in a *closed* system, the entropy of the system increases for irreversible processes and remains constant for reversible processes. It never decreases.

Although entropy may decrease in part of a closed system, there will always be an equal or larger entropy increase in another part of the system, so that the entropy of the system as a whole never decreases. This fact is one form of the **second law of thermodynamics** and can be written as

$$\Delta S \geq 0 \quad (\text{second law of thermodynamics}), \quad (21-5)$$

where the greater-than sign applies to irreversible processes, and the equals sign to reversible processes. But remember, this relation applies only to closed systems.

In the real world almost all processes are irreversible to some extent because of friction, turbulence, and other factors. So, the entropy of real closed systems undergoing real processes always increases. Processes in which the system's entropy remains constant are idealizations.

21-4 Entropy in the Real World: Engines

Engines, which are fundamentally thermodynamic devices, are everywhere around us and are a big part of what makes modern life possible. However, not all engines are the same. For example, the engine in your car is different from the engine in a typical power plant. Nevertheless, these engines are similar in that they function through the use of a *working substance* that can expand and contract as it exchanges energy with its surroundings. In a power plant, the working substance is often water, in both its vapor and liquid forms. In an automobile engine the working substance is a gasoline-air mixture. If an engine is to do work on a sustained basis, the working substance must operate in a *cycle*. That is, the working substance must pass through a repeating series of thermodynamic processes, called **strokes**, returning again and again to each state in its **cycle**. The fundamental difference between the engine in your car and that in a power plant is that these two engines use different working substances and different types of thermodynamic cycles. That is, the working substances in these two engines undergo different thermodynamic processes.

Most engines that we meet in everyday life are some version of what we will call a *heat engine*. **Heat engines** are devices that take the thermal energy transfers (or heat transfers) Q that result from temperature differences and convert them to useful work W . Internal combustion engines (like in your car) are complicated heat engines that convert chemical energy (from gasoline or diesel fuel) and thermal energy to work. We will not discuss internal combustion engines here. Instead, we will focus on a simpler class of engines in which the working substance simply cycles between two constant temperatures (isotherms) and the engine converts a portion of the resulting thermal energy transfers directly to mechanical work.

The Carnot Engine

We have seen that we can learn much about real gases by analyzing an ideal gas, which obeys the simple law $PV = nRT$. This is a useful plan because, although an ideal gas does not exist, any real gas approaches ideal behavior as closely as you wish if its density is low enough. In much the same spirit we choose to study real engines by analyzing the behavior of an **ideal engine**.

In an ideal engine, all processes are reversible and no wasteful energy transfers occur due to friction, turbulence, or other processes.

We shall focus here on a particular ideal engine called an ideal **Carnot engine** named after the French scientist and engineer N. L. Sadi Carnot (pronounced “car-no”), who first proposed the engine’s concept in 1824. A Carnot engine is an example of a heat engine. It operates between two constant temperatures and uses the resulting thermal energy transfers directly to do useful work. The ideal Carnot engine is especially important because it turns out to be the best engine of this type.

Figure 21-7 shows the operation of a Carnot engine schematically. During each cycle of the engine, energy $|Q_H|$ is transferred to the working substance from a thermal reservoir at constant temperature T_H and energy $|Q_L|$ is transferred from the working substance to a second thermal reservoir at a constant and lower temperature T_L . The Carnot engine converts the difference between the amount of energy transferred into the system $|Q_H|$ and the amount of energy transferred out of the system $|Q_L|$ into useful work.

The cycle followed by the working substance in a Carnot engine is called a **Carnot cycle**. Figure 21-8a shows a P - V plot of the Carnot cycle. As indicated by the arrows, the cycle is traversed in the clockwise direction. Imagine the working substance to be a gas, confined to an insulating cylinder with a weighted, movable piston. Figure 21-8b shows how the Carnot cycle might be accomplished. The cylinder may be placed at will on either of the two thermal reservoirs, or on an insulating slab. If we place the cylinder in contact with the high-temperature reservoir at temperature T_H , $|Q_H|$ represents the thermal energy transfer *to* the working substance *from* this reservoir as the gas undergoes an isothermal *expansion* from volume V_a to volume V_b . Similarly, when the working substance is in contact with the low-temperature reservoir at temperature T_L , the gaseous substance undergoes an isothermal *compression* from volume V_c to volume V_d . At the same time energy $|Q_L|$ is transferred *from* the working substance *to* this reservoir. Note that in our engine thermal energy transfers to or from the working substance can take place *only* during the isothermal processes ab and cd of Fig. 21-8b. Thermal energy transfers do not occur in processes bc and da in that figure, which connect the two isotherms at temperatures T_H and T_L . Therefore, those two processes must be (reversible) adiabatic processes. To ensure this, during processes bc and da , the cylinder is placed on an insulating slab as the volume of the working substance is changed.

FIGURE 21-7 ■ The elements of a Carnot engine. The two black arrowheads on the central loop suggest the working substance operating in a cycle, as if on a P - V plot. Thermal energy $|Q_H|$ is transferred from the high-temperature reservoir at temperature T_H to the working substance. Thermal energy $|Q_L|$ is transferred from the working substance to the low-temperature reservoir at temperature T_L . Work W is done by the engine (actually by the working substance) on something in the environment.

FIGURE 21-8 (a) A pressure–volume plot of the cycle followed by the working substance of the Carnot engine in Fig. 21-7. The cycle consists of two isothermal processes (ab and cd) and two adiabatic processes (bc and da). The shaded area enclosed by the cycle is equal to the work W per cycle done by the Carnot engine. (b) An example of how this set of cycles could be accomplished. The upward motions of a piston during processes ab and bc are accomplished by slowly removing weight from the piston. The downward motions of the piston during processes cd and da are accomplished by slowly adding weight to the piston.

Work Done: During the consecutive processes ab and bc of Fig. 21-8, the working substance is expanding and thus doing positive work as it raises the weighted piston. This work is represented in Fig. 21-8a by the area under curve abc . During the consecutive processes cd and da , the working substance is being compressed, which means that it is doing negative work on its environment (the environment is doing positive work on it). This work is represented by the area under curve cda . The *net work per cycle*, which is represented by W in Figs. 21-7 and 21-8a, is the difference between these two areas. It is a positive quantity equal to the area enclosed by cycle $abcda$ in Fig. 21-8a. This work W is performed on some outside object. The engine might, for example, be used to lift a weight.

To calculate the net work done by a Carnot engine during a cycle, let us apply the first law of thermodynamics ($\Delta E^{\text{int}} = Q - W$), to the working substance of a Carnot engine. That substance must return again and again to any arbitrarily selected state in that cycle. Thus, if X represents any state property of the working substance, such as pressure, temperature, volume, internal energy, or entropy, we must have $\Delta X = 0$ for every cycle. It follows that $\Delta E^{\text{int}} = 0$ for a complete cycle of the working substance. Recall that Q in Eq. 19-18 is the *net* thermal energy transfer per cycle and W is the net work. We can then write the first law of thermodynamics ($\Delta E^{\text{int}} = Q - W$) for the Carnot cycle as

$$W = |Q_H| - |Q_L|. \quad (21-6)$$

Entropy Changes: Equation 21-1 ($\Delta S = \int dQ/T$) tells us that any thermal energy transfer between a system and its surroundings must involve a change in entropy. To illustrate the entropy changes for a Carnot engine, we can plot the Carnot cycle on a temperature–entropy (T - S) diagram as in Fig. 21-9. The lettered points a , b , c , and d in Fig. 21-9 correspond to the lettered points in the P - V diagram in Fig. 21-8. The two horizontal lines in Fig. 21-9 correspond to the two isothermal processes of the Carnot cycle (because the temperature is constant). Process ab is the isothermal expansion stroke of the cycle. As the high temperature reservoir transfers thermal energy $|Q_H|$ reversibly to the working substance at temperature T_H , its entropy increases. Similarly, during the isothermal compression cd , the working substance transfers thermal energy $|Q_L|$ reversibly to the low temperature reservoir at temperature T_L . In this process the entropy of the working substance decreases.

The two vertical lines in Fig. 21-9 correspond to the two adiabatic processes of the Carnot cycle. Because no thermal energy transfers occur during the adiabatic processes, the entropy of the working substance does not change during either of these processes. So, in a Carnot engine, there are *two* (and only two) reversible thermal energy transfers, and thus two changes in entropy—one at temperature T_H and one at T_L . The net entropy change per cycle is then

$$\Delta S = \Delta S_H + \Delta S_L = \frac{|Q_H|}{T_H} - \frac{|Q_L|}{T_L}. \quad (21-7)$$

Here ΔS_H is positive because energy $|Q_H|$ is *transferred to* the working substance from the surroundings (an increase in entropy) and ΔS_L is negative because energy $|Q_L|$ is *transferred from* the working substance to the surroundings (a decrease in entropy). Because entropy is a state property, we must have $\Delta S = 0$ for a complete cycle. Putting $\Delta S = 0$ in above (Eq. 21-7) requires that

$$\frac{|Q_H|}{T_H} = \frac{|Q_L|}{T_L}. \quad (21-8)$$

Note that, because $T_H > T_L$, we must have $|Q_H| > |Q_L|$. That is, more energy is transferred from the high-temperature reservoir to the engine than the engine transfers to the low-temperature reservoir.

We shall now use our findings on the work done (Eq. 21-6) and entropy change (Eq. 21-8) in an ideal Carnot cycle to derive an expression for the efficiency of an ideal Carnot engine.

Efficiency of an Ideal Carnot Engine

The purpose of any heat engine is to transform as much of the thermal energy, Q_H , transferred to the engine’s working medium into useful mechanical work as possible. We measure its success in doing so by its **thermal efficiency** ε , defined as the work the engine does per cycle (“energy we get”) divided by the thermal energy transferred to it per cycle (“energy we pay for”):

$$\varepsilon = \frac{\text{energy we get}}{\text{energy we pay for}} = \frac{|W|}{|Q_H|} \quad (\text{efficiency, any engine}). \quad (21-9)$$

For a Carnot engine we can substitute $W = |Q_H| - |Q_L|$ from Eq. 21-6 to write

$$\varepsilon_C = \frac{|Q_H| - |Q_L|}{|Q_H|} = 1 - \frac{|Q_L|}{|Q_H|}. \quad (21-10)$$

FIGURE 21-9 ■ The Carnot cycle of Fig. 21-8 plotted on a temperature–entropy diagram. During processes ab and cd the temperature remains constant. During processes bc and da the entropy remains constant.

Using $|Q_H|/T_H = |Q_L|/T_L$ (Eq. 21-8) we can write this as

$$\epsilon_C = 1 - \frac{T_L}{T_H} \quad (\text{efficiency, ideal Carnot engine}), \quad (21-11)$$

where the temperatures T_L and T_H are in kelvin. Because $T_L < T_H$, the Carnot engine necessarily has a thermal efficiency less than unity—that is, less than 100%. This is indicated in Fig. 21-7, which shows that only part of the energy transferred to the engine from the high-temperature reservoir causes the engine's working substance to expand and do physical work on the surroundings. The rest of the energy absorbed by the engine provides for the heat transfer to the low-temperature reservoir. We will show in Section 21-6 that no real engine can have a thermal efficiency greater than that calculated for the ideal Carnot engine (Eq. 21-11).

Other Types of Cycles and Real Engines

Efficiency is typically our main concern when designing an engine. For an engine that operates on an ideal Carnot cycle, the efficiency is

$$\epsilon_C = 1 - \frac{T_L}{T_H}.$$

But remember, an ideal Carnot cycle means that the cycle is composed of the following four processes: a perfectly isothermal (constant temperature) expansion of the working substance, a perfectly adiabatic (zero thermal energy transfer) expansion of the working substance, a perfectly isothermal compression of the working substance, and a perfectly adiabatic compression of the working substance. Perfectly isothermal means the temperature of the working substance cannot change at all during these strokes. Perfectly adiabatic means that there can be no thermal energy transfer at all. These tasks are not easy to accomplish. If you do accomplish them, then you have an *ideal* Carnot cycle and the efficiency of the engine is given by the equation above. Most engines built on the Carnot cycle have efficiencies that are measurably lower than this.

It is important to note that even an ideal Carnot engine cannot have an efficiency of one. That is, it does not do a perfect job of converting thermal energy transferred to it into work. Inspection of the Carnot efficiency expression $\epsilon_C = 1 - T_L/T_H$ (Eq. 21-11) shows that we can achieve 100% engine efficiency (that is, $\epsilon = 1$) only if $T_L = 0$ K or $T_H \rightarrow \infty$. These requirements are impossible to meet. So, decades of practical engineering experience have led to the following alternative version of the second law of thermodynamics:

It is impossible to design an engine that converts thermal energy transferred to it from a thermal reservoir to useful work with 100% efficiency.

FIGURE 21-10 ■ A P - V plot for the working substance of an ideal Stirling engine, assumed for convenience to be an ideal gas. Processes ab and cd are isothermal while bc and da are constant volume.

As we mentioned earlier, Carnot engines are not the only type of heat engine in which the working substance cycles between two constant temperatures and converts some of the associated heat transferred to the engine's working medium to useful work. For example, Fig. 21-10 shows the operating cycle of an ideal **Stirling engine**. Comparison with the Carnot cycle of Fig. 21-8 shows that each cycle includes isothermal energy transfers at temperatures T_H and T_L . However, the two isotherms of the Stirling engine cycle of Fig. 21-10 are connected, not by adiabatic processes (no thermal energy transfer) as for the Carnot engine, but by constant-volume processes. To reversibly increase the temperature of a gas at constant volume from T_L to T_H (as in process da of Fig. 21-10) requires a thermal energy transfer to the working substance from a thermal reservoir whose temperature can be varied smoothly between those limits.

Note that reversible thermal energy transfers (and corresponding entropy changes) occur in all four of the processes that form the cycle of a Stirling engine, not just two processes as in a Carnot engine. Thus, the derivation that led to the efficiency expression for the Carnot engine (Eq. 21-11) does not apply to an ideal Stirling engine. More important, the efficiency of an ideal Stirling engine, or any other heat engine based on operation between two isotherms, is lower than that of a Carnot engine operating between the same two temperatures. This makes the ideal Carnot engine an ideal version of the ideal type of this class of engine! Of course, common Stirling engines have even lower efficiencies than the ideal Stirling engine discussed here.

Many engines important in our lives operate based on cycles between two isotherms and convert thermal energy transfers to work. For example, consider the nuclear power plant shown in Fig. 21-11. It, like most power plants, is an engine when taken in its entirety. A reactor core (or perhaps a coal-powered furnace) provides the high-temperature reservoir. Thermal energy transfer to the working substance (usually water) is converted to work done on a turbine (which often results in electricity production). The remaining energy $|Q_L|$ is transferred to a low-temperature reservoir, which is usually a nearby river, or the atmosphere (if cooling towers are used). If the power plant shown in Fig. 21-11 operated as an ideal Carnot engine, its efficiency would be about 40%. Its actual efficiency is about 30%.

How does the efficiency of the internal combustion engine compare to that of the ideal Carnot engine? Well, this is a bit like comparing apples and oranges since the internal combustion engine does not operate between two isotherms like the Carnot, Stirling, or power plant engines do. However, we can estimate that if your car could be powered by a Carnot engine, it would have an efficiency of about 55% according to $\varepsilon_C = 1 - T_L/T_H$ (Eq. 21-11). Its actual efficiency (with an internal combustion engine) is probably about 25%.

READING EXERCISE 21-4: Three Carnot engines operate between reservoir temperatures of (a) 400 and 500 K, (b) 600 and 800 K, and (c) 400 and 600 K. Rank the engines according to their thermal efficiencies, greatest first. ■

FIGURE 21-11 ■ The North Anna nuclear power plant near Charlottesville, Virginia, which generates electrical energy at the rate of 900 MW. At the same time, by design, it discards energy into the nearby river at the rate of 2100 MW. This plant—and all others like it—throws away more energy than it delivers in useful form. It is a real counterpart to the ideal engine of Fig. 21-7.

TOUCHSTONE EXAMPLE 21-3: Carnot Engine

Imagine an ideal Carnot engine that operates between the temperatures $T_H = 850$ K and $T_L = 300$ K. The engine performs 1200 J of work each cycle, the duration of each cycle being 0.25 s.

(a) What is the efficiency of this engine?

SOLUTION ■ The **Key Idea** here is that the efficiency ε of an ideal Carnot engine depends only on the ratio T_L/T_H of the temperatures (in kelvins) of the thermal reservoirs to which it is connected. Thus, from Eq. 21-11, we have

$$\varepsilon = 1 - \frac{T_L}{T_H} = 1 - \frac{300 \text{ K}}{850 \text{ K}} = 0.647 \approx 65\% \quad (\text{Answer})$$

(b) What is the average power of this engine?

SOLUTION ■ Here the **Key Idea** is that the average power P of an engine is the ratio of the work W it does per cycle to the time Δt that each cycle takes. For this Carnot engine, we find

$$P = \frac{W}{\Delta t} = \frac{1200 \text{ J}}{0.25 \text{ s}} = 4800 \text{ W} = 4.8 \text{ kW}. \quad (\text{Answer})$$

(c) How much thermal energy Q_H is extracted from the high-temperature reservoir every cycle?

SOLUTION ■ Now the **Key Idea** is that, for any engine including a Carnot engine, the efficiency ε is the ratio of the work W that is done per cycle to the thermal energy Q_H that is extracted from the high-temperature reservoir per cycle. This relation, $\varepsilon = |W|/|Q_H|$ (Eq. 21-9), gives us

$$Q_H = \frac{W}{\varepsilon} = \frac{1200 \text{ J}}{0.647} = 1855 \text{ J}. \quad (\text{Answer})$$

(d) How much thermal energy Q_L is delivered to the low-temperature reservoir every cycle?

SOLUTION ■ The **Key Idea** here is that for a Carnot engine, the work W done per cycle is equal to the difference in energy transfers $|Q_H| - |Q_L|$. (See Eq. 21-6.) Thus, we have

$$|Q_L| = |Q_H| - W = 1855 \text{ J} - 1200 \text{ J} = 655 \text{ J.} \quad (\text{Answer})$$

(e) What entropy change is associated with the energy transfer to the working substance from the high-temperature reservoir? From the working substance to the low-temperature reservoir?

SOLUTION ■ The **Key Idea** here is that the entropy change ΔS during a transfer of thermal energy Q at constant temperature T is given by Eq. 21-2 ($\Delta S = Q/T$). Thus, for the transfer of energy Q_H from the high-temperature reservoir at T_H , we have

$$\Delta S_H = \frac{Q_H}{T_H} = \frac{1855 \text{ J}}{850 \text{ K}} = +2.18 \text{ J/K.}$$

For the transfer of energy Q_L to the low-temperature reservoir at T_L , we have

$$\Delta S_L = \frac{Q_L}{T_L} = \frac{-655 \text{ J}}{300 \text{ K}} = -2.18 \text{ J/K.}$$

Note that the algebraic signs of the two thermal energy transfers are different. Note also that, as Eq. 21-8 requires, the net entropy change of the working substance for one cycle (which is the algebraic sum of the two quantities calculated above) is zero.

TOUCHSTONE EXAMPLE 21-4: Better Than the Ideal?

An inventor claims to have constructed a heat engine that has an efficiency of 75% when operated between the boiling and freezing points of water. Is this possible?

SOLUTION ■ The **Key Idea** here is that the efficiency of a real engine (with its irreversible processes and wasteful energy transfers) must be less than the efficiency of an ideal Carnot engine operating between the same two temperatures. From Eq. 21-11, we find that the efficiency of an ideal Carnot engine operating between

the boiling and freezing points of water is

$$\begin{aligned} \varepsilon &= 1 - \frac{T_L}{T_H} = 1 - \frac{(0 + 273) \text{ K}}{(100 + 273) \text{ K}} \\ &= 0.268 \approx 27\% \end{aligned} \quad (\text{Answer})$$

Thus, the claimed efficiency of 75% for a real heat engine operating between the given temperatures is impossible.

FIGURE 21-12 ■ The elements of a refrigerator. The two black arrowheads on the central loop suggest the working substance operating in a cycle, as if on a P - V plot. Thermal energy Q_L is transferred to the working substance from the low-temperature reservoir. Thermal energy Q_H is transferred to the high-temperature reservoir from the working substance. Work W is done on the refrigerator (on the working substance) by something in the environment.

21-5 Entropy in the Real World: Refrigerators

A heat engine operated in a reverse cycle would require an input of work and transfer thermal energy from a low-temperature reservoir to a high-temperature reservoir as it continuously repeats a set series of thermodynamic processes. We call such a device a **refrigerator**. In a household refrigerator, for example, an electrical compressor does work in order to transfer thermal energy from the food storage compartment (a low-temperature reservoir) to the room (a high-temperature reservoir). Air conditioners and heat pumps are also refrigerators. The differences are only in the nature of the high- and low-temperature reservoirs. For an air conditioner, the low-temperature reservoir is the room that is to be cooled, and the high-temperature reservoir is the (presumably warmer) outdoors. A heat pump is an air conditioner that can also be operated in such a way as to transfer thermal energy to the air in a room from the (presumably cooler) outdoors.

Let us now consider an *ideal refrigerator*:

In an ideal refrigerator, all processes are reversible and no wasteful energy transfers occur between the refrigerator and its surroundings due to friction, turbulence, or other processes.

Figure 21-12 shows the basic elements of an ideal refrigerator that operates based on a Carnot cycle. That is, it is the Carnot engine of Fig. 21-8 operating in reverse. All the energy transfers, either thermal energy or work, are reversed from those of a Carnot engine. Thus, we call such an ideal refrigerator an ideal **Carnot refrigerator**.

The designer of a refrigerator would like to do amount of work W (that we pay for) and cause as large a thermal energy transfer $|Q_L|$ as possible from the low-temperature reservoir (for example, the storage space in a kitchen refrigerator or the room to be cooled by the air conditioner). A measure of the efficiency of a refrigerator, then, is

$$K = \frac{\text{what we want}}{\text{what we pay for}} = \frac{|Q_L|}{|W|} \quad (\text{coefficient of performance, any refrigerator}), \quad (21-12)$$

where K is called the *coefficient of performance*. For a Carnot refrigerator, the first law of thermodynamics gives $|W| = |Q_H| - |Q_L|$, where $|Q_H|$ is the amount of the thermal energy transfer to the high-temperature reservoir. The coefficient of performance for our ideal Carnot refrigerator then becomes

$$K_C = \frac{|Q_L|}{|Q_H| - |Q_L|}. \quad (21-13)$$

Because an ideal Carnot refrigerator is an ideal Carnot engine operating in reverse, we can again use $|Q_H|/T_H = |Q_L|/T_L$ (Eq. 21-8) and rewrite this expression as

$$K_C = \frac{T_L}{T_H - T_L} \quad (\text{coefficient of performance, Carnot refrigerator}). \quad (21-14)$$

For typical room air conditioners, $K \approx 2.5$. For household refrigerators, $K \approx 5$. Unfortunately, but logically, the efficiency (and so the value of K) of a given refrigerator is higher the closer the temperatures of the two reservoirs are to each other. For example, a given Carnot air conditioner is more efficient on a warm day than when it is very hot outside.

It would be nice to own a refrigerator that did not require an input of work—that is, one that would run without being plugged in. Figure 21-13 represents an “inventor’s dream,” of a *perfect refrigerator* that transfers thermal energy Q from a cold reservoir to a warm reservoir without the need for work. Because the unit returns to the same state at the end of each cycle, and entropy is a state property, we know that the change in entropy of the working substance for this imagined refrigerator would be zero for a complete cycle. The entropies of the two reservoirs, however, would change. The entropy change for the low temperature reservoir would be $-|Q|/T_L$, and that for the high temperature reservoir would be $+|Q|/T_H$. Thus, the net entropy change for the entire system is

$$\Delta S = -\frac{|Q|}{T_L} + \frac{|Q|}{T_H}.$$

Because $T_H > T_L$, the right side of this equation would be negative and thus the net change in entropy per cycle for the closed system *refrigerator + reservoirs* would also be negative. Because such a decrease in entropy violates the second law of thermodynamics $\Delta S \geq 0$ (Eq. 21-5), it must be that a perfect refrigerator cannot exist. That is, if you want your refrigerator to operate, you must plug it in!

This result leads us to another (equivalent) formulation of the second law of thermodynamics:

It is impossible to design a refrigerator that can cause a thermal energy transfer from a reservoir at a lower temperature to one at a higher temperature without the input of work (that is, with 100% efficiency).

In short, *there are no perfect refrigerators*.

FIGURE 21-13 ■ The elements of a perfect (but *impossible*) refrigerator—that is, one that transfers energy from a low-temperature reservoir to a high-temperature reservoir without any input of work.

READING EXERCISE 21-5: You wish to increase the coefficient of performance of an ideal Carnot refrigerator. You can do so by (a) running the cold chamber at a slightly higher temperature, (b) running the cold chamber at a slightly lower temperature, (c) moving the unit to a slightly warmer room, or (d) moving it to a slightly cooler room. Assume that the proposed changes in the magnitude of either T_L or T_H are the same in all four cases. List the changes according to the resulting coefficients of performance, greatest first. ■

21-6 Efficiency Limits of Real Engines

As we have just seen, a “perfect” Carnot refrigerator would violate the second law of thermodynamics which states that entropy must always either remain constant or increase. Therefore, we accept that a search for a 100% efficient Carnot refrigerator is futile. They do not exist. But what about Carnot engines? Can we have a “perfect” (that is, 100% efficient) engine?

FIGURE 21-14 ■ The elements of a perfect (and impossible) engine—that is, one that converts thermal energy transfer Q_H from a high-temperature reservoir directly to work W with 100% efficiency.

Fundamentally, the inefficiency in an ideal Carnot engine is associated with the thermal energy transfer at the low temperature reservoir interface. Naive inventors continually try to improve Carnot engine efficiency by reducing the waste energy $|Q_L|$ transferred to the low-temperature reservoir and, hence, “thrown away” during each cycle. The inventor’s dream is to produce the *perfect engine*, diagrammed in Fig. 21-14, in which $|Q_L|$ is reduced to zero and $|Q_H|$ is converted completely into work. For example, if we could do it, a perfect engine on an ocean liner could use thermal energy transferred to it from seawater to drive the propellers, with no fuel cost. An automobile, fitted with such a perfect engine, could use energy transferred from the surrounding air to turn its wheels, again with no fuel cost.

Alas, what seems too good to be true usually is. A perfect engine cannot exist. We already noted in Section 21-4 that since the efficiency of an ideal Carnot engine is given by $\varepsilon_C = 1 - T_L/T_H$ (Eq. 21-11), even an ideal Carnot engine cannot have 100% efficiency. This is clear since we cannot have $T_L = 0$ K or $T_H \rightarrow \infty$. So, if a real engine is to have 100% efficiency, it will have to have a higher efficiency than our ideal Carnot engine. Let’s see if that is possible.

Let us assume for a moment that an inventor, working in her garage, has constructed an engine X , which she claims has an efficiency ε_X that is greater than ε_C , where ε_C is the efficiency of an ideal Carnot engine operating between two temperatures. Then,

$$\varepsilon_X > \varepsilon_C \quad (\text{a claim}). \quad (21-15)$$

Let us connect the inventor’s engine X to a Carnot refrigerator, as in Fig. 21-15a. We adjust the strokes of the refrigerator so that the work it requires per cycle is just equal to that provided by the engine X . Thus, no (external) work is needed for the operation

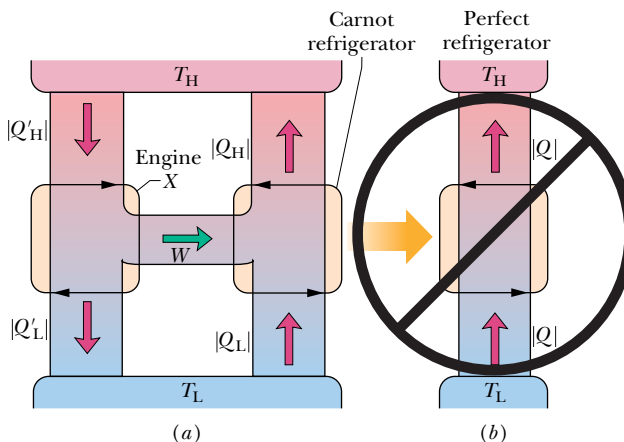

FIGURE 21-15 ■ (a) Engine X drives a Carnot refrigerator. (b) If, as claimed, engine X is more efficient than a Carnot engine, then the combination shown in (a) is equivalent to the perfect refrigerator shown here. This violates the second law of thermodynamics, so we conclude that engine X cannot be more efficient than a Carnot engine.

of the combination *engine + refrigerator* of Fig. 21-15a, which we take as our system. Since the efficiency of an engine is $\varepsilon = \text{energy we get}/\text{energy we pay for} = |W|/|Q_H|$ (Eq. 21-9), and $\varepsilon_X > \varepsilon_C$, we must have

$$\frac{|W|}{|Q'_H|} > \frac{|W|}{|Q_H|},$$

where Q'_H is the heat transfer at the high-temperature reservoir in engine X . The right side of the inequality is the efficiency of the Carnot refrigerator shown in Fig. 21-15a when it operates (in reverse) as an engine. Since $|W|$ is the same in both cases, this inequality requires that

$$|Q_H| > |Q'_H|. \quad (21-16)$$

Because the work done by engine X is equal to the work done on the Carnot refrigerator, which is (from Eq. 21-6) $W = |Q_H| - |Q_L|$, we have

$$|Q_H| - |Q_L| = |Q'_H| - |Q'_L|.$$

We can rearrange terms and write this as

$$|Q_H| - |Q'_H| = |Q_L| - |Q'_L| = Q. \quad (21-17)$$

Here Q'_L is the thermal energy transfer at the low-temperature reservoir in engine X . Because we found that $|Q_H| > |Q'_H|$ (Eq. 21-16), the quantity Q must be positive. What does Q represent? Careful evaluation of this expression (Eq. 21-17) tells us that Q is the net thermal energy transfer at the high-temperature reservoir as a result of our combined engine plus refrigerator. That is, the net effect of engine X and the Carnot refrigerator, working in combination, is to transfer thermal energy Q from a low-temperature reservoir to a high-temperature reservoir. Notably, this is done with no work input to the combined engine–refrigerator system. Thus, the combination acts like the perfect refrigerator of Fig. 21-13, whose existence is a violation of the second law of thermodynamics.

Thus, we conclude that engine X cannot be more efficient than the ideal Carnot engine. In general, *no real engine can have an efficiency greater than that of a Carnot engine when both engines work between the same two temperatures.* At most, it can have an efficiency equal to that of an ideal Carnot engine. In that case, engine X is an ideal Carnot engine. Since ideal Carnot engines cannot be 100% efficient, this means that “*perfect*” (100% efficient) engines are physically impossible.

21-7 A Statistical View of Entropy

In Chapter 20 we saw that the macroscopic properties of gases can be explained in terms of their microscopic, or molecular, behavior. For one example, recall that we were able to account for the pressure exerted by a gas on the walls of its container in terms of the momentum transferred to those walls by rebounding gas molecules. Such explanations are part of a study called **statistical mechanics**.

Here we shall focus our attention on a single problem, involving the distribution of gas molecules between the two halves of an insulated box. This problem is reasonably simple to analyze, and it allows us to use statistical mechanics to calculate the entropy change for the free expansion of an ideal gas. You will see in Touchstone Example 21-6 that statistical mechanics leads to the same entropy change we obtain in Example 21-2 using thermodynamics.

Figure 21-16 shows a box that contains six identical (and thus indistinguishable) molecules of a gas. At any instant, a given molecule will be in either the left or the

FIGURE 21-16 ■ An insulated box contains six gas molecules. Each molecule has the same probability of being in the left half of the box as in the right half. The arrangement in (a) corresponds to configuration III in Table 21-1, and that in (b) corresponds to configuration IV.

right half of the box; because the two halves have equal volumes, the molecule has the same likelihood, or probability, of being in either half.

Table 21-1 shows four of the seven possible *configurations* of the six molecules, each configuration labeled with Roman numerals. For example, in configuration I, all six molecules are in the left half of the box ($n_1 = 6$), and none are in the right half ($n_2 = 0$). The three configurations not shown are V with a (2, 4) split, VI with a (1, 5) split, and VII with a (0, 6) split. In configuration II, five molecules are in one half of the box, leaving one molecule in the other half. We see that, in general, a given configuration can be achieved in a number of different ways. We call these different arrangements of the molecules *microstates*. Let us see how to calculate the number of microstates that correspond to a given configuration.

TABLE 21-1
Six Molecules in a Box

Configuration ^a Label	n_1	n_2	Multiplicity W (number of microstates)	Calculation of W (Eq. 21-18)	Entropy 10^{-23} J/K (Eq. 21-19)
I	6	0	1	$6!/(6!0!) = 1$	0
II	5	1	6	$6!/(5!1!) = 6$	2.47
III	4	2	15	$6!/(4!2!) = 15$	3.74
IV	3	3	20	$6!/(3!3!) = 20$	4.13
Total number of microstates = 64					

^aThe configurations not listed are $n_1 = 0, n_2 = 6$; $n_1 = 1, n_2 = 5$; and $n_1 = 2, n_2 = 4$. These have the same multiplicities as I, II and III respectively.

Suppose we have N molecules, distributed with n_1 molecules in one half of the box and n_2 in the other half. (Thus $n_1 + n_2 = N$.) Let us imagine that we distribute the molecules “by hand,” one at a time. If $N = 6$, we can select the first molecule in six independent ways; that is, we can pick any one of the six molecules. We can pick the second molecule in five ways, by picking any one of the remaining five molecules, and so on. The total number of ways in which we can select all six molecules is the product of these independent ways, or $6 \times 5 \times 4 \times 3 \times 2 \times 1 = 720$. In mathematical shorthand we write this product as $6! = 720$, where 6! is pronounced “six factorial.” Your hand-held calculator can probably calculate factorials. For later use you will need to know that $0! = 1$. (Check this on your calculator.)

However, because the molecules are indistinguishable, these 720 arrangements are not all different. In the case that $n_1 = 4$ and $n_2 = 2$ (which is configuration III in Table 21-1), for example, the order in which you put four molecules in one half of the box does not matter, because after you have put all four in, there is no way that you can tell the order in which you did so. The number of ways in which you can order the four molecules is $4!$ or 24. Similarly, the number of ways in which you can order two molecules for the other half of the box is simply $2!$ or 2. To get the number of different arrangements that lead to the 4, 2 split of configuration III, we must divide 720 by 24 and also by 2. We call the resulting quantity, which is the number of microstates that correspond to a given configuration, the *multiplicity* W of that configuration. Thus, for configuration III,

$$W_{\text{III}} = \frac{6!}{4!2!} = \frac{720}{24 \times 2} = 15.$$

Thus, Table 21-1 tells us there are 15 independent microstates that correspond to configuration III. Note that, as the table also tells us, the total number of microstates for six molecules distributed over four configurations is 42.

Extrapolating from six molecules to the general case of N molecules, we have

$$W = \frac{N!}{n_1! n_2!} \quad (\text{multiplicity of configuration}). \quad (21-18)$$

You should verify that Eq. 21-18 gives the multiplicities for all the configurations listed in Table 21-1.

The basic assumption of statistical mechanics is:

All microstates are equally probable.

In other words, if we were to take a great many snapshots of the six molecules as they jostle around in the box of Fig. 21-16 and then count the number of times each microstate occurred, we would find that all 42 microstates will occur equally often. In other words, the system will spend, on average, the same amount of time in each of the 42 microstates listed in Table 21-1.

Because the microstates are equally probable, but different configurations have different numbers of microstates, the configurations are *not* equally probable. In Table 21-1 configuration IV, with 20 microstates, is the *most probable configuration*, with a probability of $20/64 = 0.313$. This means that the system is in configuration IV 31.3% of the time. Configurations I and VII, in which all the molecules are in one half of the box, are the least probable, each with a probability of $1/64 = 0.016$ or 1.6%. It is not surprising that the most probable configuration is the one in which the molecules are evenly divided between the two halves of the box, because that is what we expect at thermal equilibrium. However, it *is* surprising that there is any probability, however small, of finding all six molecules clustered in half of the box, with the other half empty. In Touchstone Example 21-5 we show that this state can occur because six molecules is an extremely small number.

For large values of N there are extremely large numbers of microstates, but nearly all the microstates belong to the configuration in which the molecules are divided equally between the two halves of the box, as Fig. 21-17 indicates. Even though the measured temperature and pressure of the gas remain constant, the gas is churning away endlessly as its molecules “visit” all probable microstates with equal probability. However, because so few microstates lie outside the very narrow central configuration peak of Fig. 21-17, we might as well assume that the gas molecules are always divided equally between the two halves of the box. As we shall see, this is the configuration with the greatest entropy.

FIGURE 21-17 ■ For a large number of molecules in a box, a plot of the number of microstates that require various percentages of the molecules to be in the left half of the box. Nearly all the microstates correspond to an approximately equal sharing of the molecules between the two halves of the box; those microstates form the central configuration peak on the plot. For $N \approx 10^{22}$ molecules, the central configuration peak is much too narrow to be drawn on this plot.

Probability and Entropy

In 1877, Austrian physicist Ludwig Boltzmann (the Boltzmann of Boltzmann's constant k_B) derived a relationship between the entropy S of a configuration of a gas and the multiplicity W of that configuration. That relationship is

$$S = k_B \ln W \quad (\text{Boltzmann's entropy equation}). \quad (21-19)$$

This famous formula is engraved on Boltzmann's tombstone.

It is natural that S and W should be related by a logarithmic function. The total entropy of two systems is the *sum* of their separate entropies. The probability of occurrence of two independent systems is the *product* of their separate probabilities. Because $\ln ab = \ln a + \ln b$, the logarithm seems the logical way to connect these quantities.

Table 21-1 displays the entropies of the configurations of the six-molecule system of Fig. 21-16, computed using Eq. 21-19. Configuration IV, which has the greatest multiplicity, also has the greatest entropy.

When you use Eq. 21-18 to calculate W , your calculator may signal "OVERFLOW" if you try to find the factorial of a number greater than a few hundred. Fortunately, there is a very good approximation, known as **Stirling's approximation**, not for $N!$ but for $\ln N!$, which as it happens is exactly what is needed in Eq. 21-19. Stirling's approximation is

$$\ln N! \approx N(\ln N) - N \quad (\text{Stirling's approximation}). \quad (21-20)$$

The Stirling of this approximation is not the Stirling of the Stirling engine.

READING EXERCISE 21-6: A box contains one mole of a gas. Consider two configurations: (a) each half of the box contains one-half of the molecules, and (b) each third of the box contains one-third of the molecules. Which configuration has more microstates? ■

TOUCHSTONE EXAMPLE 21-5: Indistinguishable

Suppose that there are 100 indistinguishable molecules in the box of Fig. 21-16. How many microstates are associated with the configuration $n_1 = 50$ and $n_2 = 50$? How many are associated with the configuration $n_1 = 100$ and $n_2 = 0$? Interpret the results in terms of the relative probabilities of the two configurations.

SOLUTION ■ The **Key Idea** here is that the multiplicity W of a configuration of indistinguishable molecules in a closed box is the number of independent microstates with that configuration, as given by Eq. 21-18. For the (n_1, n_2) configuration (50, 50), that equation yields

$$\begin{aligned} W &= \frac{N!}{n_1! n_2!} = \frac{100!}{50! 50!} \\ &= \frac{9.33 \times 10^{157}}{(3.04 \times 10^{64})(3.04 \times 10^{64})} \quad (\text{Answer}) \\ &= 1.01 \times 10^{29}. \end{aligned}$$

Similarly, for the configuration of (100, 0), we have

$$W = \frac{N!}{n_1! n_2!} = \frac{100!}{100! 0!} = \frac{1}{0!} = \frac{1}{1} = 1 \quad (\text{Answer})$$

Thus, a 50-50 distribution is more likely than a 100-0 distribution by the enormous factor of about 1×10^{29} . If you could count, at one per nanosecond, the number of microstates that correspond to the 50-50 distribution, it would take you about 3×10^{12} years, which is about 750 times longer than the age of the universe. Even 100 molecules is *still* a very small number. Imagine what these calculated probabilities would be like for a mole of molecules—say, about $N = 10^{24}$. You need never worry about suddenly finding all the air molecules clustering in one corner of your room!

TOUCHSTONE EXAMPLE 21-6: Entropy Increase

In Touchstone Example 21-1 we showed that when n moles of an ideal gas doubles its volume in a free expansion, the entropy increase from the initial state i to the final state f is $S_f - S_i = nR \ln 2$. Derive this result with statistical mechanics.

SOLUTION ■ One **Key Idea** here is that we can relate the entropy S of any given configuration of the molecules in the gas to the multiplicity W of microstates for that configuration, using Eq. 21-19 ($S = k_B \ln W$). We are interested in two configurations: the final configuration f (with the molecules occupying the full volume of their container in Fig. 21-1*b*) and the initial configuration i (with the molecules occupying the left half of the container).

A second **Key Idea** is that, because the molecules are in a closed container, we can calculate the multiplicity W of their microstates with Eq. 21-18. Here we have N molecules in the n moles of the gas. Initially, with the molecules all in the left half of the container, their (n_1, n_2) configuration is $(N, 0)$. Then, Eq. 21-18 gives their multiplicity as

$$W_i = \frac{N!}{N!0!} = 1.$$

Finally, with the molecules spread through the full volume, their (n_1, n_2) configuration is $(N/2, N/2)$. Then, Eq. 21-18 gives their multiplicity as

$$W_f = \frac{N!}{(N/2)!(N/2)!}.$$

From Eq. 21-19, the initial and final entropies are

$$S_i = k \ln W_i = k \ln 1 = 0$$

$$\text{and } S_f = k_B \ln W_f = k \ln(N!) - 2k_B \ln[(N/2)!]. \quad (21-21)$$

In writing Eq. 21-21, we have used the relation

$$\ln \frac{a}{b^2} = \ln a - 2 \ln b.$$

Now, applying Eq. 21-20 to evaluate Eq. 21-21, we find that

$$\begin{aligned} S_f &= k_B \ln(N!) - 2k_B \ln[(N/2)!] \\ &= k_B[N(\ln N) - N] - 2k_B[(N/2) \ln(N/2) - (N/2)] \\ &= k_B[N(\ln N) - N - N \ln(N/2) + N] \\ &= k_B[N(\ln N) - N(\ln N - \ln 2)] = Nk_B \ln 2. \end{aligned} \quad (21-22)$$

From Eq. 20-7 we can substitute nR for Nk_B , where R is the universal gas constant. Equation 21-22 then becomes

$$S_f = nR \ln 2.$$

The change in entropy from the initial state to the final is thus

$$\begin{aligned} S_f - S_i &= nR \ln 2 - 0 \\ &= nR \ln 2, \end{aligned} \quad (\text{Answer})$$

which is what we set out to show. In Touchstone Example 21-1 we calculated this entropy increase for a free expansion with thermodynamics by finding an equivalent reversible process and calculating the entropy change for *that* process in terms of temperature and heat transfer. Here we have calculated the same increase with statistical mechanics using the fact that the system consists of molecules.

Problems

SEC. 21-2 ■ CHANGE IN ENTROPY

1. Expands Reversibly A 2.50 mol sample of an ideal gas expands reversibly and isothermally at 360 K until its volume is doubled. What is the increase in entropy of the gas?

2. Reversible Isothermal How much thermal energy must be transferred for a reversible isothermal expansion of an ideal gas at 132 °C if the entropy of the gas increases by 46.0 J/K?

3. Four Moles Four moles of an ideal gas undergo a reversible isothermal expansion from volume V_1 to volume $V_2 = 2V_1$ at temperature $T = 400$ K. Find (a) the work done by the gas and (b) the entropy change of the gas. (c) If the expansion is reversible and adiabatic instead of isothermal, what is the entropy change of the gas?

4. Reversible Isothermal Expansion An ideal gas undergoes a reversible isothermal expansion at 77.0 °C, increasing its volume from 1.30 L to 3.40 L. The entropy change of the gas is 22.0 J/K. How many moles of gas are present?

5. Energy Absorbed Find (a) the thermal energy transfer and (b) the change in entropy of a 2.00 kg block of copper whose temperature is increased reversibly from 25 °C to 100 °C. The specific heat of copper is 386 J/kg · K.

6. Initial Temperature An ideal monatomic gas at initial temperature T_0 (in kelvins) expands from initial volume V_0 to volume $2V_0$ by each of the five processes indicated in the T - V diagram of Fig. 21-18. In which process is the expansion (a) isothermal, (b) isobaric (constant pressure), and (c) adiabatic? Explain your answers. (d) In which processes does the entropy of the gas decrease?

FIGURE 21-18 ■ Problem 6.

7. Entropy Change (a) What is the entropy change of a 12.0 g ice cube that melts completely in a bucket of water whose temperature is just above the freezing point of water? (b) What is the entropy change of a 5.00 g spoonful of water that evaporates completely on a hot plate whose temperature is slightly above the boiling point of water?

8. Ideal Gas Undergoes A 2.0 mol sample of an ideal monatomic gas undergoes the reversible process shown in Fig. 21-19. (a) How much thermal energy is transferred to the gas? (b) What is the change in the internal energy of the gas? (c) How much work is done by the gas?

FIGURE 21-19 ■ Problem 8.

9. Aluminum and Water In an experiment, 200 g of aluminum (with a specific heat of $900 \text{ J/kg}\cdot\text{K}$) at 100°C is mixed with 50.0 g of water at 20.0°C , with the mixture thermally isolated. (a) What is the equilibrium temperature? What are the entropy changes of (b) the aluminum, (c) the water and (d) the aluminum–water system?

10. Irreversible Process In the irreversible process of Fig. 21-5, let the initial temperatures of identical blocks L and R be 305.5 K and 294.5 K , respectively. Let 215 J be the thermal energy transfer between the blocks required to reach equilibrium. Then for the reversible processes of Fig. 21-6, what are the entropy changes of (a) block L , (b) its reservoir, (c) block R , (d) its reservoir, (e) the two-block system, and (f) the system of the two blocks and the two reservoirs?

11. Reversible Apparatus Use the reversible apparatus of Fig. 21-6 to show that, if the process of Fig. 21-5 happened in reverse, the entropy of the system would decrease, a violation of the second law of thermodynamics.

12. Rotating Not Oscillating An ideal diatomic gas, whose molecules are rotating but not oscillating, is taken through the cycle in Fig. 21-20. Determine for all three processes, in terms of P_1 , V_1 , T_1 , and R : (a) P_2 , P_3 , and T_3 and (b) W , Q , ΔE^{int} , and ΔS per mole?

FIGURE 21-20 ■ Problem 12.

13. Copper in Box A 50.0 g block of copper whose temperature is 400 K is placed in an insulating box with a 100 g block of lead whose temperature is 200 K . (a) What is the equilibrium temperature of the two-block system? (b) What is the change in the internal energy of the two-block system between the initial state and the equilibrium state? (c) What is the change in the entropy of the two-block system? (See Table 19-2.)

14. Initial to Final One mole of a monatomic ideal gas is taken from an initial pressure P and volume V to a final pressure $2P$ and volume $2V$ by two different processes: (I) It expands isothermally until its volume is doubled, and then its pressure is increased at constant volume to the final pressure. (II) It is compressed isothermally until its pressure is doubled, and then its volume is increased at constant pressure to the final volume. (a) Show the path of each

process on a P - V diagram. For each process calculate, in terms of P and V , (b) the thermal energy absorbed by the gas in each part of the process, (c) the work done by the gas in each part of the process, (d) the change in internal energy of the gas, ΔE^{int} , and (e) the change in entropy of the gas, ΔS .

15. Ice Cube in a Lake A 10 g ice cube at -10°C is placed in a lake whose temperature is 15°C . Calculate the change in entropy of the cube–lake system as the ice cube comes to thermal equilibrium with the lake. The specific heat of ice is $2220 \text{ J/kg}\cdot\text{K}$. (Hint: Will the ice cube affect the temperature of the lake?)

16. Ice Cube in Thermos An 8.0 g ice cube at -10°C is put into a Thermos flask containing 100 cm^3 of water at 20°C . By how much has the entropy of the cube–water system changed when a final equilibrium state is reached? The specific heat of ice is $2220 \text{ J/kg}\cdot\text{K}$.

17. Water and Ice A mixture of 1773 g of water and 227 g of ice is in an initial equilibrium state at 0.00°C . The mixture is then, in a reversible process, brought to a second equilibrium state where the water–ice ratio, by mass, is 1:1 at 0.00°C . (a) Calculate the entropy change of the system during this process. (The heat of fusion for water is 333 kJ/kg .) (b) The system is then returned to the initial equilibrium state in an irreversible process (say, by using a Bunsen burner). Calculate the entropy change of the system during this process. (c) Are your answers consistent with the second law of thermodynamics?

18. Cylinder of Gas A cylinder contains n moles of a monatomic ideal gas. If the gas undergoes a reversible isothermal expansion from initial volume V_i to final volume V_f along path I in Fig. 21-21, its change in entropy is $\Delta S = nR \ln(V_f/V_i)$. (See Touchstone Example 21-1) Now consider path II in Fig. 21-21, which takes the gas from the same initial state i to state x by a reversible adiabatic expansion, and then from that state x to the same final state f by a reversible constant volume process. (a) Describe how you would carry out the two reversible processes for path II. (b) Show that the temperature of the gas in state x is

FIGURE 21-21 ■ Problem 18.

$$T_x = T_i(V_i/V_f)^{2/3}.$$

(c) What are the thermal energy transferred along path I (Q_I) and the thermal energy transferred along path II (Q_{II})? Are they equal? (d) What is the entropy change ΔS for path II? Is the entropy change for path I equal to it? (e) Evaluate T_x , Q_I , Q_{II} , and ΔS for $n = 1$, $T_i = 500 \text{ K}$, and $V_f/V_i = 2$.

19. Through the Cycle One mole of an ideal monatomic gas is taken through the cycle in Fig. 21-22. (a) How much work is done by the gas in going from state a to state c along path abc ? What are the changes in internal energy and entropy in going (b) from b to c and (c) through one complete cycle? Express all answers in terms of the pressure P_0 , volume V_0 , and temperature T_0 of state a .

FIGURE 21-22 ■ Problem 19.

20. Initial Pressure and Temperature One mole of an ideal monatomic gas, at an initial pressure of 5.00 kPa and initial temperature of 600 K, expands from initial volume $V_i = 1.00 \text{ m}^3$ to final volume $V_f = 2.00 \text{ m}^3$. During the expansion, the pressure P and volume V of the gas are related by $P = (5.00 \text{ kPa}) \exp[(V_i - V)/a]$, where $a = 1.00 \text{ m}^3$. What are (a) the final pressure and (b) the final temperature of the gas? (c) How much work is done by the gas during the expansion? (d) What is the change in entropy of the gas during the expansion? (*Hint*: Use two simple reversible processes to find the entropy change.)

SEC. 21-4 ■ ENTROPY IN THE REAL WORLD: ENGINES

Consider all Carnot engines discussed in these problems to be ideal.

21. Work and Efficiency in a Cycle A Carnot engine absorbs 52 kJ of thermal energy and exhausts 36 kJ as thermal energy in each cycle. Calculate (a) the engine's efficiency and (b) the work done per cycle in kilojoules.

22. Low-Temp Reservoir A Carnot engine whose low-temperature reservoir is at 17°C has an efficiency of 40%. By how much should the temperature of the high-temperature reservoir be increased to increase the efficiency to 50%?

23. Operates Between A Carnot engine operates between 235°C and 115°C , absorbing $6.30 \times 10^4 \text{ J}$ per cycle at the higher temperature. (a) What is the efficiency of the engine? (b) How much work per cycle is this engine capable of performing?

24. Reactor In a hypothetical nuclear fusion reactor, the fuel is deuterium gas at temperature of about $7 \times 10^8 \text{ K}$. If this gas could be used to operate a Carnot engine with $T_L = 100^\circ\text{C}$, what would be the engine's efficiency?

25. Carnot Engine A Carnot engine has an efficiency of 22.0%. It operates between constant-temperature reservoirs differing in temperature by 75.0°C . What are the temperatures of the two reservoirs?

26. Engine Has Power A Carnot engine has a power of 500 W. It operates between constant-temperature reservoirs at 100°C and 60.0°C . What are (a) the rate of thermal energy input and (b) the rate of exhaust heat output, in kilojoules per second?

27. Process bc One mole of a monatomic ideal gas is taken through the reversible cycle shown in Fig. 21-23. Process bc is an adiabatic expansion, with $P_b = 10.0 \text{ atm}$ and $V_b = 1.00 \times 10^{-3} \text{ m}^3$. Find (a) the thermal energy transferred to the gas, (b) the thermal energy transferred from the gas, (c) the net work done by the gas, and (d) the efficiency of the cycle.

FIGURE 21-23 ■ Problem 27.

28. Enclosed Area Show that the area enclosed by the Carnot cycle on the temperature–entropy plot of Fig. 21-9 represents the net thermal energy transfer per cycle to the working substance.

29. Assume $P = 2P_0$ One mole of an ideal monatomic gas is taken through the cycle shown in Fig. 21-24. Assume that $P = 2P_0$, $V = 2V_0$, $P_0 = 1.01 \times 10^5 \text{ Pa}$, and $V_0 = 0.0225 \text{ m}^3$. Calculate (a) the work done during the cycle, (b) the thermal energy added during stroke abc , and (c) the efficiency of the cycle. (d) What is the efficiency of a Carnot engine operating between the highest and lowest temperatures that occur in the cycle? How does this compare to the efficiency calculated in (c)?

FIGURE 21-24 ■ Problem 29.

30. First Stage In the first stage of a two-stage Carnot engine, thermal energy Q_1 is absorbed at temperature T_1 , work W_1 is done, and thermal energy Q_2 is expelled at a lower temperature T_2 . The second stage absorbs that energy Q_2 , does work W_2 , and expels energy Q_3 at a still lower temperature T_3 . Prove that the efficiency of the two-stage engine is $(T_1 - T_3)/T_1$.

31. Deep Shaft Suppose that a deep shaft were drilled in Earth's crust near one of the poles, where the surface temperature is -40°C , to a depth where the temperature is 800°C . (a) What is the theoretical limit to the efficiency of an engine operating between these temperatures? (b) If all the thermal energy released as heat into the low-temperature reservoir were used to melt ice that was initially at -40°C , at what rate could liquid water at 0°C be produced by a 100 MW power plant (treat it as an engine)? The specific heat of ice is $2220 \text{ J/kg}\cdot\text{K}$; water's heat of fusion is 333 kJ/kg . (Note that the engine can operate only between 0°C and 800°C in this case. Energy exhausted at -40°C cannot be used to raise the temperature of anything above -40°C .)

32. Working Substance One mole of an ideal gas is used as the working substance of an engine that operates on the cycle shown in Fig. 21-25. BC and DA are reversible adiabatic processes. (a) Is the gas monatomic, diatomic, or polyatomic? (b) What is the efficiency of the engine?

FIGURE 21-25 ■ Problem 32.

33. Gasoline Engine The operation of a gasoline internal combustion engine is represented by the cycle in Fig. 21-26. Assume the gasoline–air intake mixture is an ideal gas and use a compression ratio of 4:1 ($V_4 = 4V_1$). Assume that $P_2 = 3P_1$. (a) Determine the pressure and temperature at each of the vertex points of the P - V diagram in terms of P_1 , T_1 , and the ratio γ of the molar specific heats of the gas. (b) What is the efficiency of the cycle?

FIGURE 21-26 Problem 33.

SEC. 21-5 ■ ENTROPY IN THE REAL WORLD: REFRIGERATORS

34. Carnot Refrigerator A Carnot refrigerator does 200 J of work to remove 600 J of thermal energy from its cold compartment. (a) What is the refrigerator's coefficient of performance? (b) How much thermal energy per cycle is exhausted to the kitchen?

35. Carnot Air Conditioner A Carnot air conditioner takes energy from the thermal energy of a room at 70°F and transfers it to the outdoors, which is at 96°F. For each joule of electric energy required to operate the air conditioner, how many joules are removed from the room?

36. Heat Pump Transfers The electric motor of a heat pump transfers thermal energy from the outdoors, which is at -5.0°C , to a room, which is at 17°C . If the heat pump were a Carnot heat pump (a Carnot engine working in reverse), how many joules would be transferred to the thermal energy of the room for each joule of electric energy consumed?

37. Heat Pump to Heat Building A heat pump is used to heat a building. The outside temperature is -5.0°C , and the temperature inside the building is to be maintained at 22°C . The pump's coefficient of performance is 3.8, and the heat pump delivers 7.54 MJ of thermal energy to the building each hour. If the heat pump is a Carnot engine working in reverse, at what rate must work be done to run the heat pump?

38. How Much Work How much work must be done by a Carnot refrigerator to transfer 1.0 J of thermal energy (a) from a reservoir at 7.0°C to one at 27°C , (b) from a reservoir at -73°C to one at 27°C , (c) from a reservoir at -173°C to one at 27°C , and (d) from a reservoir at -223°C to one at 27°C ?

39. Air Conditioner An air conditioner operating between 93°F and 70°F is rated at 4000 Btu/h cooling capacity. Its coefficient of performance is 27% of that of a Carnot refrigerator operating between the same two temperatures. What horsepower is required of the air conditioner motor?

40. Motor in Refrigerator The motor in a refrigerator has a power of 200 W. If the freezing compartment is at 270 K and the outside air is at 300 K, and assuming the efficiency of a Carnot refrigerator, what is the maximum amount of thermal energy that can be extracted from the freezing compartment in 10.0 min?

41. Engine Driving Refrigerator A Carnot engine works between temperatures T_1 and T_2 . It drives a Carnot refrigerator that works between temperatures T_3 and T_4 (Fig. 21-27). Find the ratio $|Q_3|/|Q_1|$ in terms of T_1 , T_2 , T_3 , and T_4 .

FIGURE 21-27 Problem 41.

SEC. 21-7 ■ A STATISTICAL VIEW OF ENTROPY

42. Construct a Table Construct a table like Table 21-1 for eight molecules.

43. Show for N Molecules Show that for N molecules in a box, the number of possible microstates is 2^N when microstates are defined by whether a given molecule is in the left half of the box or the right half. Check this for the situation of Table 21-1.

44. A Box of N Gas Molecules A box contains N gas molecules, equally divided between its two halves. For $N = 50$: (a) What is the multiplicity of this central configuration? (b) What is the total number of microstates for the system? (*Hint*: See Problem 43.) (c) What percentage of the time does the system spend in its central configuration? (d) Repeat (a) through (c) for $N = 100$. (e) Repeat (a) through (c) for $N = 200$. (f) As N increases, you will find that the system spends *less* time (not more) in its central configuration. Explain why this is so.

45. Three Equal Parts A box contains N gas molecules. Consider the box to be divided into three equal parts. (a) By extension of Eq. 21-18, write an equation for the multiplicity of any given configuration. (b) Consider two configurations: configuration A with equal numbers of molecules in all three thirds of the box, and configuration B with equal numbers of molecules in both halves of the box. What is the ratio W_A/W_B of the multiplicity of configuration A to that of configuration B ? (c) Evaluate W_A/W_B for $N = 100$. (Because 100 is not evenly divisible by 3, put 34 molecules into one of the three box parts and 33 in each of the other parts for configuration A .)

46. Four Particles in a Box Four particles are in the insulated box of Fig. 21-16. What are (a) the least multiplicity, (b) the greatest multiplicity, (c) the least entropy, and (d) the greatest entropy of the four-particle system?

Additional Problems

47. Velocity Spread A sample of nitrogen gas (N_2) undergoes a temperature increase at constant volume. As a result, the distribution of molecular speeds increases. That is, the probability distribution function $f(v)$ for the nitrogen molecules spreads to higher values of speed, as suggested in Fig. 20-8*b*. One way to report the spread in $f(v)$ is to measure the difference Δv between the most probable speed v^{prob} and the rms speed v^{rms} . When $f(v)$ spreads to higher speeds, Δv increases. (a) Write an equation relating the change ΔS in the entropy of the nitrogen gas to the initial difference Δv_i and the final difference Δv_f . Assume that the gas is an ideal diatomic gas with rotation but not oscillation of its molecules. Let the number of moles be 1.5 mol, the initial temperature be 250 K, and the final temperature be 500 K. What are (b) the initial difference Δv_i , (c) the final difference Δv_f , and (d) the entropy change ΔS for the gas?

48. Carnot Graph A Carnot engine is set up to produce a certain work W per cycle. In each cycle, thermal energy Q_H is transferred to the working substance of the engine from the higher-temperature thermal reservoir, which is at an adjustable temperature T_H . The lower-temperature thermal reservoir is maintained at temperature $T_L = 250$ K. Figure 21-28 gives Q_H for a range of T_H , if T_H is set at 550 K, what is Q_H ?

FIGURE 21-28 ■ Problem 48.

49. Gas Sample A gas sample undergoes a reversible isothermal expansion. Figure 21-29 gives the change ΔS in entropy of the gas versus the final volume V_f of the gas. How many moles are in the gas?

FIGURE 21-29 ■ Problem 49.

50. ΔS Graph A 364 g block is put in contact with a thermal reservoir. The block is initially at a lower temperature than the reservoir. Assume that the consequent heating of the block by the reservoir is reversible. Figure 21-30 gives the change in entropy of the block ΔS

until thermal equilibrium is reached. What is the specific heat of the block?

FIGURE 21-30 ■ Problem 50.

51. C/T Graph An object of (constant) heat capacity C is heated from an initial temperature T_i to a final temperature T_f by a constant-temperature reservoir at T_f . (a) Represent the process on a graph of C/T versus T , and show graphically that the total change in entropy ΔS of the object–reservoir system is positive. (b) Explain how the use of reservoirs at intermediate temperatures would allow the process to be carried out in a way that makes ΔS as small as desired.

52. Friction A moving block is slowed to a stop by friction. Both the block and the surface along which it slides are in an insulated enclosure. (a) Devise a reversible process to change the system from its initial state (block moving) to its final state (block stationary; temperature of the block and surface slightly increased). Show that this reversible process results in an entropy increase for the closed block–surface system. For the process, you can use an ideal engine and a constant-temperature reservoir. (b) Show, using the same process, but in reverse, that if the temperature of the system were to decrease spontaneously and the block were to start moving again, the entropy of the system would decrease (a violation of the second law of thermodynamics).

53. T - S Diagram A diatomic gas of 2 mol is taken reversibly around the cycle shown in the T - S diagram of Fig. 21-31. The molecules rotate but do not oscillate. What are the thermal energy transfers Q for (a) the path from point 1 to point 2, (b) the path from point 2 to point 3, and (c) the full cycle? (d) What is the work W for the isothermal process? The volume V_1 at point 1 is 0.200 m³. What are the volumes at (e) point 2 and (f) point 3?

FIGURE 21-31 ■ Problem 53.

What are the changes ΔE^{int} in internal energy for (g) the path from point 1 to point 2, (h) the path from point 2 to point 3, and (i) the full cycle? (*Hint*: Part (h) can be done with one or two lines of calculation using Section 20-8 or with a page of calculation using Section 20-11.) (j) What is the work W for the adiabatic process?

54. Inventor's Engine An inventor has built an engine (engine X) and claims that its efficiency ϵ_X is greater than the efficiency ϵ of an

ideal engine operating between the same two temperatures. Suppose that you couple engine X to an ideal refrigerator (Fig. 21-32*a*) and adjust the cycle of engine X so that the work per cycle that it provides equals the work per cycle required by the ideal refrigerator. Treat this combination as a single unit and show that if the inventor's claim were true (if $\epsilon_X > \epsilon$), the combined unit would act as a perfect refrigerator (Fig. 21-32*b*), transferring thermal energy from the low temperature reservoir to the high-temperature reservoir without the need of work.

FIGURE 21-32 ■ Problem 54.

55. Ideal Diatomic Gas An ideal diatomic gas with 3.4 mol is taken through a cycle of three processes:

1. its temperature is increased from 200 K to 500 K at constant volume;
2. it is then isothermally expanded to its original pressure;
3. it is then contracted at constant pressure back to its original volume.

Throughout the cycle, the molecules rotate but do not oscillate. What is the efficiency of the cycle?

22

Electric Charge

Nothing happens if you place a plastic comb near tiny scraps of paper, but immediately after you comb your hair or stroke the comb with fur, it will attract the paper scraps. In fact, the attractive force exerted on the paper by the small comb is so strong that it overcomes the opposing gravitational pull of the entire Earth. This phenomenon, commonly called “static cling,” occurs between many different objects and is especially easy to observe during cold dry weather.

What causes these pieces of paper to stick to the comb and to one another?

The answer is in this chapter.

22-1 The Importance of Electricity

If you walk across a carpet when it's cold and dry outside, you can produce a spark by bringing your finger close to a metal doorknob. Television advertisements alert us to the problem of “static cling” in clothing. On a grander scale, lightning is familiar to everyone. These phenomena represent a tiny glimpse into the vast number of electric interactions that occur every day.

The phenomenon of electricity plays a major role in modern life. Less than two hundred years ago, fire was almost the only source of heat, the only source of light when the sun or moon was not up, and the only way to cook food. Without electric water pumps, most people did not even have indoor plumbing. It's hard to imagine life without electric lights (not even flashlights), stoves, refrigerators, air conditioners, computers, telephones, radios, televisions, CD players, and a host of other electrical devices. We make extensive use of electricity, but *what is it?* In this chapter we consider this very important question.

So far in our study of the physical world we have learned how the forces acting on objects affect motion. We have also learned about the gravitational force, an action-at-a-distance force, that objects can exert on each other without touching. In this chapter, we will investigate another action-at-a-distance force—the *electrostatic* interaction force. Studying the electrostatic force will provide a foundation for our understanding of the phenomenon of electricity.

We begin our study by looking at the nature of electrical interaction forces between some everyday objects. We then develop the concepts of charging and electric charge as tools for explaining our observations of electrostatic forces on a macroscopic level. However, to obtain a more coherent understanding of electrostatic phenomena, we must turn to the findings of atomic theory.

An understanding of electrostatic interactions will give you insight into the fundamental relationship between electricity and magnetism. In Chapter 30, which is about magnetic fields due to currents, you will discover that although magnetic forces are generated by the interaction between moving charges, they have distinctly different properties than do electrostatic forces. Later, in Chapter 32, you will see how electricity and magnetism are fundamentally related to each other.

READING EXERCISE 22-1: List all the electrical devices that you use in a typical week. ■

FIGURE 22-1 ■ Fossilized resin, known as amber, is popular both for its beauty and for its ability to preserve ancient vegetation and insects, like the bees, wasps, ants, flies and mosquitos seen here. Amber also has electrical properties.

22-2 The Discovery of Electric Interactions

Amber, which is resin that oozed from trees long ago and hardened, has been admired both for its beauty and its ability to preserve early life forms mired in it (Fig. 22-1). Amber has electrical properties of interest to scientists as well. The early Greeks knew that if one rubbed a yellow-brown piece of amber with fur, it would attract bits of straw. The strength of the attraction decreased as the distance between the amber and the straw was increased. The strength of the attraction was also known to fade over time, especially in damp weather.

By the 1600s, this strange force due to amber that was sometimes present and sometimes not, prompted more careful studies. It was subsequently discovered that other materials such as glass can also attract small bits of matter after being rubbed with silk. As was the case for amber, this attractive force diminished with time, especially on humid days, and was not present if the glass had not been rubbed. Additionally, the strength of the attraction decreased as the distance between the glass and small bits of matter increased, just as was the case with the force associated with rubbed amber.

This interaction phenomenon, created by rubbing certain materials with cloth, was named *electrification*. The term is derived from the Greek word for amber, which is *electron*. Any object (not just glass or amber) is defined as becoming *electrified* if:

1. There is an interaction force between this object and another that is present after the objects have been in very close contact, usually through rubbing;
2. The magnitude of this interaction force diminishes with time and is affected by humid weather; and
3. The magnitude of the force decreases with increasing distance between the objects.

Although the similarities between electrified glass and electrified amber were interesting, it was not until 1733 that a French scientist, Charles DuFay, published articles presenting evidence that:

Two amber rods stroked with fur always repel one another.

Two glass rods stroked with silk always repel one another.

A stroked amber rod *attracts* a stroked glass rod (Fig. 22-2).

FIGURE 22-2 ■ (a) Two amber rods electrified in the same way repel each other. (b) Two glass rods electrified in the same way also repel each other. (c) An electrified glass rod and an electrified amber rod attract each other.

Provided the weather is not too humid, you may be able to repeat DuFay's observations yourself by replacing the amber and glass rods (which are difficult to find outside of a physics laboratory) with Styrofoam cups and plastic sandwich bags as shown in Fig. 22-3. Place your hand inside a plastic bag and use a rubbing motion to assure that the entire surface of the Styrofoam cup comes in contact with the entire surface of the plastic bag. Then rub another Styrofoam cup with a second sandwich bag in the same manner. If you put one of the cups on its side on a smooth, level, nonmetallic surface and bring the other cup near it, the first cup should roll away as shown in Fig. 22-3a. Note that after the two cups have been electrified in a *like manner* they *repel* one another just like DuFay's rods. Now hold the two plastic bags together at the top end. Both plastic bags have also been electrified in a like manner and they repel one another as well as shown in Fig. 22-3b. However, an electrified sandwich bag and an electrified Styrofoam cup will be *attracted* to each other just as electrified amber attracts electrified glass. Think about these observations carefully and you must conclude that there are two classes of materials that behave differently when electrified.

Not all types of materials can be electrified. Nevertheless, additional observations with electrified materials lead to the following general statements:

OBSERVATION 1. Two identical objects electrified by the same process always repel one another.

OBSERVATION 2. Two different electrified objects will always interact, but they may either repel or attract one another.

OBSERVATION 3. Any two objects that have not been electrified will neither repel nor attract one another. (They interact only by means of an imperceptibly small gravitational force.)

FIGURE 22-3 ■ (a) Two Styrofoam cups electrified in the same way repel each other. (b) The two sandwich bags used to electrify the cups also repel each other.

Suppose you have electrified two Styrofoam cups so they repel each other. What happens when you give one of the cups extra stroking? The magnitude of the interaction forces between the cups increases. This means that if we think of the first cup (that did not receive extra stroking) as a “standard object,” we can determine the degree of electrification of any other object by measuring the magnitude of the electric force exerted on it by the standard object.

One logical way of interpreting our observations regarding electrification is to assume that a substance is added or removed from an object during the stroking process. Extensive experiments done at the end of the 18th century by Benjamin Franklin and others indicate that this is correct. They also found that there are actually two types of the substance involved. Today we call these substances **electrical charge** and say that there are two types of (electrical) charge. When an object contains more of one type of charge than the other, the object is electrified or **electrically charged**. Furthermore, any process of electrification (not just rubbing) is called **charging**. Thus, in the example above, the cup that was stroked for the longer time gained the greater quantity of excess charge. (Quantity of charge is often called **amount** of charge). An object with a greater amount or quantity of charge is observed to experience more force in the presence of a standard electrified object than one with a smaller amount of excess charge.

READING EXERCISE 22-2: The creation of electrified objects can also be done with strips of Scotch™ Magic Tape using a peeling action rather than stroking. In order to charge the tape, cut 2 strips about 10 cm long. (a) If you were to stick the tapes side by side on a table and peel them both off, what do you predict would happen if you then brought the tapes close together? Explain the reasoning for your prediction. (b) Perform the experiment and describe what happens. Is this consistent with your prediction? If not, explain what you think is going on. ■

22-3 The Concept of Charge

Various observations, including our observations using Styrofoam cups and plastic bags, indicate that interaction forces between charged objects can be explained in terms of two (and only two) different kinds of charged matter. The type associated with glass rubbed with silk is one and the type associated with amber rubbed with fur is the other. We cannot prove directly that there are no other types of charge. However, the fact that no one has found a charged object that attracts both charged glass and charged amber leads us to believe that there is no third type of charge.

Today, the terms we associate with these two types of charged matter are *positive* and *negative*. Benjamin Franklin is responsible for assigning these names. He introduced the following definitions:

OBSERVATION 1. An object that is repelled by a glass rod stroked with silk is **positively charged**.

OBSERVATION 2. An object that is repelled by amber (or plastic) stroked with fur is **negatively charged**.

OBSERVATION 3. Any two nonmagnetic objects that do not interact with each other except by gravitational forces are electrically neutral.

The names given to the two varieties of charge are arbitrary. Benjamin Franklin could just as easily have used other words, such as light and dark, to distinguish be-

tween the two types of charges. However, we observe that equal amounts of the positive and negative charges combine to produce nonelectrified (i.e., **electrically neutral**) matter. That is, the two types of charge combine algebraically—like positive and negative numbers. So, positive and negative are convenient and appropriate names.

Applying this new terminology to our previous observations leads us to say that if two objects are each repelled by a piece of glass that has been rubbed with silk, then both objects must be positively charged. Furthermore, we hypothesize that these objects repel *because* they contain the same kind of charge or **like charges**. On the other hand, if we find that two objects made of different materials attract after being stroked, we hypothesize that one object has a positive charge while the other has a negative charge. We conclude that objects with **unlike** or **opposite charges** attract.

READING EXERCISE 22-3: Suppose you stroked a smooth wooden rod with a linen cloth and announced that you had created a new type of charge you decided to call *woodolin charge*. (a) If a skeptic asked you to prove that woodolin was really a new type of charge, how would you do it? Specifically what would have to happen if you were to bring two wooden rods together that had both been rubbed with linen? If you were to bring a charged wooden rod near a charged glass rod? Near a charged amber (or plastic) rod? (b) Why do you think most observers agree that there are only two types of known charge? ■

22-4 Using Atomic Theory to Explain Charging

How can we account for the fact that when certain objects are rubbed together they acquire opposite types of charge? One way to make sense of this observed fact is to use a contemporary understanding of the atomic structure of matter. The atomic model that we discuss here has been developed over the past century. We will use it as an explanatory tool without presenting evidence for it.

The Atomic Model

According to modern atomic structure theory, atoms consist of positively charged *protons*, negatively charged *electrons*, and electrically neutral *neutrons*. Electrons and protons have the same amount (although with opposite sign) of charge. We often represent this amount of charge, called the **elementary charge**, with an e (Table 22-1). Hence an electron has a charge of $-1e$ and a proton has a charge of $+1e$.

Protons and neutrons are packed tightly together in a central *nucleus*. They are much more massive than electrons, which lie outside the nucleus as depicted in Fig. 22-4. Most of the atoms that are contained in matter have equal numbers of electrons and protons, so whenever a charged object is at some distance away from the atom, the atom appears to be electrically neutral.

According to contemporary atomic theory, electric charge is an intrinsic characteristic of electrons and protons. You often encounter casual phrases—such as “the

Particle	Symbol	Charge
Electron	e or e^-	$-e$
Proton	p	$+e$
Neutron	n	0

Note: The symbols for electron and for electronic charge are the same. This can be confusing.

FIGURE 22-4 ■ The structure of the atoms representing the three lightest chemical elements, H, He, and Li. The number of protons that define the element along with the typical number of neutrons in each element's nucleus are shown. The darker circles represent protons, the lighter circles neutrons, and the white circles electrons. The diagram is simplified, as physicists do not actually believe that electrons orbit nuclei in nice neat circles and that the nuclei are much smaller relative to the size of their atoms.

FIGURE 22-5 ■ The upper diagram shows a neutral lithium atom with its full complement of electrons. The bottom atom has lost an outer electron and is now an ion with a net charge of $+1e$ because it has three protons and only two electrons.

charge on a sphere,” “the amount of charge transferred,” and “the charge carried by the electron.” Such phrases can be misleading because they suggest that charge is a substance. You should, however, keep in mind that experiments show electrons and protons are the basic substances. Charge and mass are simply two of their fundamental properties.

The mass of an electron is about 2000 times smaller than that of a neutron or proton. Electrons are attracted to the nucleus because electrons and the protons within the nucleus have opposite charges. However, the electrons that are farthest away from the nucleus are only weakly attracted to the protons within the nucleus and so they don’t always remain associated with individual atoms. In many types of materials the electrons are free to wander within the material if they experience forces. If the atom loses an electron it is no longer neutral, but has a net positive charge because there are now more protons than electrons, as seen in Fig. 22-5. Charged atoms are called **ions**. We call mobile electrons **conduction electrons**. If an electric or other force is applied to the atom, only the conduction electrons, with their negative charges, move appreciably. The much more massive positive ions stay fixed in place.

Charge Is Quantized

In Benjamin Franklin’s day, electric charge was thought to be a continuous fluid that could “contain” any arbitrary amount of charge. Today we know that fluids, such as air and water, are not continuous but are made up of atoms and molecules. Matter is discrete. In 1909 an American physicist, Robert Millikan, used opposing electric and gravitational forces to balance drops of oil between two electrified metal plates. His famous oil drop experiment and others that followed showed that the “electrical fluid” is not continuous either but is made up of multiples of the elementary charge.

Any positive or negative charge q that has ever been detected as a free particle can be written as

$$q = ne, \quad n = \pm 1, \pm 2, \pm 3, \dots, \quad (22-1)$$

in which e , the elementary charge, has the value

$$e = 1.60 \times 10^{-19} \text{ C}. \quad (22-2)$$

The SI unit of charge is the **coulomb** (C), named for Charles Augustin Coulomb, who studied electric forces in the late 1700s. When a physical quantity such as charge can have only discrete values rather than any arbitrary value, we say that the quantity is **quantized**. It is possible, for example, to find a free particle that has no charge at all or a charge of $+10e$ or $-6e$, but not a free particle with a charge of, say, $3.57e$. Modern studies of the structure of neutrons and protons have produced strong evidence that neutrons and protons are made up of tightly bound particles with charges $+2/3e$ and $-1/3e$ that we call quarks, but quarks do not seem to be able to exist as free particles. Hence, extensive experimentation confirms that:

Charge is quantized. In free particles charge has never been measured to have an amount other than an integer multiple of $1.60 \times 10^{-19} \text{ C}$.

As we noted in the introduction, if you drag your feet as you walk across a carpet, you can produce a spark caused by moving electric charge by bringing your finger close to a metal doorknob. This is a demonstration of a small sample of the vast amount of electric charge that is stored in electrically neutral objects. However, that charge is usually hidden because the object contains equal amounts of positive and negative charge. This was hinted at above when we stated that electrically neutral atoms contain equal

numbers of protons and electrons. With such an equality—or *balance*—of the amounts charge there is no *net* charge. If the two types of charge are not in balance, we say an object is *charged* to indicate that it has a charge imbalance, or nonzero net charge.

Macroscopic objects that are electrically neutral are *not* devoid of charge. Instead, they contain equal numbers of positive protons and negative electrons. This results in a cancellation of their electrical effects.

Charging Is Transferring Electrons

Glass and silk or Styrofoam and plastic become oppositely charged when they are brought into contact and we can use our modern understanding of the atom to explain why. Suppose we observe that Styrofoam becomes positively charged and plastic becomes negatively charged. It is logical to assume that outer electrons associated with atoms in the Styrofoam are attracted to the atoms in the plastic and move over to the plastic. The Styrofoam is now missing electrons so there is a net positive charge on the Styrofoam. The plastic now has excess electrons and has a net negative charge.

In general, experiment shows that an object becomes charged when a very tiny fraction of the mobile electrons with their negative charge are transferred from one object to another. This is why we must rub, stroke, or otherwise make significant contact between two objects for the objects to become charged. Thus, when a Styrofoam cup is stroked with a plastic bag, a very tiny fraction of the electrons near the surface of the Styrofoam cup are transferred to the plastic bag.

Why doesn't the plastic bag get heavier when electrons are transferred to it? Using modern atomic theory, we understand that even if we transfer a lot of electrons to the plastic bag (a typical number might be between 10^9 and 10^{12}) the increase in mass would be less than 10^{-10} kg—not measurable. In ordinary matter, positive charge is much less mobile than negative charge. For this reason, an object becomes positively charged through the *removal of negatively charged electrons* rather than through the addition of positively charged protons.

Charge Is Conserved

Careful measurements reveal that whenever there is excess charge on one of the objects after contact, there are excess charges on the other object too. These charges are equal in amount but opposite in sign. This demonstrates that when electrons are transferred from one object to another, no electrons are destroyed or created in the process. The amount of charge contained in the two objects is constant or conserved.

This hypothesis of **conservation of charge** was first proposed by Benjamin Franklin based on his experiments. It is observed to hold both for large-scale charged bodies and for atoms, nuclei, and elementary particles. No exceptions have ever been found. So, we add electric charge to our list of quantities—including energy, linear momentum, and angular momentum—that are conserved quantities. In summary, extensive experimentation confirms:

The total amount of electric charge in the universe is conserved. Although particles that carry charge can be transferred from one object to another, the charge associated with particles cannot be created or destroyed.

Force and Quantity of Charge

Because charge is conserved, we can transfer charge from one object to another without changing the total amount of charge in the system. This allows us to perform

experiments that indicate how the interaction force between charged objects depends on the amount of charge on each object. These experiments lead to surprisingly simple results when the charged objects are symmetric, made of metal, and are particle-like (so that their dimensions are small compared to the distances between their centers). For example, consider the experiment shown in Fig. 22-6. Two identical uncharged metal spheres are both electrified with a charged plastic rod. We then touch the two spheres together. Since the spheres are identical and the excess electrons repel each other, we expect electrons to travel between the spheres until both spheres have the same number of excess electrons. Next we measure the force exerted by one sphere on the other and record it (Fig. 22-6a).

FIGURE 22-6 ■ Depiction of an idealized experiment to measure the forces between small metal spheres that hold different fractions of charge. *Note:* In order to make force measurements for particle-like objects, the distance between the centers of the two balls of identical shape must be more than twice the diameter of a ball.

Then we leave sphere *A* alone and move sphere *B* a long distance from sphere *A* to place it in contact with a third sphere *C* that is uncharged. The excess electrons on sphere *B* will now be shared equally between spheres *B* and *C* so the number of excess electrons on sphere *B* will now be half of what it was before. If we return *B* to its original location and measure the magnitude $F_{\text{elec}} = |\vec{F}_{\text{elec}}|$ of the force between spheres *A* and *B*, we find that it is one-half of the force magnitude we first measured (Fig. 22-6b). If we repeat this process so we reduce the amount of charge on sphere *B* to one-fourth of what it was originally, then the magnitude of the interaction force between the spheres is also reduced to one-fourth of what it was originally (Fig. 22-6c). In a similar experiment we can reduce the charge on both spheres *A* and *B* to half their original values and then the force measures one-fourth the original force between them (Fig. 22-6d). These observations, which are summarized in Table 22-2, indicate that the magnitude of the interaction force is proportional to the *product* of the amounts of charge on the two spheres. This relationship is given by

$$F_{\text{elec}} \propto |q_A| |q_B|, \quad (22-3)$$

where the absolute value signs denote charge amounts independent of sign.

The amount of the charge on a particle-like object can be quantified through measurement of the magnitude of the interaction force between it and a standard charged object that is also particle-like.

FIGURE 22-7 ■ The electroscope can be used to measure charge. The rise of a metal foil is caused by the repulsion due to an excess of like charged particles distributed on the parts of a metal conducting system. The foil rises in proportion to the net charge contained on the conductor.

The Electroscope

The fact that like charges repel has been used in the development of the **electroscope**, a sensitive charge-measuring device, as seen in Fig. 22-7. A net charge can be transferred to an electroscope by stroking the metal ball with a charged rod. If the rod is negatively charged, some of its excess electrons will be transferred to the ball and then they will spread throughout the metal rod and the foil attached to the ball. If a flexible metal leaf is attached to the central conducting bar, the flexible conductor will be repelled from the central charges and rise. As more electrons are transferred to the electroscope, the metal leaf will rise higher. Alternatively if the rod is positively charged it will *attract* electrons from the electroscope, leaving a net positive charge on it. Once again the foil will rise.

READING EXERCISE 22-4: Assuming that solid objects are made up of atoms rather than being continuous, can you think of a plausible way to explain why it is so difficult to pull solids apart or push them together? ■

READING EXERCISE 22-5: Consider the measurements depicted in Fig. 22-6. Suppose you have measured the repulsion force between two identical metal-coated spheres that each have a total negative charge q due to excess electrons. Next, you would like to measure the force on the metal-coated spheres that each have one-fourth of the excess electrons they originally had. Describe how you could use similar uncharged spheres to reduce the excess electrons on each of the original spheres to $q/4$. ■

22-5 Induction

Let's consider some additional observations involving electrical interactions. Typically, bits of straw or paper that have not been rubbed do not attract or repel one another. They are electrically neutral. Thus, it is surprising to find that a plastic comb made negatively charged by rubbing (like the comb shown in the photograph at the beginning of this chapter) can attract bits of electrically neutral paper. It is equally surprising to find that a positively charged glass rod will attract bits of paper.

INDUCTION is the process that causes the attraction we observe between a charged object and an uncharged one.

How can we explain induction? We turn to atomic theory for an explanation. The idea that electrically neutral materials are not devoid of charge, but rather are composed of atoms that have the same number of positive protons and negative electrons, is the first step in developing a viable explanation for induction. The second important idea, mentioned in the last section, is that electrons are more mobile than protons.

Let's begin by considering how induction occurs when a charged object is placed near an uncharged *metal* object. Then in the next section, we will consider induction in a class of nonmetals known as insulators.

Induction in Metals

What happens when we dangle a very small metal rod from a string near a charged object as shown in Fig. 22-8? According to our atomic model, mobile negative electrons in the metal rod are repelled from the negatively charged object. When the mobile electrons in the neutral metal object are repelled they move away and unpaired protons are left behind. The unlike charges at the surfaces of the two objects will now attract as shown in Fig. 22-8a. An attraction between a neutral object and a positively charged object occurs as shown in Fig. 22-8b. The process of separation of positive protons and negative electrons in the neutral objects is known as **polarization**.

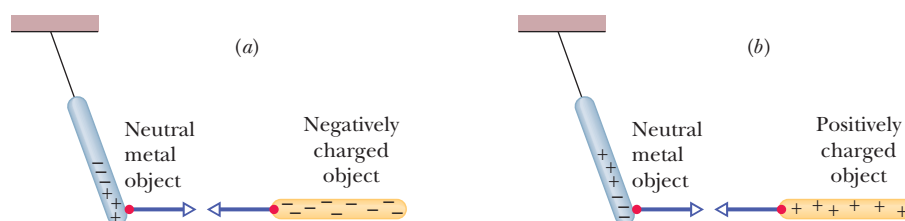

FIGURE 22-8 ■ A tiny neutral metal rod is suspended on a nonconducting thread. The part of the neutral rod that is closest to a charged object will be attracted by either: (a) a negatively charged object (such as amber) or (b) a positively charged object (such as glass). The extent of the charge separation in the metal rod is exaggerated.

READING EXERCISE 22-6: (a) If we state that two bits of paper are electrically neutral, what observation can you make to verify this is the case? Explain. (b) Can induction be used to determine whether the charged object is positive or negative? Why or why not? ■

READING EXERCISE 22-7: (a) In the figure that follows, objects made of different materials are arranged in six pairs. *A* is plastic stroked with fur, *B* is glass stroked with silk, and *C* is an electrically neutral metal object. State whether the interaction between each pair will be attractive, repulsive, or nonexistent. Explain your reasoning.

(b) According to the sign convention Benjamin Franklin decided to adopt, which of the three objects carry an excess positive charge? An excess negative charge? No excess charge? Explain.

(c) Suppose you were told that *A*, *B*, and *C* are made of new materials but you were not told what those materials are. Would it be possible to determine whether they are negatively charged, positively charged, or electrically neutral by observing how the pairs shown in the diagram above interact? Why or why not? ■

22-6 Conductors and Insulators

Whenever a charged object is near an electrically neutral object, induction and polarization occur. However, the attractive forces are stronger for neutral metal objects than for nonmetal objects. Why? Let's summarize the outcomes of some important observations you can make yourself using metal rods, Styrofoam cups, and plastic bags.

FIGURE 22-9 ■ According to atomic theory: (a) polarization induced in an insulator involves very very tiny atomic-scale charge separations as shown in exaggerated form for a Styrofoam ball, whereas (b) polarization in a conductor can involve a much larger scale migration of electrons as shown in a metal-coated ball.

OBSERVATION 1. (a) The electrification created on nonmetal objects, like plastic, does not spread out. Instead charge seems to remain in regions where the object is rubbed, and (b) touching charged nonmetal objects removes the electrification only at locations where an object is touched.

OBSERVATION 2. (a) Metal objects can be charged when mounted on nonmetal objects such as glass or plastic but they cannot be charged while being held in someone's hand, and (b) metal objects that are touched anywhere by a person will immediately lose *all* of their charge.

Even though paper is a nonmetal, the ideas of induction and polarization can be used to explain how the charged comb pictured in the puzzler at the beginning of the chapter can be used to pick up a string of paper bits. We assume the first piece of paper is attracted to the charged comb by induction and becomes polarized in the process. Then the excess negative charge at the bottom end of the first paper bit attracts the second paper bit by induction. Since the second paper bit is now polarized, the process continues. (Although experiments show that magnetic forces behave differently than do electrostatic forces, this process of electric polarization looks like a similar process in which a magnet can induce magnetic polarization in a steel paper clip, which then attracts and polarizes a second clip, and so on.)

Atomic Theory and the Behavior of Conductors and Insulators

Once again we can turn to atomic theory to develop a plausible explanation for these new observations. In materials such as metals, tap water, water droplets in air, and the human body, experiments indicate that some of the negative electrons move easily. We call such materials **conductors**. We observe that charge can flow onto or off conductors quite quickly. In other materials, such as glass, chemically pure water, and plastic, the electrons can reposition themselves within an atom but cannot migrate between atoms. We call these materials **nonconductors** or **insulators**. Electrons do not travel from atom to atom very easily in insulators. An exception is that some of the electrons at the surface of an insulator can have a greater affinity for another type of surface. For example, electrons can travel from the surface of a glass rod to the surface of a piece of silk cloth brought into contact with it, leaving the glass rod positively charged.

One implication of this difference in the mobility of charge in insulators and conductors is that the polarization process discussed in Section 22-5 is not as strong in insulators. Neutral conductors and neutral insulators both undergo charge separation (become polarized) when they are brought close to a charged object—but, the electrons in insulators are tightly bound to atoms, and the charge separation (polarization) is only a small fraction of an atomic radius. In contrast, some of the electrons in conductors can move through the material fairly freely and become separated from the atoms to which they were originally associated. This difference is shown in the comparison of the two images in Fig. 22-9. This atomic model provides a plausible explanation for the observed fact that induction is much stronger between a charged object and a conductor than between the same charged object and an insulator.

The difference in mobility of charge carriers in conductors and insulators explains why you cannot charge a metal rod by rubbing if you are holding it. Both you and the rod are conductors. Although the rubbing will cause a charge imbalance on the rod, the excess charge will immediately move from the rod through you to the floor (which is connected to Earth's surface), and the rod will quickly be neutralized. Setting up a pathway for electrons between an object and Earth's surface is called **grounding** the object, and always results in electrically neutralizing the object. If instead of holding the metal rod in your hand, you hold it by an insulating handle, you eliminate the conducting path to Earth, and rubbing can then charge the rod, as long as you do not touch it directly with your hand.

These ideas give us a very functional way to determine whether a material is a conductor or an insulator. If you have two interacting charged objects and you touch one of them, do the objects stop interacting? If so, charge must have been transferred to or from the object. Hence, it must be a conductor. If the transfer of charge does not occur, the object must be an insulator.

Charging by Induction

The rubbing methods we use to charge insulators such as glass, rubber, and amber do not work well with conductors. Fortunately, you can take advantage of the polarization model (which was used to explain induction) and a process known as **charging by induction** to accomplish this. In the example of charging by induction, an electrically neutral metal plate is brought near a negatively charged insulator shown in Fig. 22-10*b*. The charges in the metal plate are polarized by induction. Since the top of the metal plate now has an excess of electrons, touching it will cause these electrons to flow onto your body. If you now stop touching the rod, the return pathway for electrons is removed. So the metal plate is no longer electrically neutral. If you now move the metal plate away from the charged insulator, the polarization effect disappears and the metal plate remains positively charged due to a deficiency of electrons. Of course, it is also

FIGURE 22-10 ■ An electrophorus is an apparatus that can be used to charge a conductor by induction. It consists of an insulated plate such as a slab of Styrofoam and a conducting plate such as an aluminum pie plate. (a) The insulating slab is charged negatively after being stroked with fur. (b) When a conducting plate is brought near the charged insulator the conductor is polarized so that its free electrons move away from the insulator. (c) When the top of the conductor is touched these free electrons move to the hand. (d) This leaves a net positive charge on the conductor.

FIGURE 22-11 ■ This is not a parlor stunt but a serious experiment carried out in 1774 to prove that the human body is a conductor of electricity. The etching shows a person suspended by nonconducting ropes while being charged by a charged rod (which probably touched flesh instead of the trousers). When the person brought his face, left hand, or the conducting ball and rod in his right hand near bits of paper on the plates, charge was induced on the paper, which flew through the intermediate air to him.

possible to develop a similar procedure that will leave an excess of electrons on the metal plate. (Figure 22-11 shows another experiment set up for inducing charge.)

READING EXERCISE 22-9: (a) Can you charge an insulator by induction? Explain your reasoning. (b) Describe the steps you would take to give an object excess negative charge using the process of charging by induction utilizing the electrophorus apparatus shown in Fig. 22-10. ■

22-7 Coulomb's Law

So far all our explanations of electrical phenomena have been qualitative. Can a mathematical law be formulated to quantitatively describe the interaction forces between electric charges?

The observations we depicted in Fig. 22-6 led us to the conclusion that the interaction forces are proportional to the product of the charges on the objects. So the magnitude of the force on either particle is given by $F \propto |q_A q_B|$. But, what observations have been made that would lead to a mathematical relationship that also describes how interaction forces are related to the distance between charged particle-like objects?

Benjamin Franklin observed that a small cork hanging from a silk thread is attracted by induction to the outside of a charged metal can. However, if the cork is dangled inside the can, there are no apparent forces on it. Recall that in Chapter 14 on gravitation we presented a shell theorem Newton derived from the assumption that gravitational forces fall off as the inverse square of the distance between masses. Newton's shell theorem implies that a shell of mass exerts no net gravitational force on a point mass contained within it. Joseph Priestley reasoned that since an analogous shell theorem seems to hold for electric interactions, then the inverse square law ought to hold for electric forces too.

In 1785, Priestley's hypothesis regarding the dependence of electric forces on the inverse square of distance was verified by the experiments of Charles Augustin Coulomb using a sensitive torsion balance to measure the forces between charged spheres.

Coulomb assumed the forces between charged spheres would be the same as if the charge of each object was concentrated at its center. He also found that the forces between the objects lie along a line between their centers. Coulomb used a method like the one we described in Section 22-4 to reduce the charges on the metal spheres in his torsion apparatus by known fractions. Thus, he was able to verify that the interaction forces were proportional to the product of the charges on the interacting objects.

As a result of his careful experiments, Coulomb found that the magnitude of the electric (or Coulomb) force, F^{elec} , between two stationary particle-like charged objects is

$$F^{\text{elec}} = k \frac{|q_A||q_B|}{r^2} \quad (\text{Coulomb's law}), \quad (22-4)$$

where k is a positive constant of proportionality, r is the distance between the centers of the two objects, q_A is the charge on one of the objects, and q_B is the charge on the other object.

Using modern tools available in many introductory physics laboratories, we can verify the inverse square ($1/r^2$) relationship in Coulomb's law. The experiment is pictured in Fig. 22-12. Two Ping-Pong balls that are covered with conducting paint are stroked with a fur-charged rubber rod so they are negatively charged. One of the balls is hung as a pendulum from a long, nonconducting string. The other ball, which serves as a prod, is attached to a nonconducting rod.

As the prod is moved very slowly toward the hanging ball, the hanging ball is repelled and rises. The hanging ball is displaced further and further from its equilibrium as the prod is brought closer to it. This demonstrates qualitatively that the force exerted by the prod on the hanging ball is greater when the distance, r , between the centers of the two charged balls is smaller. It also indicates that the electrostatic force acts along the line connecting the two charges. We know this because the hanging ball is not pushed off to the side.

Video technology allows us to take this experiment a step further. The motion of the prod inching forward can be captured with a video camera and digitized. Then computer software can be used to perform a frame-by-frame analysis of the angular displacement of the hanging ball and of the distance between the balls. Figure 22-13 is an example of this digital analysis. When the ball is stationary, the net force consists of the vector sum of the gravitational force acting vertically downward, the tension force exerted by the string, and the electric force acting in the horizontal direction. Thus, the magnitude of the electric force on the ball can be calculated from the mass of the ball and its angle of rise, θ , with respect to the vertical.

FIGURE 22-12 ■ A charged metal-coated Ping-Pong ball is repelled from a charged prod. At equilibrium, the vector sum of the gravitational force, the tension in the string, and the Coulomb force on the hanging ball is zero.

FIGURE 22-13 ■ Three of twenty-five digitized video frames depicting the forces between two charged balls. The string holding up the hanging ball is too thin to see and its point of attachment is well above the top of the video frames.

A plot of the data is shown in Fig. 22-14. If we try to fit the data, we find that the force between electrical charges falls off with distance as $1/r^2$ just as the gravitational force does. This verifies Coulomb's result summarized in Eq. 22-4.

FIGURE 22-14 ■ A graph of the magnitude of the Coulomb force vs. the distance between two charged Ping-Pong balls each having a mass of 2.40 g. The green line represents an excellent inverse square fit to the red data points. The fit is given by $F^{\text{elec}} = (7.9 \times 10^{-4} \text{ N} \cdot \text{m}^2)/r^2$. Using a Coulomb constant of $8.99 \times 10^9 \text{ N} \cdot \text{m}^2/\text{C}^2$ (as shown in Eqs. 22-6 and 22-7), it can be shown that each ball carries about 1×10^{-8} coulombs of excess charge. VideoPoint® software was used to obtain the data from video frames (Dson015.mov).

FIGURE 22-15 ■ Two charged particles, separated by distance r , repel each other if their charges are (a) both positive or (b) both negative. (c) They attract each other if their charges are of opposite signs. In each of the three situations, the force acting on one particle is equal in magnitude to the force acting on the other particle but has the opposite direction.

We use the absolute value signs on the force and charges in Eq. 22-4 to remind ourselves that the sign of the force (a vector) indicates the *direction* of the force and not simply whether we are multiplying like or unlike charges. Hence, we should calculate the magnitude of the force between two charged objects using the amounts of the charges. We determine the direction of the force using the attraction and repulsion rules we discussed earlier, remembering that the force always acts along the line connecting the two charges. If the particles *repel* each other, the force on each particle is directed *away from* the other particle (as in Figs. 22-15a and b). If the particles *attract* each other, the force on each particle is directed *toward* the other particle (as in Fig. 22-15c).

As an example of the need for absolute values in the equation

$$F_{A \rightarrow B}^{\text{elec}} = k \frac{|q_A||q_B|}{r^2},$$

consider the two unlike charges in Fig. 22-15c. Inspection of the expression for force above indicates that each particle exerts a force of the same magnitude on the other particle,

$$F_{A \rightarrow B} = F_{B \rightarrow A}. \quad (22-5)$$

But, electrostatic interactions satisfy Newton's Third Law. The force on the positive charge (in Fig. 22-15c) due to the negative charge points to the right. The force on the negative charge due to the positive charge points to the left. If we use explicit positive and negative signs on the charges and don't make use of absolute values, the product $q_A q_B$ (or $q_B q_A$) is always negative and so the force would be negative, regardless of whether we are calculating the force on the positive charge or the force on the negative charge. This cannot be correct, since these two forces point in opposite directions and the sign denotes direction. The force cannot be negative for both charges. In this and every other situation, we avoid this pitfall if we use the absolute values of the charges in our calculations and then determine the sign associated with the force *by thinking* about our coordinate system and the issues of attraction and repulsion.

Curiously, the form of Eq. 22-4 is the same as Newton's law of gravitation presented in Chapter 14 that relates the gravitational force between two particles with masses m_A and m_B to the distance, r , between their centers,

$$F_{A \rightarrow B}^{\text{grav}} = G \frac{m_A m_B}{r^2}, \quad (\text{Eq. 14-1})$$

in which G is the gravitational constant.

Coulomb's law has survived every experimental test; no exceptions to it have ever been found. It holds even within the atom, correctly describing the force between the positively charged nucleus and each of the negatively charged electrons. This is true even though classical Newtonian mechanics fails in that realm and is replaced there by quantum physics. This simple law also correctly accounts for the forces that bind atoms together to form molecules and for the forces that bind atoms and molecules together to form solids and liquids.

The Coulomb constant k is often replaced by a factor $1/4\pi\epsilon_0$ where $\epsilon_0 = 4\pi k$. As you will see later this more complicated expression for the electrostatic constant simplifies many related equations that we have not yet introduced. Substituting the $1/4\pi\epsilon_0$ term for k gives an alternate form of Coulomb's law as

$$F_{A \rightarrow B}^{\text{elec}} = \frac{1}{4\pi\epsilon_0} \frac{|q_A||q_B|}{r^2} \quad (\text{Coulomb's law}), \quad (22-6)$$

where k has the value

$$k = \frac{1}{4\pi\epsilon_0} = 8.99 \times 10^9 \text{ N} \cdot \text{m}^2/\text{C}^2 \quad (\text{Coulomb constant}). \quad (22-7)$$

The quantity ϵ_0 , known as the **electric constant** (sometimes called the *permittivity constant* or simply *epsilon sub zero*), often appears separately in equations and is given by

$$\epsilon_0 = 8.85 \times 10^{-12} \text{ C}^2/\text{N} \cdot \text{m}^2 \quad (\text{electric constant}). \quad (22-8)$$

READING EXERCISE 22-10: Use the information provided at the end of Section 22-4 and in Fig. 22-6 to explain why the following statements cannot be true: (a) The force between two charged particle-like objects is independent of the charge on the objects. (b) The magnitude of the force between two charged particle-like objects is proportional to $1/|q_A||q_B|$. (c) The force between two charged objects is proportional to $|q_A| + |q_B|$. ■

22-8 Solving Problems Using Coulomb's Law

Coulomb's law can be used to find the forces on particle-like objects having excess charge on them. When solving quantitative (numerical) problems using Coulomb's law, there are several issues to keep in mind. For example, we must be sure to express the charges in coulombs and the distance between the charges in meters. These are the SI units for distance and charge and are required if we are to use the standard value for the Coulomb constant shown in Eq. 22-7. As we discussed in Section 22-7, we must calculate the magnitude of the force using the (positive) absolute value of the charges. We should then make a sketch of the situation, showing the direction of the force and adopting a coordinate system. If the force acts in the negative direction, then we associate a negative sign with the magnitude of the force.

What happens if there are more than two charges interacting as shown in Fig. 22-16?

FIGURE 22-16 (a) A set of particle-like objects with excess charge on them that lie along a line. The force vectors depict the forces of charges B and C on charge A . (b) A similar diagram showing the force vectors on charge A when the other charges do not lie along the same line.

Superposition of Forces

As is the case with all other forces (including the gravitational force), the electrostatic force obeys the principle of superposition. For example, if we have 4 charged particles, they interact *independently in pairs*, and the force on any one of the charges, let us say particle A , is given by the vector sum

$$\vec{F}_A^{\text{net}} = \vec{F}_{B \rightarrow A} + \vec{F}_{C \rightarrow A} + \vec{F}_{D \rightarrow A}, \quad (22-9)$$

in which, for example, $\vec{F}_{D \rightarrow A}$ is the force acting on particle A due to the presence of particle D .

Often, as is the case for the charges in Fig. 22-16b, the various forces acting on a particle do not all act along the same line. We know how to combine forces such as these, but let's review the process. First we must calculate the magnitudes of the

individual forces (in this case, using Coulomb's law), adopt a coordinate system, and determine the directions of the forces. We then calculate the orthogonal (perpendicular) components of each force and determine the direction of these components. For example, this might mean determining the x - and y -components of each of the forces as well as determining whether those components are in the positive or negative direction. We then add or subtract all of the components of forces that act along the same line. We add or subtract depending on whether the components are in the same or opposite directions. This gives us the components of the net (resultant) force. We then use trigonometry to get the magnitude and direction of the resultant force. These steps are presented in brief below.

Steps to Solving Quantitative Problems Using Coulomb's Law

Although the steps that follow are illustrated using the configuration of charges in Fig. 22-17a, they should work for any combination of charged particles.

FIGURE 22-17 ■ Diagrams used to illustrate steps in problem solving using Coulomb's law.

1. Sketch the array of charged objects and draw arrows to represent the anticipated directions of forces on the charged object of interest due to the surrounding charges. An example is shown in Fig. 22-17b where q_A is the charge of interest.
2. Use Coulomb's law to calculate the *magnitudes* of the individual forces on the charged particle of interest.
3. Determine the directions of the forces and create a free-body diagram like that shown in Fig. 22-17b.
4. Choose a coordinate system and sketch it on your diagram as shown in Fig. 22-17c.
5. Calculate the orthogonal (perpendicular) vector components of each force along the coordinate directions using the expressions $F_x = F \cos\theta$ and $F_y = F \sin\theta$, (or equivalent expressions) where F is the magnitude of the force on particle A .
6. Determine the sign of these components based on their directions.
7. Combine all the force components that act along the same line.
8. Combine the resultant components to get the magnitude of the resultant force using the expression

$$[F^{\text{net}}]^2 = [F_x^{\text{net}}]^2 + [F_y^{\text{net}}]^2. \quad (22-10)$$

9. Determine the angle at which the force acts (relative to the positive x axis) using

$$\tan \theta = \frac{F_y^{\text{net}}}{F_x^{\text{net}}}, \quad (22-11)$$

or alternatively express the force in vector notation as $\vec{F}^{\text{net}} = F_x^{\text{net}}\hat{i} + F_y^{\text{net}}\hat{j}$.

READING EXERCISE 22-11: The figure shows two protons (symbol p) and one electron (symbol e) on an axis. What are the directions of (a) the electrostatic force on the central proton due to the electron, (b) the electrostatic force on the central proton due to the other proton, and (c) the net electrostatic force on the central proton? Are there any points along the line connecting the three charges where the central proton can be moved so that the net force on it is zero? Explain your reasoning and how your answers relate to superposition for forces.

TOUCHSTONE EXAMPLE 22-1: Force on a Charge

(a) Figure 22-18a shows two positively charged particles fixed in place on an x axis. The charges are $q_A = 1.60 \times 10^{-19}$ C and $q_B = 3.20 \times 10^{-19}$ C, and the particle separation is $R = 0.0200$ m. What are the magnitude and direction of the electrostatic force $\vec{F}_{B \rightarrow A}$ on particle A from particle B?

FIGURE 22-18 (a) Two charged particles of charges q_A and q_B are fixed in place on an x axis, with separation R . (b) The free-body diagram for particle A, showing the electrostatic force on it from particle B. (c) Particle C is now fixed in place on the x axis between particles A and B. (d) The free-body diagram for particle A due to particles B and C. (e) Particle D is fixed in place on a line at angle θ to the x axis with just particles A and B present. (f) The new free-body diagram for particle A due to particles B and D.

SOLUTION ■ The **Key Idea** here is that, because both particles are positively charged, particle A is repelled by particle B, with a force magnitude given by Eq. 22-4. Thus, the direction of force $\vec{F}_{B \rightarrow A}$ on particle A is *away from* particle B, in the negative direction of the x axis, as indicated in the free-body diagram of Fig. 22-18b. Using Eq. 22-4 with separation R substituted for r , we can write the magnitude $F_{B \rightarrow A}$ of this force as

$$\begin{aligned} F_{B \rightarrow A} &= k \frac{|q_A| |q_B|}{R^2} \\ &= (8.99 \times 10^9 \text{ N} \cdot \text{m}^2/\text{C}^2) \times \frac{(1.60 \times 10^{-19} \text{ C})(3.20 \times 10^{-19} \text{ C})}{(0.0200 \text{ m})^2} \\ &= 1.15 \times 10^{-24} \text{ N}. \end{aligned}$$

Thus, force $\vec{F}_{B \rightarrow A}$ has the following magnitude and direction (relative to the positive direction of the x axis):

$$1.15 \times 10^{-24} \text{ N} \quad \text{and} \quad 180^\circ. \quad (\text{Answer})$$

We can also write $\vec{F}_{B \rightarrow A}$ in unit-vector notation as

$$\vec{F}_{B \rightarrow A} = -(1.15 \times 10^{-24} \text{ N})\hat{i}. \quad (\text{Answer})$$

(b) Figure 22-18c is identical to Fig. 22-18a except that particle C now lies on the x axis between particles A and B. Particle C has charge $q_C = -3.20 \times 10^{-19}$ C and is at a distance $\frac{3}{4}R$ from particle A. What is the net electrostatic force \vec{F}_A^{net} on particle A due to particles B and C?

SOLUTION ■ One **Key Idea** here is that the presence of particle C does not alter the electrostatic force on particle A from particle B. Thus, force $\vec{F}_{B \rightarrow A}$ still acts on particle A. Similarly, the force $\vec{F}_{C \rightarrow A}$ that acts on particle A due to particle C is not affected by the presence of particle B. Because particles A and C have charge of opposite sign, particle A is attracted to particle C. Thus, force $\vec{F}_{C \rightarrow A}$ is directed *toward* particle C, as indicated in the free-body diagram of Fig. 22-18d.

To find the magnitude of $\vec{F}_{C \rightarrow A}$, we can rewrite Eq. 22-4 as

$$\begin{aligned} F_{C \rightarrow A} &= k \frac{|q_A| |q_C|}{(\frac{3}{4}R)^2} \\ &= (8.99 \times 10^9 \text{ N} \cdot \text{m}^2/\text{C}^2) \times \frac{(1.60 \times 10^{-19} \text{ C})(3.20 \times 10^{-19} \text{ C})}{(\frac{3}{4})(0.0200 \text{ m})^2} \\ &= 2.05 \times 10^{-24} \text{ N}. \end{aligned}$$

We can also write $\vec{F}_{C \rightarrow A}$ in unit-vector notation:

$$\vec{F}_{C \rightarrow A} = +(2.05 \times 10^{-24} \text{ N})\hat{i}.$$

A second **Key Idea** here is that the net force \vec{F}_A^{net} on particle A is the vector sum of $\vec{F}_{B \rightarrow A}$ and $\vec{F}_{C \rightarrow A}$; that is, from Eq. 22-9, we can write the net force \vec{F}_A^{net} on particle A in unit-vector notation as

$$\begin{aligned} \vec{F}_A^{\text{net}} &= \vec{F}_{B \rightarrow A} + \vec{F}_{C \rightarrow A} \\ &= -(1.15 \times 10^{-24} \text{ N})\hat{i} + (2.05 \times 10^{-24} \text{ N})\hat{i} \\ &= (9.00 \times 10^{-25} \text{ N})\hat{i}. \quad (\text{Answer}) \end{aligned}$$

Thus, \vec{F}_A^{net} has the following magnitude and direction (relative to the positive direction of the x axis):

$$9.00 \times 10^{-25} \text{ N} \quad \text{and} \quad 0^\circ. \quad (\text{Answer})$$

(c) Figure 22-18e is identical to Fig. 22-18a except that particle D is now positioned as shown. Particle D has charge $q_D = -3.20 \times 10^{-19}$ C, is at a distance $\frac{3}{4}R$ from particle A, and lies on a line that makes an angle $\theta = 60^\circ$ with the x axis. What is the net electrostatic force \vec{F}_A^{net} on particle A due to particles B and D?

SOLUTION ■ The **Key Idea** here is that the net force \vec{F}_A^{net} is the vector sum of $\vec{F}_{B \rightarrow A}$ and a new force $\vec{F}_{D \rightarrow A}$ acting on particle A due to particle D. Because particles A and D have charges of opposite sign, particle A is attracted to particle D. Thus, force $\vec{F}_{D \rightarrow A}$ on

particle A is directed *toward* particle D , at angle $\theta = 60^\circ$, as indicated in the free-body diagram of Fig. 22-18f.

To find the magnitude of $\vec{F}_{D \rightarrow A}$, we can rewrite Eq. 22-4 as

$$\begin{aligned} |\vec{F}_{D \rightarrow A}| &= k \frac{|q_A||q_D|}{(\frac{3}{4}R)^2} \\ &= (8.99 \times 10^9 \text{ N} \cdot \text{m}^2/\text{C}^2) \times \frac{(1.60 \times 10^{-19} \text{ C})(3.2 \times 10^{-19} \text{ C})}{(\frac{3}{4})^2(0.0200 \text{ m})^2} \\ &= 2.05 \times 10^{-24} \text{ N}. \end{aligned}$$

Then from Eq. 22-9, we can write the net force \vec{F}_A^{net} on particle A as

$$\vec{F}_A^{\text{net}} = \vec{F}_{B \rightarrow A} + \vec{F}_{D \rightarrow A}.$$

To evaluate the right side of this equation, we need another **Key Idea**: Because the forces $\vec{F}_{B \rightarrow A}$ and $\vec{F}_{D \rightarrow A}$ are not directed along the same axis, we *cannot* sum simply by combining their magnitudes. Instead, we must add them as vectors, using one of the following methods.

Method 1. *Summing directly on a vector-capable calculator.* For $\vec{F}_{B \rightarrow A}$, we enter the magnitude 1.15×10^{-24} and the angle 180° . For $\vec{F}_{D \rightarrow A}$, we enter the magnitude 2.05×10^{-24} and the angle 60° . Then we add the vectors.

Method 2. *Summing in unit-vector notation.* First we rewrite $\vec{F}_{D \rightarrow A}$ as

$$\vec{F}_{D \rightarrow A} = (F_{D \rightarrow A} \cos \theta) \hat{i} + (F_{D \rightarrow A} \sin \theta) \hat{j}.$$

Substituting 2.05×10^{-24} N for $F_{D \rightarrow A}$ and 60° for θ , this becomes

$$\vec{F}_{D \rightarrow A} = (1.025 \times 10^{-24} \text{ N}) \hat{i} + (1.775 \times 10^{-24} \text{ N}) \hat{j}.$$

Then we sum:

$$\begin{aligned} \vec{F}_A^{\text{net}} &= \vec{F}_{B \rightarrow A} + \vec{F}_{D \rightarrow A} \\ &= -(1.15 \times 10^{-24} \text{ N}) \hat{i} + (1.025 \times 10^{-24} \text{ N}) \hat{i} + (1.775 \times 10^{-24}) \hat{j} \\ &\approx (-1.25 \times 10^{-25} \text{ N}) \hat{i} + (1.78 \times 10^{-24} \text{ N}) \hat{j}. \end{aligned} \quad (\text{Answer})$$

Method 3. *Summing components axis by axis.* The sum of the x -components gives us

$$\begin{aligned} \vec{F}_{Ax}^{\text{net}} &= F_{B \rightarrow Ax} + F_{D \rightarrow Ax} = F_{B \rightarrow A} + F_{D \rightarrow A} \cos 60^\circ \\ &= -1.15 \times 10^{-24} \text{ N} + (2.05 \times 10^{-24} \text{ N})(\cos 60^\circ) \\ &= -1.25 \times 10^{-25} \text{ N}. \end{aligned}$$

The sum of the y -components gives us

$$\begin{aligned} F_{Ay}^{\text{net}} &= F_{B \rightarrow Ay} + F_{D \rightarrow Ay} = 0 + F_{D \rightarrow A} \sin 60^\circ \\ &= (2.05 \times 10^{-24} \text{ N})(\sin 60^\circ) \\ &= 1.78 \times 10^{-24} \text{ N}. \end{aligned}$$

The net force \vec{F}_A^{net} has the magnitude

$$F_A^{\text{net}} = \sqrt{(F_{Ax}^{\text{net}})^2 + (F_{Ay}^{\text{net}})^2} = 1.78 \times 10^{-24} \text{ N}.$$

To find the direction of \vec{F}_A^{net} , we take

$$\theta = \tan^{-1} \frac{F_{Ay}^{\text{net}}}{F_{Ax}^{\text{net}}} = -86.0^\circ.$$

However, this is an unreasonable result because \vec{F}_A^{net} must have a direction between the directions of $\vec{F}_{B \rightarrow A}$ and $\vec{F}_{D \rightarrow A}$. To correct θ , we add 180° , obtaining

$$-86.0^\circ + 180^\circ = 94.0^\circ. \quad (\text{Answer})$$

TOUCHSTONE EXAMPLE 22-2: Equilibrium Point

Figure 22-19a shows two particles fixed in place: a particle of charge $q_A = +8q$ at the origin and a particle of charge $q_B = -2q$ at $x = L$. At what point (other than infinitely far away) can a proton of charge q_p be placed so that it is in *equilibrium* (meaning that the net force on it is zero)? Is that equilibrium *stable* or *unstable*?

FIGURE 22-19 (a) Two particles of charges q_A and q_B are fixed in place on an x axis, with separation L . (b)–(d) Three possible locations P , S , and R for a proton. At each location, $\vec{F}_{A \rightarrow p}$ represents the force on the proton from particle A and $\vec{F}_{B \rightarrow p}$ represents the force on the proton from particle B .

SOLUTION ■ The **Key Idea** here is that, if $\vec{F}_{A \rightarrow p}$ is the force on the proton due to charge q_A and $\vec{F}_{B \rightarrow p}$ is the force on the proton due to charge q_B , then the point we seek is where $\vec{F}_{A \rightarrow p} + \vec{F}_{B \rightarrow p} = 0$. This condition requires that

$$\vec{F}_{A \rightarrow p} = -\vec{F}_{B \rightarrow p}. \quad (22-12)$$

This tells us that at the point we seek, the forces acting on the proton due to the other two particles must be of equal magnitudes,

$$|\vec{F}_{A \rightarrow p}| = |\vec{F}_{B \rightarrow p}|, \quad (22-13)$$

and that the forces must have opposite directions.

A proton has a positive charge. Thus, the proton and the particle of charge q_A are of the same sign, and force $\vec{F}_{A \rightarrow p}$ on the proton must point away from q_A . Also, the proton and the particle of charge q_B are of opposite signs, so force $\vec{F}_{B \rightarrow p}$ on the proton must point toward q_B . “Away from q_A ” and “toward q_B ” can be in opposite directions only if the proton is located on the x axis.

If the proton is on the x axis at any point between q_A and q_B , such as P in Fig. 22-19b, then $\vec{F}_{A \rightarrow p}$ and $\vec{F}_{B \rightarrow p}$ are in the same direction and not in opposite directions as required. If the proton is at any point on the x axis to the left of q_A , such as point S in Fig. 22-9c, then $\vec{F}_{A \rightarrow p}$ and $\vec{F}_{B \rightarrow p}$ are in opposite directions. However, Eq. 22-4 tells us that $\vec{F}_{A \rightarrow p}$ and $\vec{F}_{B \rightarrow p}$ cannot have equal magnitudes there: $|\vec{F}_{A \rightarrow p}|$ must be greater than $|\vec{F}_{B \rightarrow p}|$, because $|\vec{F}_{A \rightarrow p}|$ is produced by a closer charge (with lesser r) of greater magnitude ($8q$ versus $2q$).

Finally, if the proton is at any point on the x axis to the right of q_B , such as point R in Fig. 22-19d, then $\vec{F}_{A \rightarrow p}$ and $\vec{F}_{B \rightarrow p}$ are again in opposite directions. However, because now the charge of greater

amount (q_A) is farther away from the proton than the charge of lesser amount, there is a point at which $|\vec{F}_{A \rightarrow p}|$ is equal to $|\vec{F}_{B \rightarrow p}|$. Let x be the coordinate of this point, and let q_p be the charge of the proton. Then with the aid of Eq. 22-4, we can rewrite Eq. 22-13 as

$$k \frac{8|q||q_p|}{x^2} = k \frac{2|q||q_p|}{(x-L)^2}. \quad (22-14)$$

(Note that only the charge amounts appear in Eq. 22-14.) Rearranging Eq. 22-14 gives us

$$\left(\frac{x-L}{x}\right)^2 = \frac{1}{4}.$$

After taking the square roots of both sides, we have

$$\frac{x-L}{x} = \frac{1}{2},$$

which gives us

$$x = 2L. \quad (\text{Answer})$$

The equilibrium at $x = 2L$ is unstable; that is, if the proton is displaced leftward from point R , then $|\vec{F}_{A \rightarrow p}|$ and $|\vec{F}_{B \rightarrow p}|$ both increase but $|\vec{F}_{B \rightarrow p}|$ increases more (because q_B is closer than q_A), and a net force will drive the proton farther leftward. If the proton is displaced rightward, both $|\vec{F}_{A \rightarrow p}|$ and $|\vec{F}_{B \rightarrow p}|$ decrease but $|\vec{F}_{B \rightarrow p}|$ decreases more, and a net force will then drive the proton farther rightward. In a stable equilibrium, each time the proton was displaced slightly, it would return to the equilibrium position.

22-9 Comparing Electrical and Gravitational Forces

Consider two point-like objects, A and B , separated by a distance r . What are the magnitudes of the electrical and gravitational forces between them?

$$F_{A \rightarrow B}^{\text{elec}} = k \frac{|q_A||q_B|}{r^2} \quad (\text{Coulomb's Law}), \quad (\text{Eq. 22-4})$$

has the same form as that of Newton's equation for the gravitational force between two particles with masses m_A and m_B that are separated by a distance r :

$$F_{A \rightarrow B}^{\text{grav}} = G \frac{m_A m_B}{r^2} \quad (\text{Newton's Law of gravitation}). \quad (14-2)$$

Both of these equations have the distance between the two interacting objects squared and in the denominator of the fraction. That is, they are both “inverse square laws.” Both also involve a property of the interacting particles—the mass in one case and the charge in the other. Both the gravitational force and the electrostatic force are conservative forces—the work done by these forces around a closed path is zero. Both forces act along the line connecting the two objects—such forces are called “central” forces.

However, as similar as these forces are, they are not the same force. They are not even different aspects of one force. How do we know this? Electrostatic forces are intrinsically much stronger than gravitational forces. For example, the gravitational attraction between a plastic comb and a small piece of paper is not large enough to overcome the opposing gravitational attraction of Earth on the paper. However, if

you rub the comb with fur, the resulting electrostatic force *is* large enough to overcome the gravitational attraction of Earth. Furthermore, the electrostatic force differs from the gravitational forces because the gravitational force is always attractive but the electrostatic force may be *either* attractive or repulsive, depending on the signs of the two charges. This difference arises because although there is only one kind of mass, there are two kinds of charge. That is why absolute value signs are needed in

$$F_{A \rightarrow B}^{\text{elec}} = k \frac{|q_A||q_B|}{r^2}$$

but not in

$$F_{A \rightarrow B}^{\text{grav}} = G \frac{m_A m_B}{r^2}.$$

Before concluding our discussion of the electrostatic or Coulomb force, let's compare it to another somewhat similar force—the force associated with magnets.

In addition to amber, the early Greeks knew of another special material that had the ability to attract other objects. They recorded the observation that some naturally occurring “lodestones,” known today as the mineral magnetite, would attract iron. Lodestones were the first known magnets. Could the phenomena of amber (electricity) and lodestones (magnetism) be related?

Observation of the interactions between two magnets and two electrified objects shows that the phenomena of electricity and magnetism are *not* the same. Two magnets will either attract or repel one another, depending on their orientation. Two pieces of rubbed amber (or glass) always repel one another, regardless of their orientation.

Hence, the study of electricity and magnetism developed separately for centuries—until 1820, in fact, when Hans Christian Oersted found a connection between them: an electric current in a wire can deflect a magnetic compass needle. The new science of *electromagnetism* (the combination of electrical and magnetic phenomena) was developed further by Michael Faraday, a truly gifted experimenter with a talent for physical intuition and visualization. In fact, Faraday's laboratory notebooks do not contain a single equation. In the mid-19th century, James Clerk Maxwell put Faraday's ideas into mathematical form, introduced many new ideas of his own, and put electromagnetism on a sound theoretical basis.

Table 32-1 shows the basic laws of electromagnetism, now called Maxwell's equations. We plan to work our way through them in the chapters between here and there, but you might want to glance at them now, to see where we are heading.

TOUCHSTONE EXAMPLE 22-3: Nuclear Repulsion

The nucleus in an iron atom has a radius of about 4.0×10^{-15} m and contains 26 protons.

(a) What is the magnitude of the repulsive electrostatic force between two of the protons that are separated by 4.0×10^{-15} m?

SOLUTION ■ The **Key Idea** here is that the protons can be treated as charged particles, so the magnitude of the electrostatic force on one from the other is given by Coulomb's law. Table 22-1 tells us that their charge is $+e$. Thus, Eq. 22-4 gives us

$$\begin{aligned} F^{\text{elec}} &= \frac{ke^2}{r^2} \\ &= \frac{(8.99 \times 10^9 \text{ N} \cdot \text{m}^2/\text{C}^2)(1.60 \times 10^{-19} \text{ C})^2}{(4.0 \times 10^{-15} \text{ m})^2} \\ &= 14 \text{ N}. \end{aligned} \quad (\text{Answer})$$

This is a small force to be acting on a macroscopic object like a cantaloupe but an enormous force to be acting on a proton. Such forces should blow apart the nucleus of any element but hydrogen (which has only one proton in its nucleus). However, they don't, not even in nuclei with a great many protons. Therefore, there must be some enormous attractive force to counter this enormous repulsive electrostatic force.

(b) What is the magnitude of the gravitational force between those same two protons?

SOLUTION ■ The **Key Idea** here is like that in part (a): Because the protons are particles, the magnitude of the gravitational force on one from the other is given by Newton's equation for the gravitational force (Eq. 14-2). With $m_p (= 1.67 \times 10^{-27} \text{ kg})$ repre-

sending the mass of a proton, Eq. 14-2 gives us

$$\begin{aligned}
 F &= G \frac{m_p^2}{r^2} \\
 &= \frac{(6.67 \times 10^{-11} \text{N} \cdot \text{m}^2/\text{kg}^2)(1.67 \times 10^{-27} \text{kg})}{(4.0 \times 10^{-15} \text{m})^2} \\
 &= 1.2 \times 10^{-35} \text{N}. \quad (\text{Answer})
 \end{aligned}$$

This result tells us that the (attractive) gravitational force is far too weak to counter the repulsive electrostatic forces between protons in a nucleus. Instead, the protons are bound together by an

enormous force aptly called the *strong nuclear force*—a force that acts between protons (and neutrons) when they are close together, as in a nucleus.

Although the gravitational force is many times weaker than the electrostatic force, it is more important in large-scale situations because it is always attractive. This means that it can collect many small bodies into huge bodies with huge masses, such as planets and stars, that then exert large gravitational forces. The electrostatic force, on the other hand, is repulsive for charges of the same sign, so it is unable to collect either positive charge or negative charge into large concentrations that would then exert large electrostatic forces.

22-10 Many Everyday Forces Are Electrostatic

In Chapter 6 we presented an idealized model of a solid as an array of atoms held together by forces that act like tiny springs that resist both stretching and compression forces. We then used this spring model to help explain the nature of most of the everyday forces encountered in the study of motion including normal forces, friction forces, and tension forces. We made the claim that all of these forces are basically electrical.

Let's look once again at our spring model of solids in light of our new understanding of the nature of the electrostatic forces between protons and electrons in atoms. Since protons and electrons have opposite charges they attract each other. This is what holds individual atoms together and causes a tension force to arise in a string as it resists stretching. Under compression, the outer electrons in the atoms of one object repel the outer electrons in the other object. This is the origin of the normal force. Although we imagine this repulsion starting at the surface, it is happening in other layers of atoms as well. As the electrons from one layer of atoms are being moved closer to those in the next layer, the repulsion forces increase sharply as the electrons are forced closer together.

Thus, we think of a solid as having a delicately balanced equilibrium in which the electron glue holds the atoms together at just the right spacing. Although more detailed analysis of these phenomena requires quantum mechanics, all of the everyday forces we encounter appear to be either gravitational, electrical, or magnetic. We explore the relationship between electrostatic and magnetic interactions further in Chapter 32.

Problems

SEC. 22-4 ■ USING ATOMIC THEORY TO EXPLAIN CHARGING

- 1. A Large Charge** What is the total charge in coulombs of 75.0 kg of electrons?
- 2. How Many?** How many megacoulombs of positive (or negative) charge are in 1.00 mol of neutral molecular-hydrogen gas (H_2)?
- 3. How Many Electrons** How many electrons would have to be removed from a coin to leave it with a charge of $+1.0 \times 10^{-7} \text{C}$?
- 4. Glass of Water** Calculate the number of coulombs of positive charge in 250cm^3 of (neutral) water (about a glassful).
- 5. Cosmic Ray Protons** Earth's atmosphere is constantly bombarded by *cosmic ray protons* that originate somewhere in space. If the protons all passed through the atmosphere, each square meter of Earth's surface would intercept protons at the average rate of 1500 protons per second. What would be the corresponding rate of charge flow intercepted by the total surface area of the planet?

6. Fibrillation A charge flow of 0.300 C/s through your chest can send your heart into fibrillation, disrupting the flow of blood (and thus oxygen) to your brain. If that current persists for 2.00 min , how many conduction electrons pass through your chest?

7. Beta Decay In *beta decay* a massive fundamental particle changes to another massive particle, and either an electron of charge $-e$ or a positron of charge $+e$ (positive particle with the same amount of charge and mass as an electron) is emitted. (a) If a proton undergoes beta decay to become a neutron, which particle is emitted? (b) If a neutron undergoes beta decay to become a proton, which particle is emitted?

8. Identify X Identify X in the following nuclear reactions (in the first, n represents a neutron): (a) ${}^1\text{H} + {}^9\text{Be} \rightarrow \text{X} + \text{n}$; (b) ${}^{12}\text{C} + {}^1\text{H} \rightarrow \text{X}$; (c) ${}^{15}\text{N} + {}^1\text{H} \rightarrow {}^4\text{He} + \text{X}$. Appendix F will help.

SEC. 22-8 ■ SOLVING PROBLEMS USING COULOMB'S LAW

9. What Distance At what distance between point charge $q_A = 26.0\ \mu\text{C}$ and point charge $q_B = -47.0\ \mu\text{C}$ will the electrostatic force between them have a magnitude of 5.70 N ?

10. Force on Each A point charge of $+3.00 \times 10^{-6}\text{ C}$ is 12.0 cm from a second point charge of $-1.50 \times 10^{-6}\text{ C}$. Calculate the magnitude of the force on each charge.

11. Two Equally Charged Two equally charged particles, held $3.2 \times 10^{-3}\text{ m}$ apart, are released from rest. The initial acceleration of the first particle is observed to be 7.0 m/s^2 and that of the second to be 9.0 m/s^2 . If the mass of the first particle is $6.3 \times 10^{-7}\text{ kg}$, what are (a) the mass of the second particle and (b) the amount of charge on each particle?

12. Isolated Conducting Spheres Identical isolated conducting spheres A and B have the same excess charges and are separated by a distance that is large compared with their diameters (Fig. 22-20a). The electrostatic force acting on sphere B due to sphere A is $\vec{F}_{A \rightarrow B}$. Suppose now that a third identical sphere C, having an insulating handle and initially neutral, is touched first to sphere A (Fig. 22-20b), then to sphere B (Fig. 22-20c), and finally removed (Fig. 22-20d). In terms of the force magnitude $F_{A \rightarrow B}$, what is the magnitude of the electrostatic force $\vec{F}'_{A \rightarrow B}$ that now acts on sphere B?

FIGURE 22-20 ■ Problem 12.

13. The Square In Fig. 22-21, what are the (a) horizontal and (b) vertical components of the net electrostatic force on the charged particle in the lower left corner of the square if $q = 1.0 \times 10^{-7}\text{ C}$ and $a = 5.0\text{ cm}$?

FIGURE 22-21 ■ Problem 13.

14. Where Along the Line Point charges q_A and q_B lie on the x axis at points $x = -d$ and $x = +d$, respectively. (a) How must q_A and q_B be related for the net electrostatic force on point charge $+Q$, placed at $x = +d/2$, to be zero? (b) Repeat (a) but with point charge $+Q$ now placed at $x = +3d/2$.

15. Two Identical Spheres Two identical conducting spheres, fixed in place, attract each other with an electrostatic force of 0.108 N when separated by 50.0 cm , center to center. The spheres are then connected by a thin conducting wire. When the wire is removed, the spheres repel each other with an electrostatic force of 0.0360 N . What were the initial charges on the spheres?

16. Three Charges In Fig. 22-22, three charged particles lie on a straight line and are separated by distances d . Charges q_A and q_B are held fixed. Charge q_C is

FIGURE 22-22 ■ Problem 16.

free to move but happens to be in equilibrium (no net electrostatic force acts on it). Find q_A in terms of q_B .

17. Two Free Particles Two free particles (that is, free to move) with charges $+q$ and $+4q$ are a distance L apart. A third charge is placed so that the entire system is in equilibrium. (a) Find the location, amount and sign of the third charge. (b) Show that the equilibrium is unstable.

18. Two Fixed Particles Two fixed particles, of charges $q_A = +1.0\ \mu\text{C}$ and $q_B = -3.0\ \mu\text{C}$, are 10 cm apart. How far from each should a third charge be located so that no net electrostatic force acts on it?

19. A Certain Charge Q A certain charge Q is divided into two parts q and $Q - q$, which are then separated by a certain distance. What must q be in terms of Q to maximize the electrostatic repulsion between the two charges?

20. Charges and Coordinates The charges and coordinates of two charged particles held fixed in the xy plane are $q_A = +3.0\ \mu\text{C}$, $x_A = 3.5\text{ cm}$, $y_A = 0.50\text{ cm}$, and $q_B = -4.0\ \mu\text{C}$, $x_B = -2.0\text{ cm}$, $y_B = 1.5\text{ cm}$. (a) Find the magnitude and direction of the electrostatic force on q_B . (b) Where could you locate a third charge $q_C = +4.0\ \mu\text{C}$ such that the net electrostatic force on q_B is zero?

21. Identical Ions The magnitude of the electrostatic force between two identical ions that are separated by a distance of $5.0 \times 10^{-10}\text{ m}$ is $3.7 \times 10^{-9}\text{ N}$. (a) What is the charge of each ion? (b) How many electrons are “missing” from each ion (thus giving the ion its charge imbalance)?

22. Salt Crystal What is the magnitude of the electrostatic force between a singly charged sodium ion (Na^+ , of charge $+e$) and an adjacent singly charged chlorine ion (Cl^- , of charge $-e$) in a salt crystal if their separation is $2.82 \times 10^{-10}\text{ m}$?

23. Cesium Chloride In the basic CsCl (cesium chloride) crystal structure, Cs^+ ions form the corners of a cube and a Cl^- ion is at the cube's

center (Fig. 22-23). The edge length of the cube is 0.40 nm. The Cs^+ ions are each deficient by one electron (and thus each has a charge of $+e$), and the Cl^- ion has one excess electron (and thus has a charge of $-e$).

FIGURE 22-23 ■ Problem 23.

(a) What is the magnitude of the net electrostatic force exerted on the Cl^- ion by the eight Cs^+ ions at the corners of the cube? (b) If one of the Cs^+ ions is missing, the crystal is said to have a *defect*; what is the magnitude of the net electrostatic force exerted on the Cl^- ion by the seven remaining Cs^+ ions?

24. Water Drops Two tiny, spherical water drops, with identical charges of -1.00×10^{-16} C, have a center-to-center separation of 1.00 cm. (a) What is the magnitude of the electrostatic force acting between them? (b) How many excess electrons are on each drop, giving it its charge imbalance?

25. Beads Figure 22-24 shows four tiny charged beads that can be slid or fixed in place on wires that stretch along x and y axes. A central bead at the crossing point of the wires (the origin) has a charge of $+e$. The other beads each have a charge of $-e$. Initially beads A , B , and C are at distance $d = 10.0$ cm from the central bead, and bead D is at a distance of $d/2$. (a) How far from the central bead must you position bead A so that the direction of the net electrostatic force \vec{F}^{net} on the central bead rotates counterclockwise by 30° ? (b) With bead A still in its new position, where must you slide bead C so that the direction of \vec{F}^{net} rotates back by 30° ?

FIGURE 22-24 ■ Problem 25.

26. Two Copper Coins We know that the negative charge on the electron and the positive charge on the proton are equal in amount. Suppose, however, that these amounts differ from each other by 0.00010%. With what force would two copper coins, placed 1.0 m apart, repel each other? Assume that each coin contains 3×10^{22} copper atoms. (*Hint:* A neutral copper atom contains 29 protons and 29 electrons.) What do you conclude?

27. Particles A and B Figure 22-25a shows charged particles A and B that are fixed in place on an x axis. Particle A has an amount of charge of $|q_A| = 8.00e$. Particle C , with a charge of $q_C = +8.00e$, is

FIGURE 22-25 ■ Problem 27.

initially on the x axis near particle B . Then particle C is gradually moved in the positive direction of the x axis. As a result, the magnitude of the net electrostatic force \vec{F}_B^{net} on particle B due to particles A and C changes. Figure 22-25b gives the x -component of that net force as a function of the position x of particle C . The plot has an asymptote of $\vec{F}_B^{\text{net}} = 1.5 \times 10^{-25}$ N as $x \rightarrow \infty$. As a multiple of e , what is the charge q_B of particle B ?

28. Above the Floor In Fig. 22-26, a particle of charge $+4e$ is above a floor by distance $d_1 = 2.0$ mm and a particle of charge $+6e$ is on the floor at horizontal distance $d_2 = 6.0$ mm from the first particle. What is the x -component of the electrostatic force on the second particle due to the first particle?

FIGURE 22-26 ■ Problem 28.

29. Fixed on the x Axis In Fig. 22-27a, particle A (with charge q_A) and particle B (with charge q_B) are fixed in place on an x axis, 8.00 cm apart. Particle C with a charge $q_C = +5e$ is to be placed on the line between particles A and B , so that they produce a net electrostatic force \vec{F}_C^{net} on it. Figure 22-27b gives the x -component of that force versus the coordinate x at which particle C is placed. What are (a) the sign of charge q_A and (b) the ratio q_B/q_A ?

FIGURE 22-27 ■ Problem 29.

30. Four Charged Particles Figure 22-28 shows four charged particles that are fixed along an axis, separated by distance $d = 2.00$ cm. The charges are indicated. Find the magnitude and direction of the net electrostatic force on (a) the particle with charge $+2e$ and (b) the particle with charge $-e$, due to the other particles.

FIGURE 22-28 ■ Problem 30.

31. Split in Two A charge of $6.0 \mu\text{C}$ is to be split into two parts that are then separated by 3.0 mm. What is the maximum possible magnitude of the electrostatic force between those two parts?

32. Two on the Axis Figure 22-29 shows two particles, each of charge $+2e$, that are fixed on a y axis, each at a distance $d = 17$ cm from the x axis. A third particle, of charge $+4e$, is moved slowly along the x axis, from $x = 0$ to $x = +5.0$ m. At what values of x will the magnitude of the electrostatic force on the third particle from the other two particles be (a) minimum and (b) maximum? What are (c) the minimum magnitude and (d) the maximum magnitude?

FIGURE 22-29 ■ Problem 32.

33. How Far In Fig. 22-30, how far from the charged particle on the right and in what direction is there a point where a third charged particle will be in balance?

FIGURE 22-30 ■ Problem 33.

34. Three Positive Charges In Fig. 22-31a, three positively charged particles are fixed on an x axis. Particles B and C are so close to each other that they can be considered to be at the same distance from particle A . The net force on particle A due to particles B and C is 2.014×10^{-23} N in the negative direction of the x axis. In Fig. 22-31b, particle B has been moved to the opposite side of A but is still at the same distance from it. The net force on A is now 2.877×10^{-24} N in the negative direction of the x axis. What is the ratio of the charge of particle C to that of particle B ?

FIGURE 22-31 ■ Problem 34.

35. Fixed at the Origin A particle of charge Q is fixed at the origin of an xy coordinate system. At $t = 0$ a particle ($m = 0.800$ g, $q = 4.00$ μC) is located on the x axis at $x = 20.0$ cm, moving with a speed of 50.0 m/s in the positive y direction. For what value of Q will the moving particle execute circular motion? (Assume that the gravitational force on the particle may be neglected.)

36. Seven Charges Figure 22-32 shows an arrangement of seven positively charged particles that are separated from the central particle by distances of either d ($= 1.0$ cm) or $2d$, as drawn. The charges are indicated. What are the magnitude and direction of the net electrostatic force on the central particle due to the other six particles?

FIGURE 22-32 ■ Problem 36.

37. What is q In Fig. 22-33, what is q in terms of Q if the net electrostatic force on the charged particle at the upper left corner of the square array is to be zero?

FIGURE 22-33 ■ Problem 37.

38. Charges Figure 22-34a shows an arrangement of three charged particles separated by distance d . Particles A and C are fixed on the x axis, but particle B can be moved along a circle centered on particle A . During the

FIGURE 22-34 ■ Problem 38.

movement, a radial line between A and B makes an angle θ relative to the positive direction of the x axis (Fig. 22-34b). The curves in Fig. 22-34c give, for two situations, the magnitude F^{net} of the net electrostatic force on particle A due to the other particles. That net force magnitude is given as a function of angle θ and as a multiple of a basic force magnitude F . For example on curve 1, at $\theta = 180^\circ$, we see that $F^{\text{net}} = 2F$. (a) For the situation corresponding to curve 1, what is the ratio of the charge of particle C to that of particle B (including sign)? (b) For the situation corresponding to curve 2, what is that ratio?

39. Two Electrons—Two Ions

Figure 22-35 shows two electrons (charge $-e$) on an x axis and two negative ions of identical charges $-q$ and at identical angles θ . The central electron is free to move; the other particles are fixed in place at horizontal distances R and are intended to hold the free electron in place.

FIGURE 22-35 ■ Problem 39.

(a) Plot the required amount of q versus angle θ if this is to happen. (b) From the plot, determine which values of θ will be needed for physically possible values of $q \leq 5e$.

40. Diamond

Figure 22-36 shows an arrangement of four charged particles, with angle $\theta = 30^\circ$ and distance $d = 2.00$ cm. The two negatively charged particles on the y axis are electrons that are fixed in place. The particle at the right has a charge $q_B = +5e$. (a) Find distance D such that the net force on q_A , the particle at the left,

FIGURE 22-36 ■ Problem 40.

is zero. (b) If the two electrons were moved closer to the x axis, would the required value of D be greater than, less than, or the same as in part (a)?

41. Each Positive Two particles, each of positive charge q , are fixed in place on an x axis, one at $x = 0$ and the other at $x = +d$. A particle of positive charge Q is to be placed along that axis at locations given by $x = \alpha d$. (a) Write expressions, in terms of α , that give the net electrostatic force \vec{F}^{elec} acting on the third particle when it is in the three regions $x < 0$, $0 < x < d$, and $d < x$. The expressions should give a positive result when \vec{F}^{elec} acts in the positive direction of the x axis and a negative result when \vec{F}^{elec} acts in the negative direction. (b) Graph the magnitude of \vec{F}^{elec} versus α for the range $-2 < \alpha < 3$.

42. Particles A and B

In Fig. 22-37, particles A and B are fixed in place on an x axis, at a separation of $L = 8.00$ cm. Their charges are $q_A = +e$ and $q_B = -27e$. Particle C with charge $q_C = +4e$ is to be placed on the line between particles A and B , so that they produce a net electrostatic force \vec{F}_C^{net} on it. (a) At what coordinate should particle C be placed to minimize the magnitude of that force? (b) What is that minimum magnitude?

FIGURE 22-37 ■ Problem 42.

SEC. 22-9 ■ COMPARING ELECTRICAL AND GRAVITATIONAL FORCES

43. Earth and Moon (a) What equal positive charges would have to be placed on Earth and on the Moon to neutralize their gravitational attraction? Do you need to know the lunar distance to solve this problem? Why or why not? (b) How many kilograms of hydrogen would be needed to provide the positive charge calculated in (a)?

44. A Particle with Charge Q A particle with charge Q is fixed at each of two opposite corners of a square, and a particle with charge q is placed at each of the other two corners. (a) If the net electrostatic force on each particle with charge Q is zero, what is Q in terms of q ? (b) Is there any value of q that makes the net electrostatic force on each of the four particles zero? Explain.

45. Hang from Thread In Fig. 22-38, two tiny conducting balls of identical mass m and identical charge q hang from nonconducting threads of length L . Assume that θ is so small that $\tan \theta$ can be replaced by its approximate equal, $\sin \theta$. (a) Show that, for equilibrium,

$$x = \left(\frac{2kq^2L}{mg} \right)^{1/3},$$

where x is the separation between the balls. (b) If $L = 120$ cm, $m = 10$ g, and $x = 5.0$ cm, what is q ?

FIGURE 22-38 ■ Problem 45.

46. What Happens? Explain what happens to the balls of Problem 45b if one of them is discharged (loses its charge q to, say, the ground), and find the new equilibrium separation x , using the given values of L and m and the computed value of q .

47. Pivot Figure 22-39 shows a long, nonconducting, massless rod of length L , pivoted at its center and balanced with a block of weight W at a distance x from the left end. At the left and right ends of the rod are attached small conducting spheres with positive charges q and $2q$, respectively. At distance h directly beneath each of these spheres is a fixed sphere with positive charge Q . (a) Find the distance x when the rod is horizontal and balanced. (b) What value should h have so that the rod exerts no vertical force on the bearing when the rod is horizontal and balanced?

FIGURE 22-39 ■ Problem 47.

48. An Electron in a Vacuum An electron is in a vacuum near the surface of Earth. Where should a second electron be placed so that the electrostatic force it exerts on the first electron balances the gravitational force on the first electron due to Earth?

Additional Problems

49. Opposites Attract It is said that unlike charges attract. You can observe that after the sticky side of a piece of scotch tape is pulled quickly off the smooth side of another piece of tape the tapes attract each other. Perhaps each tape has a like charge and the rule has been stated backwards. Why do you believe the charges on the two tapes are different? *Note:* It is not acceptable to answer “because unlike charges attract and I observed the attraction.”

50. Hanging Ball of Foil (a) Explain how a metal conductor such as a hanging ball of aluminum foil can be attracted to a charged insulator *even though the ball of foil has no net charge so that it is electrically neutral*. (b) Can two metal balls with no net charge attract each other? Explain. (c) Can the process of induction cause a neutral conductor to be *repelled* from a charged insulator? Explain.

51. Four Balls Consider four lightweight metal-coated balls suspended on nonconducting threads as shown in Fig. 22-40. Suppose ball A is stroked with a plastic rod that has been rubbed with fur. When you observe interactions between pairs of balls one at a time you find that:

- B , C , and D are each attracted to A .

FIGURE 22-40 ■ Problem 51.

- B and C seem to have no effect on each other.
- B and C are both attracted to D .

Use the concept of electric induction to figure out what type of net charge is on each of the balls: Negative charge? Positive charge? No charge at all? Explain your reasoning. [Based on question 5.9, Arons, *Homework and Test Questions for Introductory Physics Teaching* (Wiley, New York, 1994).]

52. Plastic Rubbed with Fur Suppose you rub a plastic rod with fur that gives it a negative charge. You then bring it close to an uncharged metal coated Styrofoam ball that is suspended from a string. (a) When the rod gets close to the ball, the ball starts moving toward it. Use the concept of induction to explain what happens to the atomic electrons and protons in the ball. Include a sketch of the ball and the rod that shows the excess negative charges on the rod. Also show how the charges are distributed on the ball just before it touches the rod. (b) After the ball touches the rod, it moves away from the rod quickly. Explain why.

53. Small Charged Sphere A small, charged sphere of mass 5.0 g is released 32 cm away from a fixed point charge of $+5.0 \times 10^{-9}$ C. Immediately after release, the sphere is observed to accelerate toward the charge at 2.5 m/s². What is the charge on the sphere? *Hint:* The force of gravity can be ignored in your calculation.

54. Lightning Bolt In a lightning bolt electrons travel from a thundercloud to the ground. If there are 1.0×10^{20} electrons in a lightning bolt, how many coulombs of charge are dumped onto the ground?

55. Estimating Charge Two hard rubber spheres of mass ~ 10 g are rubbed vigorously with fur on a dry day. They are then suspended from a rod with two insulating strings. They are observed to hang at equilibrium as shown in Fig. 22-41, which is drawn approximately to scale. Estimate the amount of charge that is found on each sphere.

FIGURE 22-41 ■ Problem 55.

56. Various Arrangements Various arrangements of two fixed charges are shown in Fig. 22-42 along with a point labeled P . The amount of each charge is the same but the charges are positive or negative as indicated. All the distances between charges and between point P and the charge nearest to it are the same. Rank

these arrangements in order of the strength of the force (that is, its magnitude) on a tiny positive test charge located at point P in each case. Go from greatest to least and indicate when force magnitudes are the same using an equal to sign. For example, if the force magnitudes at (d) and (c) were the same as each other and were the greatest and (b) was less than (d) and (c) with (a) being the least, your answer would be $(d) = (c) > (b) > (a)$. Include a diagram and sketch the individual force vectors in each case. [Based on Ranking Task 128 O’Kuma, et. al., *Ranking Task Exercises in Physics* (Prentice Hall, Upper Saddle River NJ, 2000).]

FIGURE 22-42 ■ Problem 56.

23

Electric Fields

Coal-burning power plants account for 56% of the electricity generated in the United States. But coal is dirty, and smokestack emissions containing sulfur dioxide, nitrogen oxides, and fine particles are a health hazard. A demonstration model of a new Advanced Hybrid Particulate Collector (AHPC) was recently installed at South Dakota's Big Stone plant. This new collector virtually eliminates particulate emissions. Although there are filters in the collector, 90% of the smoke particles are removed using another method.

What technology is used to remove most of the pollutants in the AHPC?

The answer is in this chapter.

FIGURE 23-1 (a) Force field maps for gravitational forces near the Earth are relatively simple: This map shows the uniform nature of the gravitational force on a “test mass” placed at different locations within a vertical and horizontal distance of 10 km. Mt. Everest is in the background. The tails of the force vectors have been placed at various possible test mass locations. (b) When distances become much larger than 10 km, the map is not quite so simple. The direction “downward” changes at different points. Also, the gravitational force on a test mass can decrease significantly at altitudes comparable to the Earth’s radius.

23-1 Implications of Strong Electric Forces

In Section 3-9 we discuss the experimental fact that the gravitational force the Earth exerts on a mass has essentially the same magnitude and acts in a downward direction for all locations near the surface of the Earth as shown in Fig. 23-1a. By comparison the gravitational force exerted on the mass by other objects is negligible. In contrast, we learned in Section 22-2 that the electric forces between small objects are so strong that even Styrofoam cups rubbed with plastic can exert observable forces on each other. Also, it is not easy to calculate the net electric force exerted on a charged object by a complex array of charges in its vicinity. We would have to use the techniques introduced in Section 22-8 that combine Coulomb’s law and the principle of superposition to obtain a vector sum of forces. To make matters worse, as our charged object (which we’ll call a *test charge*) is moved, we often find the electric forces on it vary in direction and magnitude from point to point. The same can be said for the variation of gravitational forces on a space vehicle when large distances are involved as shown in Fig. 23-1b.

How can we describe the effect of the Earth’s gravity or the electric force when a small test object is placed at various locations? What is the net effect of a collection of charges on a small test charge located in their vicinity? Answers lie in the concept of a force field.

We begin this chapter by creating a map of the force on a point-like test mass (due to gravitational interactions) or test charge (due to electrostatic interactions) at various locations in space. These maps introduce the concept of a *force field*. We then refine the field concept to define *electric fields* and *gravitational fields*, which are properties of a local space. Knowledge of a gravitational or electric field is useful because it allows us to determine the net force on a small object regardless of its mass or charge.

23-2 Introduction to the Concept of a Field

The temperature at every point in a room can be measured. If the room contains both a good heater and a window open to cold winter air, the temperature at each point in the room might be different. We call the resulting distribution of temperatures around the room a *temperature field*. In much the same way, you can imagine a *pressure field* in the atmosphere. Temperature and pressure are scalar quantities because they have no direction associated with them, so both temperature fields and pressure fields are *scalar fields*. In general,

A **field** is defined as a representation of any physically measurable quantity that can vary in space.

Vector Fields

We can also have fields associated with vector quantities like force. In contrast to scalar fields like temperature, forces have direction, so it’s not good enough to attach just a number to each point in space—the quantity must be identified with a vector. For example, let’s ask, “What force would an object feel if it were placed at various locations in space?” and then represent the result pictorially. Consider the simple example of the gravitational force shown in Fig. 23-1b. We can calculate (or measure) the gravitational force exerted by the Earth on another object of known mass at several locations. The magnitude of each force vector is directly proportional to both the mass of the Earth and the mass of the object of interest. That is, the gravitational force of the Earth on different objects is different. Objects are pulled more strongly when they

have more mass. A similar representation of the electrostatic forces on a test charge at various locations due to a source charge is shown in Fig. 23-2.

Note that there are two separate aspects to creating a map of the fields we discuss above. The first aspect involves the sources of the quantity being measured. For example, the heater and window can be thought of as stimulating thermal energy transfer that can affect the temperature at different locations in the room. In the gravitational case, the Earth and other large astronomical bodies are the sources of gravitational forces. The second aspect involved in creating a field map is a single measurement device that can be moved to different locations. In the case of the pressure field, it is a pressure gauge. In the case of gravitational force, our measurement tool is the motion of the test mass being acted on. Without some kind of sensing tool, we could not “know” the force fields.

In mapping force fields, the fixed objects are called **source objects** because they are the objects that exert forces on another object of interest. We use this other object that the forces are exerted *on* as our measurement tool. We refer to this other object as the **test object**.

Test Objects Should Not Be Large Enough to Move Source Objects

Since all forces occur in pairs, a test object exerts forces on the source objects, trying to change their locations, and hence to change the nature of the field. This issue makes the determination of the field values very complex unless the amount of a source object is much greater than the amount of a test object or the source object is somehow fixed in space. The fact that the field concept is only useful in cases where the test object does not move the source objects is an example of a universal issue involved in making measurements. Namely, the measurement device or tool should not change the value of the quantity being measured. For example, one should not use a large bathtub thermometer to measure the temperature of water in a tiny cup. The presence of the thermometer itself would affect the temperature of the water. Here are several examples of circumstances in which a field can be mapped:

1. In the Earth’s gravitational interactions, the location of a much smaller test mass has a negligible effect on the Earth’s location and hence on its force field (Fig. 23-3).
2. A conducting sphere with billions of excess electrons that can act as source charges that can exert a net force on a test charge consisting of a single proton. Each excess electron stays put because the net force from all the other charges in its vicinity is much stronger than that from the single proton (unless the proton gets very close to a particular electron).
3. A few electrons on the surface of an insulator such as a piece of Styrofoam can act as source charges that exert a net force on a single electron. The source charges are trapped on the insulator and do not reconfigure themselves.

The field concept is useful when the test object is too small to change the location of the source objects or if the source objects are fixed.

Mapping a Vector Field

How can we map the force field for a test object at various locations in space? The procedure that follows can be used to create a field map for any kind of force. The force on the test object could be the result of its interaction with a single source object or a collection of source objects at several locations. The procedure is as follows:

1. Choose a grid or array of points in the vicinity of the sources. The grid should be fine enough to give you a good idea of how the force field looks. However, if the

FIGURE 23-2 ■ Vectors representing the direction and relative magnitude of the force that would be exerted *by* a fixed positive source charge shown on a second positive test charge if the second charge was placed at the various locations of the vector tails. The magnitude of the force is given by the length of the vector.

FIGURE 23-3 ■ An Earth–object system in which the interaction forces between a much less massive object and the Earth have, as always, the same magnitude. As the object falls, the movement of the Earth is negligible, so the gravitational force field surrounding the Earth does not change.

FIGURE 23-4 ■ Here the positive test charge is twice what it was in Fig. 23-2. Coulomb’s law tells us that if the test charge is doubled, the electrostatic force it experiences at each location will be doubled.

- grid is too fine the procedure will be tedious and the arrows will clutter up the page.
2. Determine the magnitude and direction of the force on the test object at each point on the grid. (Note that we place our test object at one location at a time. If we put down lots of test objects at the same time, they would exert forces on each other and the source object and mess things up.) We must ensure that our test object is not so large that it disturbs the locations of the source objects. We might determine the force at the various points in space experimentally by making direct measurements. Alternatively, if we know the field sources, we can use theoretical relationships such as the law of gravitation or Coulomb’s law to make theoretical calculations of the forces on our test object at the different grid locations.
 3. Place an arrow representing the force vector at each of the grid locations. Each arrow should point in the direction of the force with a length that is proportional to the force magnitude at that location. It is conventional to locate the tail of the arrow (rather than its tip) at the point for which we have calculated (or measured) the force on the test charge.

Note: We are free to choose a convenient length for the first arrow we draw on our map. Once the length of the first arrow is chosen, a second arrow can be drawn at another point in space. However, the ratio of the lengths of the two arrows must be the same as the ratio of the magnitudes of the two forces. For example, according to Coulomb’s law, if the distance between our test charge and the center of the source charge is doubled, the new force on it has only one-fourth the magnitude. This is shown in Fig. 23-4, where the arrows at twice the distance have one-fourth the length.

This type of *vector field plot* is valuable when used to map forces because it immediately tells us important information about characteristics of the forces. For example, Figs. 23-1*b* and 23-4 allow us to infer that the gravitational force exerted by the Earth is everywhere attractive and the electrostatic (or Coulomb) force exerted by one positively charged object on another is everywhere repulsive. These two figures also show us that both of these forces act along the line connecting the centers of the two objects (they are “central forces”). They immediately remind us that these forces are large close to the source (long arrows) and small farther away (short arrows).

READING EXERCISE 23-1: In Fig. 23-4, suppose we chose an arrow that had a length of 36 mm to represent the electrostatic force at a distance of 2 cm from the source charge. What would the length of the arrows representing the magnitude of the force on the same test charge be if it was (a) 4 cm away from the center of the source charge? (b) 6 cm away from the center of the source charge? ■

READING EXERCISE 23-2: In measuring a field that has different values at each point in space, the “test” or measurement device must be small relative to the region of space over which the measurements are to be made. Why? ■

23-3 Gravitational and Electric Fields

Although the lengths of the arrows shown in Figs. 23-1 and 23-4 represent the magnitudes of the gravitational and electrostatic forces experienced by a test object at various locations, we note that the force magnitudes (and hence lengths of the arrows) are different for different test objects.

For example, Figure 23-4 shows the force field of a test object with twice as much charge as the one depicted in Fig. 23-2. Note that every arrow shown in the figure

doubles in length. That is, each arrow is scaled by the same factor based on how much larger or smaller the test object's charge is. The force vectors scale as they do because for a given source charge, the electrostatic force is directly proportional to the amount of the test charge. The same is true for the gravitational force due to a given source mass. These changes in the force fields with test object strength are difficult, because we need an infinite number of field plots to represent all different test objects.

Actually, we have already dealt with the problem of test masses for gravitational forces. Recall from Section 14-2 that the magnitude of the gravitational force exerted by a spherical source mass m_s such as the Earth on a test mass m_t (perhaps a ball) is given by

$$F_{s \rightarrow t}^{\text{grav}} = |\vec{F}_{s \rightarrow t}^{\text{grav}}| = \left(\frac{Gm_s}{r^2} \right) m_t, \quad (23-1)$$

where G is the gravitational constant and r is the distance between the objects. To facilitate calculation of the force *exerted on* various objects by the same source object (typically the Earth) we took advantage of this proportionality to define the *local gravitational strength* g_s as a scalar given by

$$g_s = |\vec{g}_s| \equiv \left(\frac{F_{s \rightarrow t}^{\text{grav}}}{m_t} \right) = \left(\frac{Gm_s}{r^2} \right) \quad (\text{spherical source}). \quad (23-2)$$

Using the field concept that we have now developed, we can call the vector \vec{g}_s the **local gravitational field vector**. Combining Eqs. 23-1 and 23-2, we see that the gravitational force exerted by a source mass m_s on a test mass m_t can be determined using the simple expression

$$\vec{F}_{s \rightarrow t}^{\text{grav}} = m_t \vec{g}_s. \quad (23-3)$$

In other words, the gravitational force on an object at a certain point in space is the product of its mass and the gravitational field vector at that point. The gravitational field vector is especially convenient because it is solely a property of space. It is completely determined by locations and the masses of the source objects. It is independent of the mass of the test object we might choose to investigate in any given instance.

Similarly, we can take advantage of the direct proportionality involved in electrostatic forces. That is, there is a similar proportionality between the amount of a test charge and the forces exerted on it by a source or a set of sources. Our approach is to define a new field, the *electric field*, which allows us to focus on the influence of the source of the force. To do this, we define the **electric field vector** due to one or more source charges as

$$\vec{E}_s \equiv \frac{\vec{F}_{s \rightarrow t}^{\text{elec}}}{q_t} \quad (\text{definition of electric field}), \quad (23-4)$$

where $\vec{F}_{s \rightarrow t}^{\text{elec}}$ represents the net electrostatic force a test charge q_t experiences from a set of source charges.

The force in Eq. 23-4 is the vector sum of the electrostatic forces on the test charge q_t from all the source charges. Since the force from each source charge is proportional to q_t , dividing the force by q_t cancels it out in each term, leaving the electric field vector \vec{E}_s *independent* of q_t . Thus, the electric field vector shares the convenient characteristics of the gravitational field vector. It is solely a property of space and source and is independent of the test charge one might choose to probe it. *The electric field depends only on the source charges, not on the test charge.*

TABLE 23-1
Some Electric Field Magnitudes

Field Location or Situation	Value (N/C)
At the surface of a uranium nucleus	$\sim 3 \times 10^{21}$
Within a hydrogen atom, at a radius of 5.29×10^{-11} m	$\sim 5 \times 10^{11}$
Nerve cell membrane	$\sim 1 \times 10^7$
Electric breakdown in air (sparking)	$\sim 3 \times 10^6$
Near the charged drum of a photocopier	$\sim 1 \times 10^5$
Near a charged plastic comb	$\sim 1 \times 10^3$
In the lower atmosphere	$\sim 1 \times 10^2$
Inside the copper wire of household circuits	$\sim 1 \times 10^{-2}$

According to this definition, the **electric field** is the ratio of the electrostatic force on a test charge to the amount of that test charge. In other words, in SI units the electric field is the force per unit of test charge. This gives an SI unit for electric field as newtons per coulomb (N/C). In comparison, recall that the gravitational field was a measure of force per unit of *mass* and the SI unit for the gravitational field g was the N/kg.

The number given for the electric field can also be thought of as the force exerted on a 1 C test charge. To give you some idea of how much force is exerted on a one coulomb charge in various circumstances, Table 23-1 shows the electric fields that occur in a few physical situations. Remember, though, that one coulomb is a very large amount of charge and not an appropriate test charge. For example, an object with 10 000 more protons than electrons would have only a charge on the order of 10^{-15} C.

Although we use a test charge to determine the electric field associated with a charged object, remember that the electric field's existence is independent of the test charge just as the temperature in a room's existence is independent of whether or not there is a thermometer present to detect it. The test charge is simply the measurement device. The field at point P in Fig. 23-5 exists both before and after the test charge is put there. (We must always assume the test charge does not alter the electric field we are defining.)

The remainder of this chapter is primarily devoted to exploring how to use Coulomb's law and the principle of superposition to find the electric fields associated with a single point charge and with relatively simple arrangements of charged objects. We will also explore the concept of *electric field lines* as an alternative to electric field vectors to represent electric fields visually.

FIGURE 23-5 ■ The electric field associated with a negatively charged source object points inward at all locations outside of the source. Since a legitimate test charge does not noticeably influence the electric field created by the source charges, we think of the electric field as existing whether or not a small test charge is present to experience a force.

TOUCHSTONE EXAMPLE 23-1: Predicting Forces on Charges

Consider a set of hidden source charges that cannot move. Suppose you are trying to explore the nature of electrical forces in the vicinity of the source charges using a positive test charge given by $q_t = 14$ nC. You discover that at a point A shown in Fig. 23-6, the test charge experiences a force given by $\vec{F}_{s \rightarrow tA}^{\text{elec}} = +(2.8 \text{ N})\hat{i}$ and at point B it experiences a force given by $\vec{F}_{s \rightarrow tB}^{\text{elec}} = -(4.2 \text{ N})\hat{j}$.

(a) What will the forces at points A and B be on a different point charge given by $q_1 = -15$ nC? Or on another given by $q_2 = +25$ nC? *Note:* nC stands for nanocoulomb, which is 10^{-9} C.

SOLUTION ■ The **Key Idea** here is that you can use the information about the electrostatic forces experienced by the test

FIGURE 23-6 ■ Two points A and B are in the vicinity of a set of hidden fixed charges. A test charge experiences different electrostatic forces at each location.

charge to map the electric field in the region of our source charges. Once that is done you can then use your knowledge of the electric field to determine the forces on other charges (as long as the source charges are fixed or are large relative to any additional charges you are bringing into their vicinity). Using the definition of electric field given by Eq. 23-4, we see that the electric field at points A and B are

$$\begin{aligned}\vec{E}_A &\equiv \frac{\vec{F}_{s \rightarrow t}^{\text{elec}}}{q_t} = \frac{+(2.8 \text{ N})\hat{i}}{14 \times 10^{-9} \text{ C}} = +(2.0 \times 10^8 \text{ N/C})\hat{i} \\ \vec{E}_B &\equiv \frac{\vec{F}_{s \rightarrow t}^{\text{elec}}}{q_t} = \frac{-(4.2 \text{ N})\hat{i}}{14 \times 10^{-9} \text{ C}} = -(3.0 \times 10^8 \text{ N/C})\hat{j}.\end{aligned}\quad (23-5)$$

Now that we know the values of the electric field at points A and B we can find the forces on other charges by rearranging Eq. 23-5 to solve for electrostatic force and using the values of the new charges q_1 and q_2 in our calculations.

For q_1 :

$$\begin{aligned}\vec{F}_{s \rightarrow q_1}^{\text{elec}} &= q_1 \vec{E}_A = (-15 \times 10^{-9} \text{ C})[(+2.0 \times 10^8 \text{ N/C})\hat{i}] = (-3.0 \text{ N})\hat{i} \\ \vec{F}_{s \rightarrow q_1}^{\text{elec}} &= q_1 \vec{E}_B = (-15 \times 10^{-9} \text{ C})[-(3.0 \times 10^8 \text{ N/C})\hat{j}] = (+4.5 \text{ N})\hat{j}\end{aligned}\quad (\text{Answer})$$

For q_2 :

$$\begin{aligned}\vec{F}_{s \rightarrow q_2}^{\text{elec}} &= q_2 \vec{E}_A = (+25 \times 10^{-9} \text{ C})[(+2.0 \times 10^8 \text{ N/C})\hat{i}] = (+5.0 \text{ N})\hat{i} \\ \vec{F}_{s \rightarrow q_2}^{\text{elec}} &= q_2 \vec{E}_B = (+25 \times 10^{-9} \text{ C})[-(3.0 \times 10^8 \text{ N/C})\hat{j}] = (-7.5 \text{ N})\hat{j}\end{aligned}\quad (\text{Answer})$$

(b) Explain how the direction and magnitude of the forces on small charges in an electric field are related to the direction and magnitude of the electric field vector at point A and at point B . *Hint:* Sketching the force vectors will help you visualize the situation.

SOLUTION ■ The **Key Idea** here is that charge is a scalar so when you multiply it by the electric field vector to determine a

force, the force vector must either be in exactly the same direction as the electric field vector (for a positive charge) or opposite to it (negative charge). For example, the equations just above show that the force on q_1 , which is negative, is in the *opposite* direction from the electric field at both points A and B . On the other hand, the equations just above show that the force on q_2 , which is positive, is in the *same* direction as the electric field at points A and B . This is illustrated in Fig. 23-7.

FIGURE 23-7 ■ A diagram showing the force vectors on two charges at points A and B due to an electric field acting on them. (a) $q_1 = -15 \text{ nC}$ and (b) $q_2 = +25 \text{ nC}$.

23-4 The Electric Field Due to a Point Charge

The simplest of all possible charge distributions is a charge that can be approximated by a point with zero size. Protons, electrons, nuclei, and ions can all be considered to be point charges. Understanding the interactions of these objects is vital to our understanding of the physical world. In fact, even large charged objects can be viewed as point charges when considered from afar.

In this section, we determine the magnitude of the electric field due to a point-like charge q_s . We do this with the understanding that if we know the mathematical expression for the electric field of the charge, we know the mathematical expression for the force exerted per unit charge on any other charge that we might bring into the region surrounding it.

Here we discuss how to calculate the theoretical value of the electric field created by a positive charge q_s . We can also use another positive charge q_t to probe the region around q_s , testing the magnitude and direction of the force exerted on q_t by q_s . The

FIGURE 23-8 ■ When a source charge and a point-like test charge are both positive, the force between them is repulsive and both the vector representing the force on the test charge q_t and the electric field vector at its location point radially outward in the same direction. Since the units of \vec{E} and \vec{F} are different, the relative lengths of the vectors are arbitrary.

force vector and electric field vector for two positive point-like charges separated by a distance r are shown in Fig. 23-8. We develop a mathematical expression for the electric field associated with a positive charge below. As we do so, we consider how the situation would be different for negative charges.

We know that q_t experiences a repulsive force caused by q_s because they are like charges. The magnitude of the force $F_{s \rightarrow t}^{\text{elec}} = |\vec{F}_{s \rightarrow t}^{\text{elec}}|$ on our test charge q_t can be found using Coulomb's law:

$$F_{s \rightarrow t}^{\text{elec}} = k \frac{|q_s| |q_t|}{r^2}. \quad (23-6)$$

The absolute value signs on q_s and q_t serve as a reminder that the magnitude of the force is independent of the type (sign) of charge we have chosen to use in this development. Using our concept of the electric field vector from Section 23-3 above, we can express the magnitude of the force on the test charge q_t due to the electric field created by the source charge q_s as

$$F_{s \rightarrow t}^{\text{elec}} = |q_t| E_s, \quad (23-7)$$

where E_s is the magnitude of the electric field due to the source charge.

By combining Eq. 23-6 with Eq. 23-7, we can express the magnitude of the electric field at a distance r from a point charge of magnitude q_s as

$$E_s = k \frac{|q_s|}{r^2} \quad (\text{magnitude of the electric field due to a point charge}). \quad (23-8)$$

In agreement with our definition of the electric field as the force *per unit* charge, this expression is independent of the amount (and sign) of the test charge q_t we use as the probe. This expression is valid everywhere around the point charge q_s .

The magnitude of the electric field due to a positive or negative point charge is given by the expression above. However, the electric field is a vector. Hence, we must still determine the direction of the electric field associated with our positive point charge q_s . Recall the definition of electric field magnitude in Eq. 23-4,

$$\vec{E}_s \equiv \frac{\vec{F}_{s \rightarrow t}^{\text{elec}}}{q_t}. \quad (23-9)$$

For a positive test charge q_t , this means that the direction of the field vector \vec{E}_s is the same as the electrostatic force vector $\vec{F}_{s \rightarrow t}^{\text{elec}}$. This force points radially away from q_s as shown in Fig. 23-8. Since the direction of the field is the same as the direction of the force for the positive charge q_t , we know the electric field created by the positive point charge q_s must also point radially away from the charge q_s as shown in Fig. 23-8.

Would the direction of the field change if the charge q_s producing the field was negative rather than positive? The answer is yes. Consider a positive test charge q_t . The vector relationship between force and field (Eq. 23-4) tells us that since q_t is positive, the direction (sign) of the field is still the same as the direction of the force on q_t . However, now q_s is negative and q_t is positive. These unlike charges will attract one another. Hence, as shown in Fig. 23-9, the direction of the force on q_t due to q_s points radially *toward* q_s . Since the directions of the force and the field are the same, so does the electric field. According to the force-field relationship, if we used a negative test charge, the electric field would not change but the force on a negative test charge would act in the opposite direction.

FIGURE 23-9 ■ When the charge on a source charge is negative while a point-like test charge is positive, the forces between them are attractive and both the vector representing the force on the test charge and the electric field vector at its location point radially inward in the same direction.

FIGURE 23-10 ■ There are two methods commonly used to depict the pattern of forces a test charge might experience at different locations in space. For the special case of forces associated with a single negative source charge: (a) shows a vector force field on a positive test charge, and (b) shows a vector electric field. The vector electric field is solely a property of space, independent of the test charge used to generate (a).

FORCE AND ELECTRIC FIELD DIRECTIONS: The direction of the force on a positive test charge is always the same as the electric field at the location of the positive test charge. So, at any point in space, the direction of the electric field produced by a positive point charge is radially away from the charge. The direction of the electric field produced by a negative point charge is radially toward the charge. “Radially” means along the line connecting the charge and the point of evaluation.

The Electric Field Vector Representation

The electric field vector representation is extremely useful when we want to determine the force on a charge placed at a given location (Fig. 23-10). We merely have to multiply the electric field vector at the location by the value of the charge. *This method of using the electric field to find force on a charge is valid for any charge, q , that is not large enough to disturb the electric field, regardless of the source of the field.*

READING EXERCISE 23-3: Rewrite the discussion of how we determine the direction of the field using a negative test charge rather than a positive test charge. Does it make any difference which type of charge we decide to use in determining the direction of the field? ■

23-5 The Electric Field Due to Multiple Charges

In the real world, problems are seldom as simple as one charged object exerting a force on another. It is more common for several charges to be present and the force exerted on the test charge to be the net result of the forces due to each of the source charges. As we mention in Section 22-8, experiments involving both gravitational and electrical forces have confirmed that the net force exerted on a test object by a collection of source objects is the vector sum of the forces exerted by each individual source object.

If we place a positive test charge q_t near n point charges q_A, q_B, \dots, q_n , as shown for only three charges in Fig. 23-11, the forces exerted by the individual charges superimpose so that the net force \vec{F}_t^{net} from the n point charges acting on the test charge is

$$\vec{F}_t^{\text{net}} = \vec{F}_{A \rightarrow t} + \vec{F}_{B \rightarrow t} + \dots + \vec{F}_{n \rightarrow t}. \quad (23-10)$$

For each of the terms in the expression above, we can replace the individual forces with the equivalent expressions based on the definition of the electric field. For example,

FIGURE 23-11 ■ Three point charges exert forces on a small positive test charge at a point in space. These force vectors superimpose to yield a net force.

FIGURE 23-12 ■ When charges are arranged symmetrically it is often the case that electric field components cancel each other. In this case the x -components cancel everywhere along a line bisecting the line connecting the charge centers.

$$\vec{F}_{A \rightarrow i} = q_i \vec{E}_A, \quad (23-11)$$

where \vec{E}_A is the electric field associated with charge q_A . If we make such replacements for each force term in the expression above we have:

$$\vec{F}_i^{\text{net}} = q_i \vec{E}^{\text{net}} = q_i \vec{E}_A + q_i \vec{E}_B + \cdots + q_i \vec{E}_n. \quad (23-12)$$

Here \vec{E}^{net} is the resultant electric field associated with the entire group of charges. If we divide both sides of the expression

$$q_i \vec{E}^{\text{net}} = q_i \vec{E}_A + q_i \vec{E}_B + \cdots + q_i \vec{E}_n \quad (23-13)$$

by q_i , the result is an expression for the net electric field associated with a group of charges. Namely,

$$\vec{E}^{\text{net}} = \vec{E}_A + \vec{E}_B + \cdots + \vec{E}_n. \quad (23-14)$$

This expression shows us that the principle of superposition applies to electric fields as well as to electrostatic forces. When doing calculations, however, it is important to remember that we are adding vectors here. Hence, the addition is more complex than simply adding numbers together.

If the array of point charges is symmetric, sometimes the addition of vectors at certain points in the vicinity of the charges is simplified. In Figs. 23-12 and 23-13 we show examples of symmetric situations for which the net electric field only has one component everywhere on a line bisecting the line that connects the two charges.

FIGURE 23-13 ■ A symmetrical arrangement for which y -components of the electric field cancel everywhere along a line, bisecting the line connecting the charge centers.

READING EXERCISE 23-4: The figure here shows a proton p and an electron e on an x axis. Draw vectors indicating the direction of the electric field due to the electron and describe the direction in words at (a) point S and (b) point R . Draw vectors indicating the direction of the electric field due to both charges and describe the direction in words at (c) point R and (d) point S .

TOUCHSTONE EXAMPLE 23-2: Three Charges

Figure 23-14 shows three particles with charges $q_A = +2Q$, $q_B = -2Q$, and $q_C = -4Q$, each a distance d from the origin. We assume Q is positive. What net electric field \vec{E}^{net} is produced at the origin?

FIGURE 23-14 ■ Three particles with charges q_A , q_B , and q_C are at the same distance d from the origin.

SOLUTION ■ We need to find the electric field vectors \vec{E}_A , \vec{E}_B , and \vec{E}_C that act at the origin. The **Key Idea** is that we can pick a more convenient coordinate system to describe these electric field vectors. An x' - y' coordinate system that is rotated by 30° in a clockwise direction has q_A and q_B lying along its x' axis, as shown in Fig. 23-15a.

Another **Key Idea** is that charges q_A , q_B , and q_C produce electric field vectors \vec{E}_A , \vec{E}_B , and \vec{E}_C , respectively, at the origin, and the net electric field is the vector sum $\vec{E}^{\text{net}} = \vec{E}_A + \vec{E}_B + \vec{E}_C$. To find this sum, we first must find the magnitudes and orientations of the three field vectors. To find the magnitude of \vec{E}_A , which is due to q_A , we use Eq. 23-8, substituting d for r and $2Q$ for $|q|$ and obtaining

$$E_A = k \frac{2Q}{d^2}.$$

Similarly, we find the magnitudes of the fields \vec{E}_B and \vec{E}_C to be

$$E_B = k \frac{2Q}{d^2} \quad \text{and} \quad E_C = k \frac{4Q}{d^2}.$$

We next must find the orientations of the three electric field vectors at the origin. Because q_A is a positive charge, the field

vector it produces points directly *away* from it, and because q_B and q_C are both negative, the field vectors they produce point directly *toward* each of them. Thus, the three electric fields produced at the origin by the three charged particles are oriented as in Fig. 23-15b. (*Caution:* Note that we have placed the tails of the vectors at the point where the fields are to be evaluated; doing so decreases the chance of misinterpretation.)

We can now add the fields vectorially as outlined for forces in Touchstone Example 22-1c. However, here we can use symmetry to simplify the procedure. From Fig. 23-15b, we see that \vec{E}_A and \vec{E}_B have the same direction. Hence, their vector sum points along the positive x' axis and has the magnitude

$$\vec{E}_A + \vec{E}_B = k \frac{2Q}{d^2} \hat{i}' + k \frac{2Q}{d^2} \hat{i}' = k \frac{4Q}{d^2} \hat{i}'$$

or
$$E_{Ax'} + E_{Bx'} = k \frac{4Q}{d^2},$$

where \hat{i}' and \hat{j}' are unit vectors in the x' - y' coordinate system. This sum happens to equal the magnitude of \vec{E}_C .

We must now combine two vectors, \vec{E}_C and the vector sum $\vec{E}_A + \vec{E}_B$, that have the same magnitude. We do this by resolving \vec{E}_C into its x' and y' components.

$$E_{Cx'} = E_C \cos 60^\circ = \frac{1}{2} E_C$$

$$E_{Cy'} = E_C \sin 60^\circ = \frac{\sqrt{3}}{2} E_C.$$

Then we find $E_{x'}^{\text{net}}$ and $E_{y'}^{\text{net}}$ components.

$$\begin{aligned} E_{x'}^{\text{net}} &= E_{Ax'} + E_{Bx'} + E_{Cx'} \\ &= k \frac{4Q}{d^2} + \frac{1}{2} k \frac{4Q}{d^2} \\ &= \frac{3}{2} \left(k \frac{4Q}{d^2} \right). \\ E_{y'}^{\text{net}} &= \frac{\sqrt{3}}{2} \left(k \frac{4Q}{d^2} \right). \end{aligned}$$

Using vector notation we get

$$\vec{E}^{\text{net}} = \left(k \frac{4Q}{d^2} \right) \left(\frac{3}{2} \hat{i}' + \frac{\sqrt{3}}{2} \hat{j}' \right). \quad (\text{Answer})$$

The magnitude of \vec{E}^{net} is given by

$$\begin{aligned} E^{\text{net}} &= |\vec{E}^{\text{net}}| = \sqrt{(E_{x'}^{\text{net}})^2 + (E_{y'}^{\text{net}})^2} \\ &= k \frac{6.93Q}{d^2}. \end{aligned}$$

FIGURE 23-15 ■ (a) The same three charges in the new x' - y' coordinate system. (b) The electric field vectors \vec{E}_A , \vec{E}_B , and \vec{E}_C at the origin due to the three particles. (c) The electric field vector \vec{E}_C and the vector sum $\vec{E}_A + \vec{E}_B$ at the origin.

FIGURE 23-16 (a) An electric dipole. The electric field vectors $\vec{E}_{(+)}$ and $\vec{E}_{(-)}$ at point P on the dipole axis result from the dipole's two charges. P is at distances $r_{(+)}$ and $r_{(-)}$ from the individual charges that make up the dipole. (b) By definition, the dipole moment \vec{p} is a vector that points from the negative to the positive charge of the dipole.

23-6 The Electric Field Due to an Electric Dipole

Figure 23-16a shows two charged particles of amount $|q|$ but of opposite sign, separated by a distance d . We call this configuration an **electric dipole**. Separation of positive and negative charge in an electrically neutral object occurs quite naturally. For example, recall the discussion of polarization in Chapter 22. As a result, true electric dipoles and approximations of electric dipoles are reasonably common. Hence, we take some time to develop an expression for the electric field due to a dipole. We start with the idea of superposition of electric fields that we discuss in Section 23-5.

Let us find the electric field due to the dipole of Fig. 23-16a at a point P , a distance z from the midpoint of the dipole and on the axis through the particles, which is called the dipole axis. From symmetry, the electric field \vec{E} at point P —and also the fields $\vec{E}_{(+)}$ and $\vec{E}_{(-)}$ due to the separate charges that make up the dipole—must lie along the dipole axis, which we have taken to be a z axis. Applying the superposition principle for electric fields, we find that the magnitude $E = |\vec{E}|$ of the electric field at P is

$$\begin{aligned} E &= |\vec{E}_{(+)}| - |\vec{E}_{(-)}| \\ &= k \frac{|q|}{r_{(+)}^2} - k \frac{|q|}{r_{(-)}^2} \\ &= \frac{k|q|}{(z - \frac{1}{2}d)^2} - \frac{k|q|}{(z + \frac{1}{2}d)^2}, \end{aligned} \quad (23-15)$$

where k is the Coulomb constant. Using algebra, we can rewrite this equation as

$$E = \frac{k|q|}{z^2} \left[\left(1 - \frac{d}{2z}\right)^{-2} - \left(1 + \frac{d}{2z}\right)^{-2} \right]. \quad (23-16)$$

We are usually interested in the electrical effect of a dipole only at distances that are large compared with the dimensions of the dipole—that is, at distances such that $z \gg d$. At such large distances, we have $d/z \ll 1$ in the expression above. We can then expand the two quantities in the brackets in that equation by the binomial theorem (Appendix E), obtaining for those quantities

$$\left[\left(1 + \frac{2d}{2z(1!)} + \dots\right) - \left(1 - \frac{2d}{2z(1!)} + \dots\right) \right].$$

Thus,

$$E = \frac{k|q|}{z^2} \left[\left(1 + \frac{d}{z} + \dots\right) - \left(1 - \frac{d}{z} + \dots\right) \right]. \quad (23-17)$$

The unwritten terms in these two expansions involve d/z raised to progressively higher powers. Since $d/z \ll 1$, the contributions of those terms are progressively less, and to approximate the electric field magnitude, E , at large distances, we can neglect them. Then, in our approximation, we can rewrite this expression as

$$E \approx \frac{k|q|}{z^2} \frac{2d}{z} = 2k \frac{|q|d}{z^3} \quad (\text{for } d/z \ll 1). \quad (23-18)$$

The product $|q|d$, which involves the two intrinsic properties of charge q and separation d of the dipole, is the magnitude $|\vec{p}|$ of a vector quantity known as the **electric dipole moment** \vec{p} of the dipole. (The unit of \vec{p} is the coulomb-meter and

should not be confused with either momentum or pressure.) Thus, we can rewrite Eq. 23-18 as

$$E = 2k \frac{|\vec{p}|}{z^3} \quad (\text{electric field magnitude for a dipole along axis with } dz \ll 1). \quad (23-19)$$

The direction of \vec{p} is taken to be from the negative to the positive end of the dipole, as indicated in Fig. 23-16*b*. We can use \vec{p} to specify the orientation of a dipole.

The expression for the electric field due to a dipole shows that if we measure the electric field of a dipole only at distant points, we can never find both $|q|$ and d separately, only their product. The field at distant points would be unchanged if, for example, $|q|$ were doubled and d simultaneously halved. Thus, the dipole moment is a basic property of a dipole.

Although Eq. 23-19 holds only for distant points along the dipole axis, it turns out that \vec{E} for a dipole varies as $1/r^3$ for all distant points, regardless of whether they lie on the dipole axis. Here r is the distance between the point in question and the dipole center.

Inspection of the electric field vectors in Fig. 23-16 shows that the direction of \vec{E} for distant points on the dipole axis is always the direction of the dipole moment vector \vec{p} . This is true whether point P in Fig. 23-16*a* is on the upper or the lower part of the dipole axis.

Inspection of Eq. 23-19 shows that if you double the distance of a point from a dipole, the electric field at the point drops by a factor of 8. If you double the distance from a single point charge, however (see Eq. 23-8), the electric field drops only by a factor of 4. Thus the electric field of a dipole decreases more rapidly with distance than does the electric field of a single charge. The physical reason for this rapid decrease in electric field for a dipole is that from distant points a dipole looks like two equal but opposite charges that almost—but not quite—coincide. Thus, their electric fields at distant points almost—but not quite—cancel each other.

23-7 The Electric Field Due to a Ring of Charge

So far we have considered the electric field produced by one or, at most, a few point charges. We now consider charge distributions consisting of a great many closely spaced point charges (perhaps billions) spread along a line, a curve, over a surface, or within a volume. Such distributions can be treated as if they were **continuous** rather than discrete. Since these distributions can include an enormous number of point charges, we find the electric fields that they produce using integral calculus rather than by considering the point charges one by one. In this section we discuss the electric field caused by a ring of charge. In the next chapter, we shall find the field inside a uniformly charged sphere.

When we deal with continuous charge distributions, it is most convenient to express the charge on an object as a *charge density* rather than as a total charge. For a line of charge, for example, we would report the linear charge density (or charge per unit length) λ , whose SI unit is the coulomb per meter. If we have a total amount of charge q distributed uniformly along a line or curve then the **linear charge density** is defined as

$$\lambda \equiv q/L$$

where L is the total length of the path taken by the line or curve. For example, the curve subscribed by the uniformly charged circular ring of radius R shown in Fig. 23-17 has a total length of $L = 2\pi R$.

TABLE 23-2
Some Measures of Charge Density

Name	Symbol	Definition*	SI Unit
Charge	q	q	C
Linear charge density	λ	q/L	C/m
Surface charge density	σ	q/A	C/m ²
Volume charge density	ρ	q/V	C/m ³

*These definitions assume a uniform charge density. Otherwise the charge densities depend on location so that $\lambda(x) = dq/dx$, $\sigma(x, y) = dq/dA(x, y)$, $\lambda(x, y, z) = dq/dV(x, y, z)$.

Table 23-2 summarizes information about the types of charge densities we use in this text.

We may imagine the ring in Fig. 23-17 to be made of plastic or some other insulator, so the charges can be regarded as fixed in place. What is the electric field \vec{E} at point P , a distance z from the plane of the ring along its central axis?

To answer this question, we cannot just use the expression for the electric field set up by a point charge, because the ring is obviously not a point charge. However, we can mentally divide the ring into differential elements of charge. If these charge elements are small they act like point charges, and then we can use Eq. 23-8 to find the electric field magnitude contributed by a single element. This gives us

$$E_q = k \frac{|q|}{r^2},$$

where the value of the coulomb constant k is given in Eq. 22-7. Next, we can add the electric fields set up at location P due to all the differential elements. The vector sum of all those fields gives us the net electric field set up at P by the entire ring.

Let ds be the (arc) length of any differential element of the ring. Since λ is the charge per unit length, the amount of charge in the element is given by

$$|dq| = |\lambda| ds. \quad (23-20)$$

FIGURE 23-17 (a) A ring of uniform positive charge. A differential element of charge occupies a length ds (greatly exaggerated for clarity). This element sets up an electric field $d\vec{E}$ at point P . The magnitude of the component of $d\vec{E}$ along the central axis of the ring is $|d\vec{E}|\cos\theta$. (b) Each ring element ds_1 has an opposite element ds_2 . As a result of this symmetry the on-axis $d\vec{E}$ components (along z) add while those perpendicular to the axis cancel (in the x - y plane).

This differential charge sets up a differential electric field $d\vec{E}$ at point P , which is a distance r from the element. Treating the element as a point charge and using the equation above for dq , we can express the magnitude of $d\vec{E}$ as

$$|d\vec{E}| = k \frac{|dq|}{r^2} = k \frac{|\lambda| ds}{r^2}. \quad (23-21)$$

From Fig. 23-17a, we see we can use the Pythagorean theorem to rewrite the equation above as

$$|d\vec{E}| = k \frac{|\lambda| ds}{z^2 + R^2}. \quad (23-22)$$

Figure 23-17a also shows us that the vector $d\vec{E}$ is at an angle θ to the central axis (which we have taken to be a z axis) and has components perpendicular to and parallel to that axis.

Every element of charge in the ring sets up a differential field $d\vec{E}$ at P , with magnitude given by the expression above. All the $d\vec{E}$ vectors have identical components parallel to the central axis. All these $d\vec{E}$ vectors also have components perpendicular to the central axis. However, these perpendicular components are identical in magnitude but point in different directions. In fact, for any perpendicular component that points in a given direction, there is another one that points in the opposite direction as shown in Fig. 23-17b. The sum of this pair of components, like the sum of all other pairs of oppositely-directed components, is zero. Thus, the perpendicular components cancel and we need not consider them further. This leaves only the parallel components. They all have the same direction, so the net electric field at P is just their algebraic sum.

The parallel component of $d\vec{E}$ shown in Fig. 23-17a has magnitude $|d\vec{E}|(\cos\theta)$. The figure also shows us that

$$\cos\theta = \frac{z}{r} = \frac{z}{(z^2 + R^2)^{1/2}}. \quad (23-23)$$

Then combining our expressions for $d\vec{E}$ and $\cos\theta$ gives us the magnitude of the parallel component of $d\vec{E}$,

$$|d\vec{E}_{||}| = |d\vec{E}|\cos\theta = \frac{k|\lambda| ds}{(z^2 + R^2)^{3/2}}. \quad (23-24)$$

To add the parallel components, $|d\vec{E}|\cos\theta$, produced by all the elements, we integrate this expression around the circumference of the ring, from $s = 0$ to $s = 2\pi R$. Since the only quantity that varies during the integration is s , the other quantities can be moved outside the integral sign. The integration then gives us an electric field magnitude of

$$\begin{aligned} E = |\vec{E}| &= \int |d\vec{E}|\cos\theta = \frac{k|\lambda|}{(z^2 + R^2)^{3/2}} \int_0^{2\pi R} ds \\ &= \frac{k|\lambda|(2\pi R)}{(z^2 + R^2)^{3/2}}. \end{aligned} \quad (23-25)$$

Since λ is the charge per unit length of the ring, the term $\lambda(2\pi R)$ is q , the total charge on the ring. We can then rewrite this expression as

$$E = \frac{k|qz|}{(z^2 + R^2)^{3/2}} \quad (\text{electric field magnitude of a charged ring}). \quad (23-26)$$

If the charge on the ring is negative, rather than positive as we have assumed, the magnitude of the field at P is still given by this expression. However, the electric field vector then points toward the ring instead of away from it.

Let us evaluate this equation for the electric field for a point on the central axis so far away that $z \gg R$. For such a point, the expression $z^2 + R^2$ can be approximated as z^2 , and Eq. 23-26 becomes

$$E = \frac{k|q|}{z^2} \quad (\text{on central axis for } z \gg R \text{ at large distance}). \quad (23-27)$$

This is a reasonable result, because from a large distance, the ring simply “looks” like a point charge. So, if we replace z with r then Eq. 23-27 becomes the expression for the electric field due to a point charge.

Let us next check Eq. 23-26 for a point at the center of the ring—that is, for $z = 0$. At that point, this expression tells us that $\vec{E} = 0$. This is a reasonable result, because if we were to place a test charge at the center of the ring, there would be no net electrostatic force acting on it. The force due to any element of the ring would be canceled by the force due to the element on the opposite side of the ring. If the force at the center of the ring is zero, the electric field there also has to be zero.

TOUCHSTONE EXAMPLE 23-3: Charged Arc

Figure 23-18a shows a plastic rod having a uniformly distributed charge $-Q$. We assume Q is positive, so $-Q$ is negative. The rod has been bent in a 120° circular arc of radius r . We place coordinate axes such that the axis of symmetry of the rod lies along the x axis and the origin is at the center of curvature P of the rod. In terms of Q and r , what is the electric field \vec{E} due to the rod at point P ?

SOLUTION ■ The **Key Idea** here is that, because the rod has a continuous charge distribution, we must find an expression for the electric fields due to differential elements of the rod and then sum those fields via integration. Consider a differential element having arc length ds and located at an angle θ above the x axis (Fig. 23-18b). If we let λ represent the linear charge density of the rod, our element ds has a differential charge of magnitude

$$dq = \lambda ds. \quad (23-28)$$

Our element produces a differential electric field $d\vec{E}$ at point P , which is a distance r from the element. Treating the element as a point charge, we can rewrite Eq. 23-21 to express the magnitude of $d\vec{E}$ as

$$|d\vec{E}| = k \frac{|dq|}{r^2} = k \frac{|\lambda| ds}{r^2}. \quad (23-29)$$

The direction of $d\vec{E}$ is toward ds , because charge dq is negative.

FIGURE 23-18 ■ (a) A plastic rod of charge $-Q$ in a circular section of radius r and central angle 120° ; point P is the center of curvature of the rod. (b) A differential element in the top half of the rod, at an angle θ to the x axis and of arc length ds , sets up a differential electric field $d\vec{E}$ at P . An element ds' , symmetric to ds about the x axis, sets up a field $d\vec{E}'$ at P with the same magnitude. (c) Arc length ds makes an angle $d\theta$ about point P .

Our element has a symmetrically located (mirror image) element ds' in the bottom half of the rod. The electric field $d\vec{E}'$ set up at P by ds' also has the magnitude given by Eq. 23-29, but the field vector points toward ds' as shown in Fig. 23-18b. If we resolve the electric field vectors due to ds and ds' into x - and y -components as shown in Fig. 23-18b, we see that their y -components cancel

(because they have equal magnitudes and are in opposite directions). We also see that their x -components have equal magnitudes and are in the same direction.

Thus, to find the electric field set up by the rod, we need sum (via integration) only the x -components of the differential electric fields set up by all the differential elements of the rod. From Fig. 23-18*b* and Eq. 23-29, we can write the component dE_x set up by ds as

$$|dE_x| = |d\vec{E}| \cos \theta = k \frac{|\lambda|}{r^2} \cos \theta ds. \quad (23-30)$$

Equation 23-30 has two variables, θ and s . Before we can integrate it, we must eliminate one variable. We do so by replacing ds , using the relation

$$ds = r d\theta,$$

in which $d\theta$ is the angle at P that includes arc length ds (Fig. 23-18*c*). *Note:* We choose to replace ds here rather than $d\theta$ because we know the angle into which the arc is bent. With this replacement, we can integrate Eq. 23-30 over the angle made by the rod at P , from $\theta = -60^\circ$ to $\theta = 60^\circ$. That will give us E , the magnitude of the electric field at P due to the rod:

$$\begin{aligned} E &= \int |dE_x| = \int_{-60^\circ}^{60^\circ} \frac{k|\lambda|}{r^2} \cos \theta r d\theta \\ &= \frac{k|\lambda|}{r} \int_{-60^\circ}^{60^\circ} \cos \theta d\theta = \frac{k|\lambda|}{r} [\sin \theta]_{-60^\circ}^{60^\circ} \end{aligned}$$

$$\begin{aligned} &= \frac{k|\lambda|}{r} [\sin 60^\circ - \sin(-60^\circ)] \\ &= \frac{1.73k|\lambda|}{r}. \end{aligned} \quad (23-31)$$

(If we had reversed the limits on the integration, we would have gotten the same result but with a minus sign. Since the integration gives only the magnitude of \vec{E} , we would then have discarded the minus sign.)

To evaluate the amount of charge per unit length, $|\lambda|$, we note that the rod has an angle of 120° and so is one-third of a full circle. Its arc length is then $2\pi r/3$, and its linear charge density must be

$$|\lambda| = \frac{\text{charge}}{\text{length}} = \frac{Q}{2\pi r/3} = \frac{0.477Q}{r}.$$

Substituting this into Eq. 23-31 and simplifying give us an electric field magnitude of

$$\begin{aligned} E &= |\vec{E}| = \frac{(1.73)(0.477)kQ}{r^2} \\ &= \frac{0.83kQ}{r^2}. \end{aligned} \quad (\text{Answer})$$

The direction of \vec{E} is toward the rod, along the axis of symmetry of the charge distribution. We can write \vec{E} in unit-vector notation as

$$\vec{E} = \frac{0.83kQ}{r^2} \hat{i}.$$

23-8 Motion of Point Charges in an Electric Field

So far we have concentrated on finding electric field values by doing theoretical calculations. However, the electric field concept is especially valuable when we have little or no knowledge about source charges. In such a case, we can use measured values of the forces on our test charge to create an experimentally determined map of the field. In either case, once the electric field is known, we can determine forces on any point-like object with a known quantity of excess charge at any location in the field (provided that our test charge doesn't disturb the source charges). Assuming we know the mass of our charge, knowing the force means we can calculate the magnitude and direction of the particle's acceleration. Knowing the acceleration allows us to accurately predict its subsequent motion.

In the preceding sections we worked at the first of two tasks: given a charge distribution, find the electric field it produces in the surrounding space. Here we begin the second task: to determine what happens to a charged particle when it is in an electric field. When a charged particle is placed in an electric field, an electrostatic force acts on the particle. This force, a vector quantity, is given by

$$\vec{F}_t^{\text{elec}} = q_t \vec{E}_s \quad (23-32)$$

in which q_t is the charge of the test particle (including its sign) and \vec{E}_s is the electric field that source charges have produced at the location of the particle. (The field is not

the field set up by the test particle itself. A charged particle is not affected by its own electric field.) Equation 23-32 tells us:

The electrostatic force \vec{F}^{elec} acting on a charged test particle located in an external electric field \vec{E}_s has the direction of \vec{E}_s if the charge q_t of the test particle is positive and is opposite the direction of \vec{E}_s if q_t is negative.

Knowing the force on the particle allows us to directly calculate the acceleration, but determining the exact motion of the object is more complicated. The electric field determines the force that a charged particle feels. That, in turn, determines its acceleration, *not its velocity*. So at first a charged particle starting from rest follows the direction of the field. This is because without an initial velocity, the direction of the force and acceleration are in the direction of the velocity. However, if the field changes direction, the path of the particle quickly deviates from the direction of the field. If the charged particle is given an initial velocity that is not aligned with the field, it may never follow the direction of the field. A good analogy to this situation is the path of a projectile in Earth's gravitational field. The gravitational field is uniformly directed downward. Yet this is the direction of the force (and acceleration), not necessarily the direction of the velocity at any given moment. The path of a launched projectile may never follow the direction of the gravitational field.

FIGURE 23-19 ■ An end-on side view of AHPC components. (a) Tubular filter. (b) Discharge electrode. (c) Collector plate with holes.

FIGURE 23-20 ■ Simplified AHPC top view showing arrangement of components with collector plates surrounding the filters.

Electrostatic Precipitation

A few years ago, an Advanced Hybrid Particulate Collector (AHPC) was added to the Big Stone coal-fired power plant shown in the chapter's opening photograph. This hybrid collector eliminates essentially all the particulates in the smoke by combining the best features of filtration systems with a new type of **electrostatic precipitation** system. When the smoke from the coal boiler enters the device, more than 90% of the tiny smoke particles become electrically charged and then are attracted to one of the collection plates. The other 10% of particles flow through holes in the collection plates and are trapped by tubular filter bags that are especially efficient at removing extremely small particles (Fig. 23-19a).

The use of strong electric fields is a key factor in the effectiveness of electrostatic precipitation. Discharge electrodes (Fig. 23-19b) consisting of metal wires are negatively charged. The electric fields surrounding the electrodes are so intense that electrons are discharged. When the electrons fly away from the electrodes and encounter smoke particles, negative ions are formed. These ions are repelled from the electrodes, attracted to neutral metal collector plates (Fig. 23-19c), and captured. In short, these electrons and ions act like point charges in the presence of the electrodes' electric field.

The configuration of components in an AHPC system is shown in Fig. 23-20. A collector plate with holes in it is installed between wire discharge electrodes and filters to protect the filters. On the other side of the electrodes, another collector plate is installed to yield an arrangement in which each row of filters has collector plates on both sides of it. With this arrangement, the collector plates with holes function both as the primary collection surface and as a protective shield for the filters.

READING EXERCISE 23-5: (a) In the figure, what is the direction of the electrostatic force on the electron due to the uniform electric field shown? (b) In which direction does the electron accelerate if it is moving parallel to the y axis before it encounters the electric field? What path does it follow? (c) If, instead, the electron is initially moving rightward, does its speed increase, decrease, or remain constant? What path will it follow in this case?

TOUCHSTONE EXAMPLE 23-4: Deflecting an Ink Drop

Figure 23-21 shows the deflecting plates of an ink-jet printer, with superimposed coordinate axes. An ink drop with a mass m of 1.3×10^{-10} kg and an amount of negative charge $|Q| = 1.5 \times 10^{-13}$ C enters the region between the plates, initially moving along the x axis with speed $v_x = 18$ m/s. The length L of the plates is 1.6 cm. The plates are charged and thus produce an electric field at all points between them. Assume that field \vec{E} is downward directed, uniform, and has a magnitude of 1.4×10^6 N/C. What is the vertical deflection of the drop at the right edge of the plates? (The gravitational force on the drop is small relative to the electrostatic force acting on the drop and can be neglected.)

FIGURE 23-21 ■ An ink drop of mass m and an amount of charge $|Q|$ is deflected in the electric field of an ink-jet printer.

SOLUTION ■ The drop is negatively charged and the electric field is directed *downward*. The **Key Idea** here is that, from Eq. 23-4, a constant electrostatic force of magnitude $|Q|E$ acts *upward* on the charged drop. Thus, as the drop travels parallel to the x axis

at constant speed v_x , it accelerates upward with some constant acceleration of magnitude a_y where a_y is positive. Applying Newton's Second Law ($F_y^{\text{net}} = ma_y$) for components along the y axis, we find that the y -component of the acceleration is directly proportional to the y -component of the electrostatic force so that

$$a_y = \frac{F_y^{\text{elec}}}{m} = + \frac{|Q|E}{m}. \quad (23-33)$$

Let Δt represent the time required for the drop to pass through the region between the plates. In Chapter 4, we found that during the time Δt the vertical and horizontal displacements of the drop are

$$\Delta y = \frac{1}{2}a_y\Delta t^2 \quad \text{and} \quad \Delta x = L = v_x\Delta t, \quad (23-34)$$

respectively. Eliminating Δt between these two equations and substituting Eq. 23-33 for a_y , we find

$$\begin{aligned} \Delta y &= \frac{|Q|EL^2}{2mv_x^2} \\ &= \frac{(1.5 \times 10^{-13} \text{ C})(1.4 \times 10^6 \text{ N/C})(1.6 \times 10^{-2} \text{ m})^2}{(2)(1.3 \times 10^{-10} \text{ kg})(18 \text{ m/s})^2} \\ &= 6.4 \times 10^{-4} \text{ m} \\ &= 0.64 \text{ mm}. \end{aligned} \quad (\text{Answer})$$

23-9 A Dipole in an Electric Field

Many electrical effects in matter can be understood by considering matter to be made up of many little electric dipoles. When an electric field is applied to that matter, the dipoles change their orientation in a consistent way. Although each dipole is small, since they all do the same thing, they can produce a substantial electrical effect. In this section, we consider the torque that can be exerted on a dipole that is placed in a uniform electric field.

We have defined the electric dipole moment \vec{p} of an electric dipole to be a vector pointing from the negative to the positive end of the dipole. It turns out that behavior of a dipole in a uniform external electric field \vec{E}_s can be described completely in terms of the two vectors \vec{E}_s and \vec{p} , with no need of any details about the dipole's structure.

A molecule of water (H_2O), as shown in Fig. 23-22, is an electric dipole. There the black dots represent the oxygen nucleus (having eight protons) and the two hydrogen nuclei (having one proton each). The colored enclosed areas represent the region in which electrons can be located around the nuclei.

In a water molecule, the two hydrogen atoms and the oxygen atom do not lie on a straight line but form an angle of about 105° . As a result, the molecule has a definite “oxygen side” and “hydrogen side.” Moreover, the 10 electrons of the molecule tend to remain closer to the oxygen nucleus than to the hydrogen nuclei. This makes the oxygen side of the molecule slightly more negative than the hydrogen side and creates an electric dipole moment \vec{p} that points along the symmetry axis of the molecule as shown. If the water molecule is placed in an external electric field, it behaves like the idealized electric dipole shown in Fig. 23-16.

To examine this behavior, we now consider what happens to an idealized electric dipole placed in a *uniform external electric field* \vec{E}_s . This is shown in Fig. 23-23a.

FIGURE 23-22 ■ This H_2O molecule has 3 nuclei (shown as dots). The electrons orbiting the nuclei spend more time near the oxygen nucleus, so the molecule behaves like a dipole. Its moment \vec{p} points from the (negative) oxygen side to the (positive) hydrogen side.

FIGURE 23-23 (a) An electric dipole in a uniform electric field \vec{E} . Two equal but opposite charges are separated by a distance d . The line between them represents their rigid connection. (b) Field \vec{E} causes a torque $\vec{\tau}$ on the dipole. The direction of $\vec{\tau}$ is into the plane of the page, as represented by the symbol \otimes .

Assume that the dipole is a rigid structure that consists of two charges of opposite sign, each having an amount $|q|$, separated by a distance d . Assume that the dipole moment \vec{p} makes an angle ϕ with field \vec{E}_s . Recall from our discussion in Section 23-6 above that the electric field far from the dipole depends only on \vec{p} (the product of charge q and separation d). The detailed structure of the water molecule is not important as long as the interaction between it and the electric field isn't strong enough to change the shape of either the molecule or the electric field.

Electrostatic forces act on the charged ends of the dipole. Because the electric field is uniform, those forces act in opposite directions (as shown in Fig. 23-23) and with the same magnitude $|\vec{F}_i^{\text{elec}}| = |q_i \vec{E}_s|$. Thus, because the field is uniform, the net force on the dipole from the field is zero and the center of mass of the dipole does not move. However, the forces on the charged ends do produce a net torque $\vec{\tau}$ on the dipole about its center of mass. Since the charges on a dipole do not necessarily have the same mass, we assume the center of mass lies on the line connecting the charged ends, at some distance x from one end and thus a distance $d - x$ from the other. From Eq. 11-29 ($|\vec{\tau}| = |\vec{r}| |\vec{F}| \sin\phi$), we can express the net torque magnitude $\tau = |\vec{\tau}|$ as

$$\tau = F^{\text{elec}} |x| \sin\phi + F^{\text{elec}} |(d - x)| \sin\phi = F^{\text{elec}} d \sin\phi. \quad (23-35)$$

We can also write the magnitude of the torque in terms of the magnitudes of the electric field $E = |\vec{E}|$ and the dipole moment $p = |\vec{p}| = |q|d$. To do so, we substitute $|q|E$ for the magnitude of the electrostatic force, F^{elec} , and $p/|q|$ for the dipole spacing, d , to find an expression for the magnitude of the torque. This magnitude is given by

$$\tau = pE \sin\phi. \quad (23-36)$$

We know the direction of the vector $\vec{\tau}$ is given by the right-hand rule. So, we see the result for both the magnitude and direction can be written in terms of the cross product as

$$\vec{\tau} = \vec{p} \times \vec{E} \quad (\text{torque on a dipole}). \quad (23-37)$$

Vectors \vec{p} and \vec{E} are shown in Fig. 23-23b. The torque acting on a dipole tends to rotate \vec{p} (hence the dipole) into the direction of \vec{E} , thereby reducing ϕ . In Fig. 23-23, such rotation is clockwise. As we discuss in Chapter 11, we can represent a torque component τ that gives rise to such a rotation as

$$\vec{\tau} = -\tau \hat{k} = -(pE \sin\phi) \hat{k}, \quad (23-38)$$

where \hat{k} is a unit vector pointing along the z axis (not the Coulomb constant).

READING EXERCISE 23-6: The figure shows four orientations of an electric dipole in an external electric field. Rank the orientations according to the magnitude of the torque on the dipole.

23-10 Electric Field Lines

So far in this chapter we have represented electric fields using vector arrows and creating force vector field plots. There is another common method for creating a visual

representation of information about electric fields in a region of space. It involves drawing *electric field lines*.

In the electric field line representation, we use continuous lines to convey information about the direction of the field at different points. Since the magnitude and direction of the electric field usually changes smoothly, this turns out to be rather convenient. Michael Faraday, who introduced the idea of electric fields in the 19th century, thought of the space around a charged body as filled with *lines of force*. Although we attach no reality to these lines, they provide a nice way to visualize patterns of changing force. The field line representation is used in Chapter 24 where we introduce Gauss' law. The field line representation is also used in Chapters 29–33 to describe magnetic fields.

Field lines are a good way to visualize the directions of a vector field in a region of space. To draw an **electric field line**, we start at any point and look at the direction of the field at that point. We then draw a short line in that direction. We determine the field direction at the new location and draw another short line in that direction. We continue this process until we reach a charge or get to infinity. Compare Figs. 23-24 and 23-25 for an example. Note that field *lines* shown in Fig. 23-25 and Fig. 23-26 differ from the short straight field *vectors* shown in Fig. 23-24 because they always start or end on the source charge(s). The direction of a straight field line or the direction of the tangent to a curved field line gives the direction of the electric field vector \vec{E}_s at that point. Because the field lines point in the direction of the field, field lines must originate on positive charges and terminate on negative charges.

It is important to note we could draw field lines through every point in space. However, this would not be very helpful since our paper would be totally filled with field lines and we couldn't distinguish one from another. Instead, we choose to draw a few field lines, with the number of lines leaving each positive charge (or ending on each negative charge) being proportional to the amount of each charge. If we choose to have 16 lines originating on a $+4\ \mu\text{C}$ charge, then we should have 8 lines ending on a $-2\ \mu\text{C}$ charge. This scaling of the number of field lines with amount of the charge turns out to be quite convenient since then the field lines are forced to be closely packed together where the field is strong and far apart where it is weak. We can see this in Figs. 23-25 and 23-26. In other words, the average density of field lines (the number of lines crossing through a small area perpendicular to their direction) is proportional to the strength of the field. We then have the following rules:

At any point along an electric field line, the direction of the corresponding electric field vector is always tangent to the line at that point. **Electric field lines** extend away from positive charge (where they originate) and toward negative charge (where they terminate). The density of field lines is proportional to the strength of the field.

Electric Field Near a Nonconducting Sheet

Figure 23-27a shows part of an infinitely large, nonconducting *sheet* (or plane) with a uniform distribution of positive charge on its right side. The electric field lines shown in Fig. 23-27b are uniformly spaced and always perpendicular to the sheet. Why? If the sheet can be treated as if it is infinitely large, then it looks the same in any direction. The pulls or pushes sideways from any bit of the sheet to one side of the test charge are cancelled by those from a symmetric bit of the sheet on the opposite side of the charge. As a result, the electric force vector at that point must point directly toward the sheet (if the sheet is negative) or directly away from the sheet (if the sheet is positive).

Since the field lines are perpendicular to the sheet and have to start and end on charges, they don't diverge or get closer as you move farther from the sheet. This suggests the surprising result that the field should not get weaker or stronger as you get

Electric field vectors

FIGURE 23-24 ■ There are two methods commonly used to depict an electric field. This figure shows a vector electric field map (or plot). See Fig. 23-25 for a comparison method.

Electric field lines

FIGURE 23-25 ■ The second common representation of an electric field is the field line representation shown here. See Fig. 23-24 for a comparison method.

FIGURE 23-26 ■ Electric field lines for a $-2q$ and $+4q$ charge configuration.

FIGURE 23-27 ■ Depictions of the electric field lines due to a very large, nonconducting sheet with uniformly distributed positive charge on one side. The vector fields shown in both figures are uniform and perpendicular to the charged sheet. (a) The electric field vector \vec{E} is shown at the location of a test charge, and (b) a side view of (a) showing electric field lines pointing away from the positive charges in the space near the sheet.

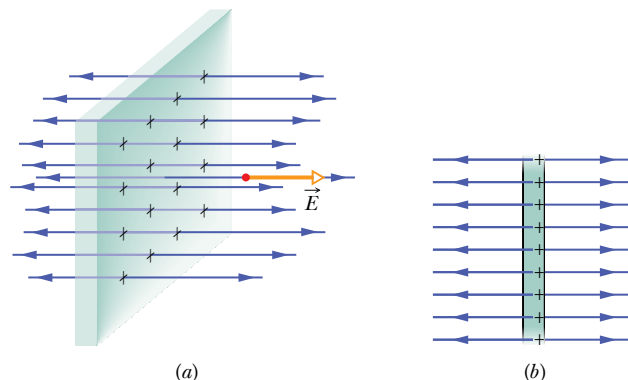

FIGURE 23-28 ■ Field lines for two equal positive point charges. The charges repel each other. (The lines terminate on distant negative charges.) To “see” the actual three-dimensional pattern of field lines, mentally rotate the pattern shown here about an axis passing through both charges in the plane of the page. The three-dimensional pattern and the electric field it represents are said to have rotational symmetry about that axis. The electric field vector at one point is shown; note that it is tangent to the field line through that point.

farther from the sheet. This is even more strongly suggested by a dimensional analysis argument. An E -field has dimensions that look like those of kq/r^2 . For an infinite sheet we can’t talk about the total charge (it’s infinite) but only the charge density sigma, denoted as σ . Sigma already has units of kq/r^2 so it is not possible to put in an extra distance. Doing the integral (which can be generalized from our integral for the ring) is messy but confirms this result. Because the charge is uniformly distributed along the sheet and all the field vectors have the same magnitude, the sheet creates a **uniform electric field**.

Of course, no real nonconducting sheet (such as a flat expanse of plastic) is infinitely large, but if we consider a region near the middle of a real sheet and not near its edges, the field lines through that region are arranged as in Figs. 23-27a and b.

Field Lines for Two Positive Charges

Figure 23-28 shows the field lines for two equal positive charges. Although we do not often use field lines quantitatively, they are very useful to visualize what is going on. It takes practice to learn to draw electric field lines even for a simple array of point sources. The steps include: (1) creating an electric field map, (2) deciding how detailed the field line representation should be and assigning a certain number of lines per unit charge, (3) placing the assigned number of lines at each point source. The lines should be equally spaced at the source with initial directions that depend on the sign of the source charge. The lines pass radially out from each positive source (and should be marked with an outward arrow). Or the lines pass radially into each negative source (and should be marked with an inward arrow as shown in Figs. 23-25 and 23-26). (4) Each line through the vector field map should be drawn so it is always tangent to the electric field vectors. (5) If the net charge in the region on the map is zero, each line begins on a positive charge and ends on a negative charge. If the net charge is negative, some of the lines come from infinity (off the field line diagram). If the net charge is positive, some of the lines veer off to infinity as shown in Fig. 23-26.

READING EXERCISE 23-7: Explain why the definition that says electric field lines point in the direction of the electric field means electric field lines must originate on positive charges and terminate on negative charges. ■

READING EXERCISE 23-8: Examine Fig. 23-12 showing that the net electric field along a line that bisects the two charges is always perpendicular to the line connecting the charges. How does the construction of this diagram help explain the fact that the net electric field due to a uniformly charged sheet (shown in Fig. 23-27) is always perpendicular to the sheet of charge? ■

Problems

In the following problems, all electric fields referenced are those produced by the source charge(s). That is, $\vec{E} = \vec{E}_s$.

SEC. 23-4 ■ THE ELECTRIC FIELD DUE TO A POINT CHARGE

- Point Charge** What is the amount of charge on a small particle whose electric field 50 cm away has the amount of 2.0 N/C?
- What Amount?** What is the amount of a point charge that would create an electric field of 1.00 N/C at points 1.00 m away?
- Plutonium-239** A plutonium-239 nucleus of radius 6.64 femptometers has an atomic number $Z = 94$. Assuming that the positive charge is distributed uniformly within the nucleus, what are the magnitude and direction of the electric field at the surface of the nucleus? Assume the influence of the positive charge at the nuclear surface is the same as that of a point charge.

SEC. 23-5 ■ THE ELECTRIC FIELD DUE TO MULTIPLE CHARGES

- Two Particles** Two particles with equal charge amounts 2.0×10^{-7} C but opposite signs are held 15 cm apart. What are the magnitude and direction of \vec{E} at the point midway between the charges?
- Two Point Charges** Two point charges $q_A = 2.1 \times 10^{-8}$ C and $q_B = -4.0q_A$ are fixed in place 50 cm apart. Find the point along the straight line passing through the two charges at which the electric field is zero.

- Two Fixed Charges** In Fig 23-29, two fixed point charges $q_A = +1.0 \times 10^{-6}$ C and $q_B = +3.0 \times 10^{-6}$ C are separated by a distance $d = 10$ cm. Plot their net electric field $\vec{E}(x)$ as a function of x for both positive and negative values of x , taking \vec{E} to be positive when \vec{E} points to the right and negative when \vec{E} points to the left.

FIGURE 23-29 ■ Problems 6 and 8.

- Four Charges** In Fig. 23-30, what is the magnitude of the electric field at point P due to the four point charges shown? The distance d is between charge centers.

FIGURE 23-30 ■ Problem 7.

- Separation of d** In Fig. 23-29, two fixed point charges $q_A = -5q$ and $q_B = +2q$ are separated by distance d . Locate the point (or points) at which the net electric field due to the two charges is zero.

FIGURE 23-31 ■ Problem 9.

- Square** What are the magnitude and direction of the electric field at the center of the square of Fig. 23-31 if $q = 1.0 \times 10^{-8}$ C and the distance between charge centers $a = 5.0$ cm?

- Three Charges** Calculate the direction and magnitude of the electric field at point P in Fig. 23-32, due to the three point charges. The distance between charge centers is a .

FIGURE 23-32 ■ Problem 10.

- Equilateral Triangle** Two particles, each with an amount of $|q|$ equal to charge of 12 nC, are placed at two of the vertices of an equilateral triangle. The length of each side of the triangle is 2.0 m. What is the magnitude of the electric field at the third vertex of the triangle if (a) both of the charges are positive and (b) one of the charges is positive and the other is negative?

- Plastic Ring** Figure 23-33 shows a plastic ring of radius $R = 50.0$ cm. Two small charged beads are on the ring: Bead 1 of charge $+2.00 \mu\text{C}$ is fixed in place at the left side; bead 2 of charge $+6.00 \mu\text{C}$ can be moved along the ring. The two beads produce a net electric field of magnitude E at the center of the ring. At what angle θ should bead 2 be positioned such that $E = 2.00 \times 10^5$ N/C?

FIGURE 23-33 ■ Problem 12.

- Three Particles Two** Three particles, each with positive charge q , form an equilateral triangle, with each side of length d . What is the magnitude of the electric field produced by the particles at the midpoint of any side?

- Separation L** Figure 23-34a shows two charged particles fixed in place on an x axis with separation L . The ratio q_A/q_B of their charge amounts is 4.00. Figure 23-34b shows the x -component E_x^{net} of their

FIGURE 23-34 ■ Problem 14.

net electric field along the x axis just to the right of particle B . (a) At what value of $x > 0$ is E_x^{net} maximum? (b) If particle B has charge $-q_B = -3e$, what is the value of that maximum?

- Two Charges Two** Figure 23-35 shows two charged particles on an x axis: $-q = -3.20 \times 10^{-19}$ C at $x = -3.00$ m and $q = 3.20 \times$

FIGURE 23-35 ■ Problem 15.

10^{-19} C at $x = +3.00$ m. What are the magnitude and direction of the net electric field they produce at point P at $y = 4.00$ m?

16. Eight Charges In Fig. 23-36, eight charged particles form a square array; charge $q = e$ and distance $d = 2.0$ cm. What are the magnitude and direction of the net electric field at the center?

FIGURE 23-36 Problem 16.

SEC. 23-6 ■ THE ELECTRIC FIELD DUE TO AN ELECTRIC DIPOLE

17. Calculate the Moment Calculate the electric dipole moment of an electron and a proton 4.30 nm apart.

18. Field at P In Fig. 23-16, let both charges be positive. Assuming $z \gg d$, show that the magnitude of the vector \vec{E} at point P in that figure is then given by

$$|\vec{E}| = k \frac{2|q|}{z^2}.$$

19. Electric Quadrupole Figure 23-37 shows an electric quadrupole. It consists of two dipoles with dipole moments that are equal in magnitude but opposite in direction. Show that the magnitude of the vector \vec{E} on the axis of the quadrupole for a point P a distance z from its center (assume $z \gg d$) is given by

FIGURE 23-37 Problem 19.

$$|\vec{E}| = \frac{3|Q|}{4\pi\epsilon_0 z^4},$$

in which $Q (= 2qd^2)$ is known as the *quadrupole moment* of the charge distribution.

20. Electric Dipole Find the magnitude and direction of the electric field at point P due to the electric dipole in Fig 23-38. The distance between charge center is d and P is located at a distance $r \gg d$ along the perpendicular bisector of the line joining the charges. Express your answer in terms of the magnitude and direction of the electric dipole moment \vec{p} .

FIGURE 23-38 Problem 20.

SEC. 23-7 ■ THE ELECTRIC FIELD DUE TO A RING OF CHARGE

21. Electron Constrained An electron is constrained to the central axis of the ring of charge of radius R discussed in Section 23-7. Show that the electrostatic force on the electron can cause it to oscillate through the center of the ring with an angular frequency

$$\omega = \sqrt{\frac{eq}{4\pi\epsilon_0 m R^3}},$$

where q is the ring's charge and m is the electron's mass.

22. Two Rings Figure 23-39 shows two parallel nonconducting rings arranged with their central axes along a common line. Ring A has uniform charge q_A and radius R ; ring B has uniform charge q_B and the same radius R . The rings are separated by a distance $3R$.

FIGURE 23-39 Problem 22.

The net electric field at point P on the common line, at distance R from ring A, is zero. What is the ratio q_A/q_B ?

23. Thin Glass Rod A thin glass rod is bent into a semicircle of radius r . A charge $+q$ is uniformly distributed along the upper half, and a charge $-q$ is uniformly distributed along the lower half, as shown in Fig. 23-40a. Find the magnitude and direction of the electric field \vec{E} at P , the center of the semicircle.

FIGURE 23-40 Problems 23 and 24.

24. Two Curved Plastic Rods In Fig. 23-40b, two curved plastic rods, one of charge $+q$ and the other of charge $-q$, form a circle of radius R in an xy plane. The x axis passes through their connecting points, and the charge is distributed uniformly on both rods. What are the magnitude and direction of the electric field \vec{E} produced at P , the center of the circle?

25. Nonconducting Rod In Fig. 23-41, a nonconducting rod of length L has charge $-q$ uniformly distributed along its length. (a) What is the linear charge density of the rod? (b) What is the electric

FIGURE 23-41 Problem 25.

field at point P , a distance a from the end of the rod? (c) If P were very far from the rod compared to L , the rod would look like a point charge. Show that your answer to (b) reduces to the electric field of a point charge for $a \gg L$.

26. What Distance? At what distance along the central axis of a ring of radius R and uniform charge is the magnitude of the electric field due to the ring's charge maximum?

27. Semi-Infinite Rod In Fig. 23-42, a “semi-infinite” nonconducting rod (that is, infinite in one direction only) has uniform linear charge density λ . Show that the electric field at point P makes an angle of 45° with the rod and that this result is independent of the distance R . (*Hint:* Separately find the parallel and perpendicular (to the rod) components of the electric field at P , and then compare those components.)

FIGURE 23-42 ■ Problem 27.

28. Length L Rod A thin nonconducting rod of finite length L has a charge q spread uniformly along it. Show that

$$|\vec{E}| = \frac{|q|}{2\pi\epsilon_0 y} \frac{1}{(L^2 + 4y^2)^{1/2}}$$

FIGURE 23-43 ■ Problem 28.

gives the magnitude $|\vec{E}|$ of the electric field at point P on the perpendicular bisector of the rod (Fig. 23-43).

29. Density, Density, Density. (a) A charge of $-300e$ is uniformly distributed along a circular arc of radius 4.00 cm, which subtends an angle of 40° . What is the linear charge density along the arc? (b) A charge of $-300e$ is uniformly distributed over one face of a circular disk of radius 2.00 cm. What is the surface charge density over that face? (c) A charge of $-300e$ is uniformly distributed over the surface of a sphere of radius 2.00 cm. What is the surface charge density over that surface? (d) A charge of $-300e$ is uniformly spread through the volume of a sphere of radius 2.00 cm. What is the volume charge density in that sphere?

30. Nonconducting Rod Two A thin nonconducting rod with a uniform distribution of positive charge Q is bent into a circle of radius R (Fig. 23-44). The central axis through the ring is a z axis, with the origin at the center of the ring. What is the magnitude of the electric field due to the rod at (a) $z = 0$ and (b) $z = \pm \infty$? (c) In terms of R , at what values of z is that magnitude maximum? (d) If radius $R = 2.00$ cm and charge $Q = 4.00 \mu\text{C}$, what is the maximum magnitude?

FIGURE 23-44 ■ Problem 30.

31. Circular Rod A circular rod has a radius of curvature R and a uniformly distributed charge Q and it subtends an angle θ (in radians). What is the magnitude of the electric field it produces at the center of curvature?

FIGURE 23-45 ■ Problem 32.

32. Two Concentric Rings Figure 23-45 shows two concentric rings, of radii R and $R' = 3.00R$, that lie on the same plane. Point P lies on the central z axis, at distance $D = 2.00R$ from the center of the rings. The smaller ring has uniformly distrib-

uted charge $+Q$. What must be the uniformly distributed charge on the larger ring if the net electric field at point P due to the two rings is to be zero?

33. Charge $+Q$ In Fig. 23-46a, a particle of charge $+Q$ produces an electric field with a magnitude E_{part} at point P , at distance R from it. In Fig. 23-46b, that same amount of charge is spread uniformly along a circular arc that has radius R and subtends an angle θ . The charge on the arc produces an electric field with a magnitude E_{arc} at its center of curvature P . For what value of θ does $E_{\text{arc}} = 0.500 E_{\text{part}}$? (*Hint:* You can use a graphical solution.)

(a)

(b)

FIGURE 23-46 ■ Problem 33.

34. Half Circle Figure 23-47a shows a nonconducting rod with a uniformly distributed charge $+Q$. The rod forms a half circle with radius R and produces an electric field of magnitude E_{arc} at its center of curvature P . If the arc is collapsed to a point at distance R from P (Fig. 23-47b), by what factor is the magnitude of the electric field at P multiplied?

(a)

(b)

FIGURE 23-47 ■ Problem 34.

SEC. 23-8 ■ MOTION OF POINT CHARGES IN AN ELECTRIC FIELD

35. Electron Released from Rest An electron is released from rest in a uniform electric field of magnitude 2.00×10^4 N/C. Calculate the acceleration of the electron. (Ignore gravitation.)

36. Accelerated Electron An electron is accelerated eastward at 1.80×10^9 m/s² by an electric field. Determine the magnitude and direction of the electric field.

37. Force Due to Dipole Calculate the magnitude of the force, due to an electric dipole of dipole moment 3.6×10^{-29} C · m, on an electron 25 nm from the center of the dipole, along the dipole axis. Assume that this distance is large relative to the dipole's charge separation.

38. Alpha Particle An alpha particle (the nucleus of a helium atom) has a mass of 6.64×10^{-27} kg and a charge of $+2e$. What are the magnitude and direction of the electric field that will balance the gravitational force on it?

39. Charged Cloud A charged cloud system produces an electric field in the air near Earth's surface. A particle of charge -2.0×10^{-9} C is acted on by a downward electrostatic force of 3.0×10^{-6} N when placed in this field. (a) What is the magnitude of the electric field? (b) What are the magnitude and direction of the electrostatic force exerted on a proton placed in this field? (c) What is the gravitational force on the proton? (d) What is the ratio of the

magnitude of the electrostatic force to the magnitude of the gravitational force in this case?

40. Humid Air Humid air breaks down (its molecules become ionized) in an electric field of 3.0×10^6 N/C. In that field, what is the magnitude of the electrostatic force on (a) an electron and (b) an ion with a single electron missing?

41. High-Speed Protons Beams of high-speed protons can be produced in “guns” using electric fields to accelerate the protons. (a) What acceleration would a proton experience if the gun’s electric field were 2.00×10^4 N/C? (b) What speed would the proton attain if the field accelerated the proton through a distance of 1.00 cm?

42. Floating a Sulfur Sphere An electric field E with an average magnitude of about 150 N/C points downward in the atmosphere near Earth’s surface. We wish to “float” a sulfur sphere weighing 4.4 N in this field by charging the sphere. (a) What charge (both sign and magnitude) must be used? (b) Why is the experiment impractical?

43. Two Oppositely Charged Plates A uniform electric field exists in a region between two oppositely charged plates. An electron is released from rest at the surface of the negatively charged plate and strikes the surface of the opposite plate, 2.0 cm away, in a time 1.5×10^{-8} s. (a) What is the speed of the electron as it strikes the second plate? (b) What is the magnitude of the electric field \vec{E} ?

44. Field Retards Motion An electron with a speed of 5.00×10^8 cm/s enters an electric field of magnitude 1.00×10^3 N/C, traveling along the field lines in the direction that retards its motion. (a) How far will the electron travel in the field before stopping momentarily and (b) how much time will have elapsed? (c) If the region with the electric field is only 8.00 mm long (too short for the electron to stop within it), what fraction of the electron’s initial kinetic energy will be lost in that region?

45. Two Copper Plates Two large parallel copper plates are 5.0 cm apart and have a uniform electric field between them as depicted in Fig. 23-48. An electron is released from the negative plate at the same time that a proton is released from the positive plate. Neglect the force of the particles on each other and find their distance from the positive plate when they pass each other. (Does it surprise you that you need not know the electric field to solve this problem?)

FIGURE 23-48 ■ Problem 45.

46. Velocity Components At some instant the velocity components of an electron moving between two charged parallel plates are $v_x = 1.5 \times 10^5$ m/s and $v_y = 3.0 \times 10^3$ m/s. Suppose that the electric field between the plates is given by $\vec{E} = (120 \text{ N/C})\hat{j}$. (a) What is the acceleration of the electron? (b) What will be the velocity of the electron after its x coordinate has changed by 2.0 cm?

47. Uniform Upward Field In Fig. 23-49, a uniform, upward-directed electric field \vec{E} of magnitude 2.00×10^3 N/C has been set up between two horizontal plates by charging the lower plate positively and the upper plate negatively. The plates have length

FIGURE 23-49 ■ Problem 47.

$L = 10.0$ cm and separation $d = 2.00$ cm. An electron is then shot between the plates from the left edge of the lower plate. The initial velocity \vec{v}_1 of the electron makes an angle $\theta = 45.0^\circ$ with the lower plate and has a magnitude of 6.00×10^6 m/s. (a) Will the electron strike one of the plates? (b) If so, which plate and how far horizontally from the left edge will the electron strike?

48. Charge in an E Field A 10.0 g block with a charge of $+8.00 \times 10^{-5}$ C is placed in electric field $\vec{E} = (3.00 \times 10^3 \text{ N/C})\hat{i} - 600 \text{ N/C})\hat{j}$. (a) What are the magnitude and direction of the force on the block? (b) If the block is released from rest at the origin at $t = 0.00$ s, what will be its coordinates at $t = 3.00$ s?

49. Entering a Field An electron enters a region of uniform electric field with an initial velocity of 40 km/s in the same direction as the electric field, which has magnitude $E = 50$ N/C. (a) What is the speed of the electron 1.5 ns after entering this region? (b) How far does the electron travel during the 1.5 ns interval?

50. An Electron Is Shot In Fig. 23-50, an electron is shot at an initial speed of $v_1 = 2.00 \times 10^6$ m/s, at angle $\theta_1 = 40^\circ$ from an x axis. It moves in a region with uniform electric field $\vec{E} = (5.00 \text{ N/C})\hat{j}$. A screen for detecting electrons is positioned parallel to the y axis, at distance $x = 3.00$ m. In unit-vector notation, what is the velocity of the electron when it hits the screen?

FIGURE 23-50 ■ Problem 50.

51. TV Tube Figure 23-51 shows the deflection-plate system of a conventional TV tube. The length of the plates is 3.0 cm and the electric field between the two plates is 10^6 N/C (vertically up). If the electron enters the plates with a horizontal velocity of 3.9×10^7 m/s, what is the vertical deflection Δy at the end of the plates?

FIGURE 23-51 ■ Problem 51.

SEC. 23-9 ■ A DIPOLE IN AN ELECTRIC FIELD

52. Dipole in a Field An electric dipole, consisting of charges of magnitude 1.50 nC separated by $6.20 \mu\text{m}$, is in an electric field of strength 1100 N/C. (a) What is the magnitude of the electric dipole moment? (b) What is the difference between the potential energies corresponding to dipole orientations parallel to and antiparallel to the field?

53. Torque on a Dipole An electric dipole consists of charges $+2e$ and $-2e$ separated by 0.78 nm. It is in an electric field of strength 3.4×10^6 N/C. Calculate the magnitude of the torque on the dipole when the dipole moment is (a) parallel to, (b) perpendicular to, and (c) antiparallel to the electric field.

54. Work Required Find the work required to turn an electric dipole end for end in a uniform electric field \vec{E} , in terms of the magnitude $|\vec{p}|$ of the dipole moment, the magnitude $|\vec{E}|$ of the field, and the initial angle θ_1 between \vec{p} and \vec{E} .

55. Frequency of Oscillation Find the frequency of oscillation of an electric dipole, of dipole moment \vec{p} and rotational inertia I , for small amplitudes of oscillation about its equilibrium position in a uniform electric field of magnitude $|\vec{E}|$.

56. A Certain Dipole A certain electric dipole is placed in a uniform electric field \vec{E} of magnitude 40 N/C. Figure 23-52 gives the magnitude τ of the torque on the dipole versus the angle θ between \vec{E} and the dipole moment \vec{p} . What is the magnitude of \vec{p} ?

FIGURE 23-52 ■

Problem 56.

57. How Much Energy How much energy is needed to flip an electric dipole from being lined up with a uniform external electric field to being lined up opposite the field? The dipole consists of an electron and a proton at a separation of 2.00 nm, and it is in a uniform field of magnitude 3.00×10^6 N/C.

58. See Graph A certain electric dipole is placed in a uniform electric field \vec{E} of magnitude 20 N/C. Figure 23-53 gives the potential energy U of the dipole versus the angle θ between \vec{E} and the dipole moment \vec{p} . What is the magnitude of \vec{p} ?

FIGURE 23-53 ■ Problem 58.

SEC. 23-10 ■ ELECTRIC FIELD LINES

59. Twice the Separation In Fig. 23-54, the electric field lines on the left have twice the separation of those on the right. (a) If the magnitude of the field at A is 40 N/C, what force acts on a proton at A ? (b) What is the magnitude of the field at B ?

FIGURE 23-54 ■ Problem 59.

60. Sketch Sketch qualitatively the electric field lines both between and outside two concentric conducting spherical shells when a uniform positive charge q_A is on the inner shell and a uniform negative charge $-q_B$ is on the outer. Consider the cases $q_A > q_B$, $q_A = q_B$ and $q_A < q_B$.

61. Thin Circular Disk Sketch qualitatively the electric field lines for a thin, circular, uniformly charged disk of radius R . (*Hint:* Consider as limiting cases points very close to the disk, where the electric field is directed perpendicular to the surface, and points very far from it, where the electric field is like that of a point charge.)

62. Particles and Lines In Fig. 23-55, particles with charges $+1.0q$ and $-2.0q$ are fixed a distance d apart. Find the magnitude and direction of the net electric field at points (a) A , (b) B , and (c) C . (d) Sketch the electric field lines.

FIGURE 23-55 ■ Problem 62.

63. Three Point Charges Two In Fig. 23-56, three point charges are arranged in an equilateral triangle. (a) Sketch the field lines due to $+Q$ and $-Q$, and from them determine the direction of the force that acts on $+q$ because of the presence of the other two charges. (b) What is the magnitude of that net electric force on $+q$?

FIGURE 23-56 ■ Problem 63.

Additional Problems

64. Two Electric Charges—Electric Force Figure 23-57 shows seven arrangements of two electric charges. In each figure, a point labeled P is also identified. All of the charges are the same size, 20 nC, but they can be either positive or negative. The charges and point P all lie on a straight line. The distances between adjacent items, either between two charges or between a charge and point P , are all 5 cm. There are no other charges in this region. For this problem, we will place a $+5$ nC charge at point P . Rank these arrangements from greatest to least on the basis of the magnitude of the electric force on the $+5$ nC charge when it is placed at point P . [Based on Ranking Task 126, O’Kuma, et. al., *Ranking Task Exercises* (Prentice Hall, Upper Saddle River, NJ, 2000).]

FIGURE 23-57 ■ Problem 64.

65. Fixed and Suspended Charges—Angle Figure 23-58 shows m_A , a stationary sphere with charge q_A . The charge m_B is suspended from the ceiling by a nonconducting string and has charge q_B . The masses m_A and m_B are conducting spheres of the same size. The charges q_A and q_B have the same sign. From the combinations below, rank the angle the string will form with the vertical from highest to lowest value. If any of the angles are the same, state that. Explain your reasoning.

- | | | | |
|--------------------------------|--------------------------|--------------------------------|--------------------------|
| (a) $m_A = m;$
$m_B = m;$ | $q_A = q$
$q_B = q$ | (d) $m_A = 2m;$
$m_B = 2m;$ | $q_A = q$
$q_B = q$ |
| (b) $m_A = 2m;$
$m_B = 2m;$ | $q_A = q$
$q_B = 2q$ | (e) $m_A = m;$
$m_B = 2m;$ | $q_A = 2q$
$q_B = 2q$ |
| (c) $m_A = m;$
$m_B = m;$ | $q_A = 2q$
$q_B = 2q$ | (f) $m_A = m;$
$m_B = m;$ | $q_A = q$
$q_B = 2q$ |

[Based on Ranking Task 138, O’Kuma, et. al., *Ranking Task Exercises* (Prentice Hall, Upper Saddle River, NJ, 2000).]

66. Electric Force on Same Charge Figure 23-59 shows a large region of space that has a uniform electric field in the x direction. At the

FIGURE 23-58 ■ Problem 65.

point $(0, 0)$ m, the electric field is $(30 \text{ N/C})\hat{i}$. Rank the magnitude of the electric force from greatest to least on a 5 C charge when it is placed at each of the following points: A , $(0 \text{ m}, 0 \text{ m})$; B , $(0 \text{ m}, 3 \text{ m})$; C , $(-3 \text{ m}, 0 \text{ m})$; D , $(3 \text{ m}, 0 \text{ m})$; E , $(3 \text{ m}, 3 \text{ m})$; F , $(6 \text{ m}, 0 \text{ m})$. Explain your reasoning. [Based on Ranking Task 139, O’Kuma, et. al., *Ranking Task Exercises* (Prentice Hall, Upper Saddle River, NJ, 2000).]

FIGURE 23-59 ■ Problem 66.

67. Dependence of E Figure 23-60 shows a fixed charge (specified by a circle) and a location (specified by the x). A test charge is placed at the x to measure the electric effect of the fixed charge. Complete the following two statements as quantitatively as you can. (For example, if the result is larger by a factor of three, don’t say “increases”—say “triples” or “is multiplied by three.”) Each statement is meant to be compared with the original situation. (The changes don’t accumulate).

FIGURE 23-60 ■ Problem 67.

(a) If the test charge is replaced by one with half the amount of charge, then the electric field it experiences will _____.

(b) If the fixed charge is replaced by one with twice the amount of charge, then the electric field experiences by the test charge will _____.

68. What Is Going on at P ? Figure 23-61 shows two charges of $-q$ arranged symmetrically about the y axis. Each produces an electric field at point P . (a) Are the magnitudes of the fields equal? Why or why not? (b) Does each electric field point toward or away from the charge producing it? Explain. (c) Is the magnitude of the net electric field equal to the sum of the magnitudes of the two field vectors (that is, equal to $2E$)? Why or why not? (d) Do the x -components of the two fields add or cancel? Explain. (e) Do the y -components of the two fields add or cancel? Explain. [Based on question 5.20, Arons, *Homework and Test Questions for Introductory Physics Teaching* (Wiley, New York, 1994).]

FIGURE 23-61 ■ Problem 68.

69. Field Lines Figure 23-62 shows the region in the neighborhood of a negatively charged conducting sphere and a large positively charged conducting plate extending far beyond the region shown. Someone claims that lines A – F are possible field lines representing the electric field lying in the region between the two conductors. (a)

Examine each of the lines and indicate whether it is a correctly drawn field line. If a line is not correct, explain why. (b) Redraw the diagram with a pattern of field lines that is more correct.

FIGURE 23-62 ■ Problem 69.

70. Field Lines Two Figure 23-63 shows the electric field lines for three point charges that are positive and negative as indicated. (a) Show the *direction* of each of the electric field lines with an arrow, and (b) if the central charge is $+1.0 \mu\text{C}$ what are the values of the outer charges?

FIGURE 23-63 ■ Problem 70.

71. Field Lines Three Figure 23-64 shows the electric field lines for three point charges separated by a small distance. The two outer charges are identical and the one in the center is different. (a) Determine the ratio, q_A/q_B , of one of the outer charges to the inner one. (b) Determine the signs of q_A and q_B .

FIGURE 23-64 ■ Problem 71.

72. Functional Dependence and the Electric Field (a)

Suppose you want to purchase a sweater in Maryland that has a list price of \$40 for which you pay \$2 in sales tax. Your friend bought the same sweater in Maryland, but it had a list price of \$80 for which she paid \$4 in sales tax. How does the ratio of sales tax to price of the sweater compare for you and your friend [i.e., compare the ratios (sales tax)/(sweater price)]? What does that ratio tell us? As what is that ratio defined? (b) Suppose a charge exerts a repulsive force of 4 N on a test charge of $0.2 \mu\text{C}$ that is 2 cm from it. However, the charge exerts a repulsive force of 8 N on a test charge of $0.4 \mu\text{C}$ that is 2 cm from it. How does the ratio of the force on the test charge to the test charge itself compare in each case [i.e., compare (force felt by test charge)/(test charge)]? What does that ratio tell us? What is that ratio defined as? (c) Suppose a charge Q exerts a force F on a test charge q that is placed near it. By how much would the force exerted by Q increase if the test charge increased by a factor of α , where α can be any constant (i.e., $\alpha = -17$ or 5 or 7.812 , etc.)? By how much would the ratio of the force on the test charge to the test charge itself increase if the test charge increased by a factor of α ?

Explain. (d) When the value of one quantity depends on the value of a second quantity (and perhaps on others), we say that the first quantity is a *function of* the second. *How* the first quantity changes when the second changes is called the *functional dependence*. For example, if $t = As$, we say that t has a linear functional dependence on s . When s doubles, so does t . If s is divided by 10, so is t . As a second example, if we had $y = Bx^2$, we would say that y depends quadratically on x . If x doubles, y quadruples. If x is divided by 10, then y is divided by 100. (Try this with some numbers, picking whatever values of the constants A and B you would like.)

- (i) What is the functional dependence on the sales tax paid on the price of the sweater in part (a)? Explain. Write an equation that relates the tax paid (t) to the cost of the sweater (s).
- (ii) What is the functional dependence of the sales tax percentage rate on the price of the sweater in part (a)? Explain.
- (iii) In part (c), what is the functional dependence of the force magnitude, F , on the amount of the test charge, $|q|$? Explain.
- (iv) In part (c), what is the functional dependence of the electric field magnitude established by Q , E_Q , on the test charge, q ? Explain.

73. E-Field Multiple Representations Figure 23-65a displays a grid with coordinates measured in meters. On the grid two charges are placed with their positions indicated as red circles. We call the charge at the position (1 m, 0 m) q_A , and the charge at the position (-1 m, 0 m) q_B . Figure 23-65b shows a set of possible vector directions. Below is a list of the components of possible E fields. For each of the following three cases:

- | | | | |
|-----|--------------------------|--------------------------|---|
| I | $q_A = 0$ | $q_B = 8\pi\epsilon_0$ | E field at the point
(x, y) = (-1 m, 1 m) |
| II | $q_A = 0$ | $q_B = -8\pi\epsilon_0$ | E field at the point
(x, y) = (-1 m, -1 m) |
| III | $q_A = 160\pi\epsilon_0$ | $q_B = -16\pi\epsilon_0$ | E field at the point
(x, y) = (0 m, -1 m) |

specify an arrow corresponding to the directions of the E field from figure (b) and a set of components from the list on the right. Each of your answers should consist of a capital letter and a small letter.

(Note: The values of the charges in Coulombs are chosen to make the messy “ $4\pi\epsilon_0$ ” in Coulomb’s law cancel. Don’t put in numbers first!)

74. The Size of an Oil Drop In the Millikan oil drop experiment, an atomizer (a sprayer with a fine nozzle) is used to introduce many tiny droplets of oil between two oppositely charged parallel metal plates. Some of the droplets pick up one or more excess electrons. The charge on the plates is adjusted so that the electric force on the excess electrons exactly balances the weight of the droplet. The idea is to look for a droplet that has the smallest electric force and assume that it has only one excess electron. This lets the observer measure the charge on the electron. Suppose we are using an electric field of $3 \times 10^4 \text{ N/C}$. The charge on one electron is about $1.6 \times 10^{-19} \text{ C}$. Estimate the radius of an oil drop whose weight could be balanced by the electric force of this field on one electron.

75. What’s a Field? In this class, we repeatedly refer to an “electric field.” Describe what an electric field is. Discuss how you would know a nonzero field was present and how you would measure it.

76. Charge from Field Lines Figure 23-66 shows some representative electric field lines associated with some charges. Both pictures show the same charges, but they are masked in different ways by imaginary closed surfaces drawn for the purpose of hiding the charges from your view.

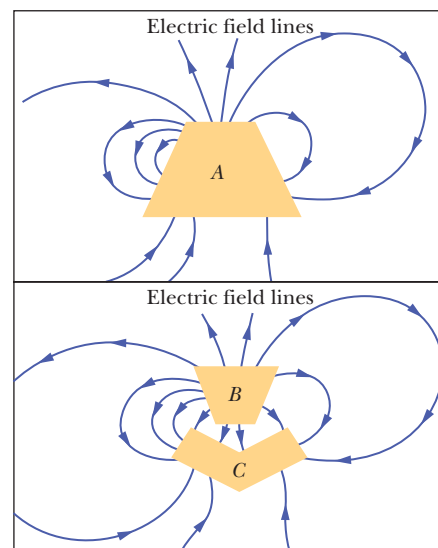

FIGURE 23-66 ■ Problem 76.

- (a) From the field lines in the two pictures, which of the following statements is most likely to be true?
 - A. There are no charges contained in A.
 - B. The charge contained in A is positive.
 - C. The charge contained in A is negative.
 - D. The total charge contained in A is zero.
 - E. None of the above can be true.
- (b) From the field lines in the two pictures, which of the following statements is most likely to be true?
 - A. There are no charges contained in B.
 - B. The charge contained in B is positive.
 - C. The charge contained in B is negative.
 - D. The total charge contained in B is zero.
 - E. None of the above.
- (c) From the field lines in the two pictures, which of the following statements is most likely to be true?
 - A. The charge contained in C is positive and greater in amount than the charge in B.
 - B. The charge contained in C is positive and smaller in amount than the charge in B.
 - C. The charge contained in C is negative and greater in amount than the charge in B.
 - D. The total charge contained in C is negative and smaller in amount than the charge in B.
 - E. None of the above.

77. Finding the E Field Figure 23-67 shows two charges placed on a coordinate grid. Each of the tic marks on the axes represents 1 m. The amount of the charge is represented by the solid circle is q_A and is at the position (2 m, 0 m), while the charge represented by the open circle is q_B and is at the position (0 m, 2 m). Below is a list of five sets of configurations (labeled a–e) specifying the value of the charges and the positions at which the E field is to be measured. For ease of calculation, these are represented in terms of the Coulomb constant $k = 1/4\pi\epsilon_0$. On the right is a list of 12 possible electric fields represented as x - and y -components. For each of the five configurations, select the E -field components that represent the field found at that position.

- $(2 \text{ N/C})\hat{j}$
- $(-2 \text{ N/C})\hat{i}$
- None of the above

78. Beads on a Ring Two charged beads are on the plastic ring in Fig. 23-68a. Bead 2, which is not shown, is fixed in place on the ring, which has radius $R = 60.0$ cm. Bead 1 is initially at the right side of the ring, at angle $\theta = 0^\circ$. It is then moved to the left side, through the first and second quadrants of the xy coordinate system. Figure 23-68b gives the x -component of the net electric field produced at the origin by the two beads as a function of θ . Similarly, Fig. 23-68c gives the y -component. (a) At what angle θ is bead 2 located? What are the charges of (b) bead 1 and (c) bead 2?

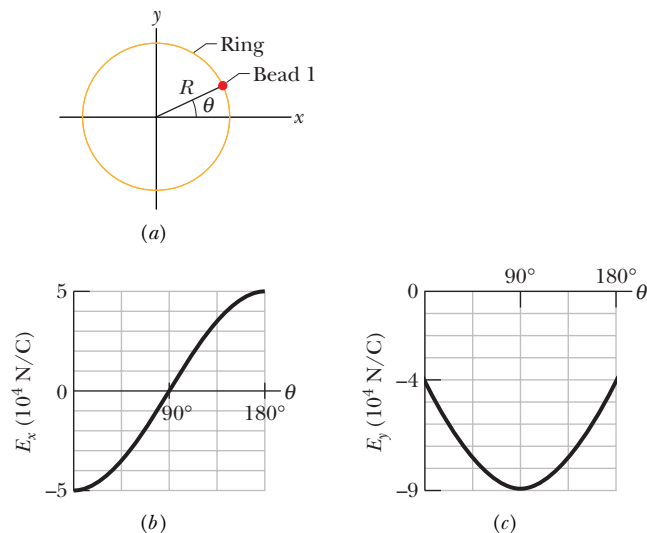

FIGURE 23-68 ■ Problem 78.

24

Gauss' Law

A demonstrator at the Boston Museum of Science is enclosed in a large conducting cage made of wire mesh. An electrical discharge from a giant Van de Graaff generator, like the one discussed in Chapter 25, is charging the metal cage to a dangerously high voltage. Yet the demonstrator cannot detect the fact that the cage is electrically charged even while touching the inside of the cage.

How can a closed conducting surface such as this metal cage or an automobile prevent someone from being harmed by lightning or other high-voltage sources?

The answer is in this chapter.

FIGURE 24-1 ■ If a single charge is located at the center of an imaginary sphere, Coulomb's law tells us the magnitudes of the electric field vectors are the same at all points on the surface of the sphere and the direction of each electric field vector is normal (perpendicular) to the surface. Only the field vectors that lie in the plane of the page are shown in this drawing.

24-1 An Alternative to Coulomb's Law

We associate a vector electric field with a distribution of charges. The electric field has a vector at every location in space telling us what force a test charge q_t will experience at that location. In Sections 23-5 through 23-10 in the last chapter, we used Coulomb's law and the principle of superposition to calculate the electric field vectors at various points in space due to charges that were distributed in different ways. Although Coulomb's law can be used to calculate the electric force (and hence electric field) exerted on a test charge by any possible arrangement of charges we could imagine, this is usually a very difficult task. For example, even calculating the electric field outside the surface of a hollow, charged, conducting sphere would require us to do a triple integration.

In Chapter 23 we used Coulomb's law to find electric fields from charge distributions, but what if we want to turn our calculation around and determine a distribution of charges from an electric field pattern? Unless our distribution of charges is very simple, this reverse calculation is also difficult to perform using Coulomb's law. Thus Coulomb's law appears to be valid but difficult to use in many circumstances. In this chapter we introduce Gauss' law as another method for relating a known electric field to the charge distribution generating it and, conversely, for relating a known charge distribution to its associated electric field. Gauss' law in the integral form discussed in this chapter allows us to find electric fields easily for very symmetrical charge distributions.

To explore how we might find a general relationship between a collection of charges and their electric field, let's consider the electric field associated with the simplest possible charge distribution—a point charge (see Fig. 24-1). By applying Coulomb's law we have already found that the magnitude of the charge's electric field *decreases* as the inverse square of the distance r , as expressed in Eq. 23-8,

$$E = |\vec{E}| = k \frac{|q|}{r^2}.$$

However, if we construct an imaginary spherical surface around our source charge we find that the surface area of the sphere *increases* as the square of the distance of the spherical surface from the source charge. The equation for the surface area is given by $A = 4\pi r^2$. Thus, we see that the product of the electric field magnitude and the surface area of any imaginary spherical boundary is constant no matter how large or small the distance from the charge is, as shown in Eq. 24-1,

$$EA = k \frac{|q|}{r^2} (4\pi r^2) = \frac{1}{4\pi\epsilon_0} \frac{|q|}{r^2} (4\pi r^2) = \frac{|q|}{\epsilon_0}. \quad (24-1)$$

Here we use Eq. 22-7 to replace the electrostatic constant k with $1/4\pi\epsilon_0$ where ϵ_0 is the electric (or permittivity) constant.

Equation 24-1 is remarkable for two reasons. First, as the electric field magnitude gets smaller, the area over which it can act gets larger by exactly the same factor. Second, the product of the electric field magnitude anywhere on a spherical surface and the area of the spherical surface is *proportional* to the amount of charge $|q|$ enclosed by that surface. Does this proportionality still exist when the closed surface takes on other shapes? These questions were addressed by German mathematician and physicist Carl Friedrich Gauss (1777–1855). We begin our study of Gauss' approach to relating charge distributions, electric fields, and closed surfaces to each other by defining a new quantity called electric flux.

24-2 Electric Flux

For the case of a single point charge at the center of an imaginary sphere, Eq. 24-1 tells us that the product of the electric field magnitude (at the surface of a sphere) and the surface area of the sphere are proportional to the charge. This product EA is known as the **electric flux** through the sphere. In our simple situation the directions of electric field vectors created by the point charge happen to be normal (that is, perpendicular) to the surface of our imaginary sphere at all points along its surface. What if we have a complex array of charges or decide to surround our charge with an imaginary enclosure with a different shape? In that case we need to break our surface into little elements of area and find the component of the electric field vector that is normal to each area element as depicted in Fig. 24-2. We took a similar approach in Section 15-10 in defining *volume flux* for fluids flowing in pipes and streams. If the definitions of volume flux and normal vector for an area are not familiar to you, we suggest you read this earlier section.

FIGURE 24-2 (a) A small area vector element $\Delta\vec{A}$ is perpendicular to the plane of a square loop of area A with a magnitude of A . (b) The component of \vec{E} perpendicular to the plane of the loop is $|\vec{E}|\cos\theta$, where θ is the angle between \vec{E} and a normal to the plane. (c) The area vector $\Delta\vec{A}$ makes an angle θ with \vec{E} .

If we know the nature of the velocity vector field, \vec{v} , characterizing the motion of the fluid, we can use the definition of volume flux presented in Chapter 15 to calculate the amount of fluid flowing through any very small element, $\Delta\vec{A}_i$, of a larger surface area*. If we look at the i th element of a larger area, the *volume flux* element, Φ_i , for that small area is defined as the scalar or dot product of the normal vector representing an area element and the velocity vector at the location of the area element as shown in Eq. 15-33,

$$\Phi_i \equiv \vec{v}_i \cdot \Delta\vec{A}_i \quad (\text{volume flux definition for a small area element}).$$

What is a normal vector? Recall that we defined the normal vector to a small flat area to allow us to represent both the magnitude and the orientation of an element of area. If the element of area is part of a closed surface completely surrounding a space, we define the normal vector to be pointing *out* of the surface (Fig. 24-3). The normal vector points at right angles, or normal, to the plane of the area and has a magnitude equal to the area (Fig. 24-4).

Although *electric flux* does not involve the flow of anything, we define it in a way mathematically analogous to volume flux introduced in Chapter 15. An **electric flux element** is defined as the dot product of the normal vector representing an area element and the electric field vector at the location of the area element as shown in Fig. 24-2 and in Eq. 24-2,

$$\Phi_i \equiv (E_i)(\Delta A_i)\cos\theta = \vec{E}_i \cdot \Delta\vec{A}_i \quad (\text{electric flux definition for a small area}), \quad (24-2)$$

where E_i and ΔA_i are magnitudes while θ is the angle between the two vectors. If a curved surface like the one in Fig. 24-3 is broken into small area elements, each of the $\Delta\vec{A}_i$ vectors can point in different directions.

*Our use of the symbol ΔA_i instead of just A_i is to signify that the areas are very small. In this context, the delta does not signify change.

FIGURE 24-3 In order to make net flux calculations, a curved surface area must be divided into N small area elements. Each element must be small enough so it is essentially flat and has electric field vectors that have the same magnitude and direction at every location on a given surface element. The i th area element and its normal vector are shown assuming that an outside piece of a closed surface is being shown here.

FIGURE 24-4 ■ Three small areas that subtend different angles with respect to various electric field vectors. The first flux element is negative, the second zero, and the third positive. Note that nothing is “flowing” in the case of electric flux to exist.

As is the case for volume flux, if our area is not small enough to be considered as flat or if the electric field vectors are not uniform over the area we choose, then we must break the area into smaller elements that are essentially flat (Fig. 24-4). We can then determine the net electric flux as the sum of individual flux elements. For N flux elements, this is given by

$$\begin{aligned}\Phi^{\text{net}} &= \Phi_1 + \Phi_2 + \cdots + \Phi_N \\ &= \vec{E}_1 \cdot \Delta\vec{A}_1 + \vec{E}_2 \cdot \Delta\vec{A}_2 + \cdots + \vec{E}_N \cdot \Delta\vec{A}_N \quad (\text{net electric flux}), \quad (24-3) \\ &= \sum_{n=1}^N \vec{E}_n \cdot \Delta\vec{A}_n\end{aligned}$$

where \vec{E}_1 , \vec{E}_2 , \vec{E}_3 , and so on represent the electric field vectors at the location of each of the N area elements. The flux associated with an electric field is a scalar, and its SI unit is the newton-meter-squared per coulomb or $[\text{N} \cdot \text{m}^2/\text{C}]$.

Some possible orientations for area elements and electric field vectors needed to calculate electric flux elements are shown in Fig. 24-4.

In everyday language the term flux is often used to represent flow or change. This is suggested by expressions such as “an influx of population” or “the economy is in a state of flux.” These popular uses of the word flux can be deceptive when applied to electrostatic phenomena that we are dealing with in Chapters 22 through 25. Electric flux can be defined whenever an electric field exists, even when an electric field is static and not changing. Furthermore, even if a redistribution of charges causes an electric field to change over time, the changing flux associated with electric field is not related to the flow of anything.

Instead of representing change or flow, **electric flux** at an area represents the summation over a surface of flux elements. Each flux element represents the product of an essentially flat area element on the surface and the component of the electric field vector that lies along the normal to that area element.

READING EXERCISE 24-1: The figure shows two situations in which the angle between a field vector and the normal vector representing the orientation of the area is $\theta = 60^\circ$. Assume the magnitude of the area in each case is $\Delta A = 2 \times 10^{-4} \text{ m}^2$. (a) If the imaginary area element is placed at a location in a stream where the magnitude of the stream velocity is $v = 3 \text{ m/s}$, what is the volume flux through the area? Is anything flowing through the area element? If so, what? (b) Suppose the imaginary area element is placed in an electric field where the magnitude of the field vector is $E = 3 \text{ N/C}$. What is the electric flux through the area element? Is anything flowing through the area element? If so, what? ■

24-3 Net Flux at a Closed Surface

In the introductory section we posed the question of whether there is a proportionality between an enclosed charge distribution and the flux at a surface that encloses it. To answer this question we need to examine carefully the procedures for determining net electric flux at an imaginary surface that encloses charges. The word “enclose” is

important here. In the discussion that follows, we will not be discussing calculations of electric flux at any arbitrary surface. We will limit our discussion to the electric flux at closed surfaces that are continuous and connected. That is, a **closed** surface must be without cuts or edges. Nothing can get into or out of such surfaces without passing through the surface itself.

In order to define the net electric flux at any closed surface, consider Fig. 24-5, which shows an arbitrary (irregularly shaped) imaginary surface immersed in a *nonuniform* electric field. For historical reasons, any imaginary closed surface used in the calculation of a net electric flux is called a **Gaussian surface**. Since the electric field vector might be different at each location on our Gaussian surface, we must divide the entire surface into small area elements and take the sum as shown in Eq. 24-3.

Let's consider the arbitrary closed surface shown in Fig. 24-5. The vectors $\Delta\vec{A}_i$ and \vec{E}_i for each square have some angle θ_i between them. Figure 24-5 shows an enlarged view of three small squares (1, 2, and 3) on the Gaussian surface, and the angle θ_i between \vec{E}_i and $\Delta\vec{A}_i$. Our net flux equation (Eq. 24-3) instructs us to visit each square on the Gaussian surface, to evaluate the scalar product $\vec{E}_i \cdot \Delta\vec{A}_i$ at the location of each, and to sum the results algebraically (that is, with signs included) for all the squares that make up the surface. The sign or a zero resulting from each scalar product determines whether the flux at a square is positive, negative, or zero. Squares like 1, in which \vec{E}_1 points inward, make a negative contribution to the sum. Squares like 2, in which \vec{E}_2 lies in the surface, make zero contribution. Squares like 3, in which \vec{E}_3 points outward, make a positive contribution. (Note that the particular signs for the flux elements discussed above are a consequence of the convention adopted on the previous page; the area vectors point outward for closed surfaces.)

The exact definition of the flux of the electric field at a surface is found by allowing the area of the squares shown in Fig. 24-5 to become smaller and smaller, approaching a differential limit dA . The normal vectors for each tiny surface area then approach a differential limit $d\vec{A}$. Thus, the electric flux at a closed surface is given by the integral of the electric field components parallel to the normal of each surface area element over the magnitude of each surface area element. In mathematical notation the equation for electric flux becomes

$$\begin{aligned}\Phi^{\text{net}} &\equiv \lim_{\Delta A \rightarrow 0} \sum_{i=1}^N \vec{E}_i \cdot \Delta\vec{A}_i \\ &= \oint \vec{E} \cdot d\vec{A} \quad (\text{net electric flux at a Gaussian surface}). \quad (24-4)\end{aligned}$$

The circle on the integral sign indicates that the integration is to be taken over the entire closed surface (Gaussian surface).

FIGURE 24-5 ■ A Gaussian surface of arbitrary shape is immersed in an electric field. The surface is divided into small area elements. The electric field vectors and the area vectors are shown for three representative area elements marked 1, 2, and 3. The other electric field vectors are not shown.

TOUCHSTONE EXAMPLE 24-1: Net Flux for a Uniform Field

Figure 24-6 shows a Gaussian surface in the form of a cylinder of radius R immersed in a uniform electric field \vec{E} , with the cylinder axis parallel to the field. What is the flux Φ^{net} of the electric field through this closed surface?

FIGURE 24-6 ■ A cylindrical Gaussian surface, closed by end caps, is immersed in a uniform electric field. The cylinder axis is parallel to the field direction.

SOLUTION ■ The **Key Idea** here is that we can find the flux Φ through the surface by integrating the scalar product $\vec{E} \cdot d\vec{A}$ over the Gaussian surface. We can do this by writing the flux as the sum of three terms: integrals over the left disk cap a , the cylinder surface b , and the right disk cap c . Thus, from Eq. 24-4,

$$\begin{aligned}\Phi^{\text{net}} &= \oint \vec{E} \cdot d\vec{A} \\ &= \int_a \vec{E} \cdot d\vec{A} + \int_b \vec{E} \cdot d\vec{A} + \int_c \vec{E} \cdot d\vec{A}. \quad (24-5)\end{aligned}$$

For all points on the left cap, the angle θ between \vec{E} and $d\vec{A}$ is 180° , and the magnitude E of the field is constant. Thus,

$$\int_a \vec{E} \cdot d\vec{A} = \int E(\cos 180^\circ) dA = -E \int dA = -EA,$$

where $\int dA$ gives the cap's area, $A (= \pi R^2)$. Similarly, for the right cap, where $\theta = 0$ for all points,

$$\int_c \vec{E} \cdot d\vec{A} = \int E(\cos 0^\circ) dA = E \int dA = +EA.$$

Finally, for the cylindrical surface, where the angle θ is 90° at all points,

$$\int_b \vec{E} \cdot d\vec{A} = \int E(\cos 90^\circ) dA = 0.$$

Substituting these results into Eq. 24-5 leads us to

$$\Phi = -EA + EA = 0. \quad (\text{Answer})$$

This result is perhaps not surprising because the field lines that represent the electric field all pass entirely through the Gaussian surface, entering through the left end cap, leaving through the right end cap, and giving a net flux of zero.

TOUCHSTONE EXAMPLE 24-2: Flux for a Nonuniform Field

A *nonuniform* electric field given by $\vec{E} = (3.0 \text{ N/C} \cdot \text{m})x\hat{i} + (4.0 \text{ N/C})\hat{j}$ pierces the Gaussian cube shown in Fig. 24-7. What is the electric flux through the right face, the left face, and the top face?

SOLUTION ■ The **Key Idea** here is that we can find the flux Φ through the surface by integrating the scalar product $\vec{E} \cdot d\vec{A}$ over each face.

Right face: An area vector \vec{A} is always perpendicular to its surface and always points away from the interior of a Gaussian surface. Thus, the vector $d\vec{A}$ for the right face of the cube must point in the positive x direction. In unit vector notation, then,

$$d\vec{A} = dA\hat{i}.$$

From Eq. 24-4, the flux Φ_r through the right face is then

$$\begin{aligned} \Phi_r &= \int \vec{E} \cdot d\vec{A} = \int [(3.0 \text{ N/C} \cdot \text{m})x\hat{i} + (4.0 \text{ N/C})\hat{j}] \cdot (dA\hat{i}) \\ &= \int [(3.0 \text{ N/C} \cdot \text{m})(x)(dA)\hat{i} \cdot \hat{i} + (4.0 \text{ N/C})(dA)\hat{j} \cdot \hat{i}] \\ &= \int (3.0 \text{ N/C} \cdot \text{m})x dA + (0.0 \text{ N} \cdot \text{m}^2/\text{C}) = (3.0 \text{ N/C} \cdot \text{m}) \int x dA. \end{aligned}$$

FIGURE 24-7 ■ A Gaussian cube with one edge on the x axis lies within a nonuniform electric field.

We are about to integrate over the right face, but we note that x has the same value everywhere on that face—namely, $x = 3.0 \text{ m}$. This means we can substitute that constant value for x . Then

$$\Phi_r = (3.0 \text{ N/C} \cdot \text{m}) \int (3.0 \text{ m}) dA = (9.0 \text{ N/C}) \int dA.$$

Now the integral merely gives us the area $A = 4.0 \text{ m}^2$ of the right face, so

$$\Phi_r = (9.0 \text{ N/C})(4.0 \text{ m}^2) = 36 \text{ N} \cdot \text{m}^2/\text{C}. \quad (\text{Answer})$$

Left face: The procedure for finding the flux through the left face is the same as that for the right face. However, two factors change. (1) The differential area vector $d\vec{A}$ points in the negative x direction and thus $d\vec{A} = -dA\hat{i}$. (2) The term x again appears in our integration, and it is again constant over the face being considered. However, on the left face, $x = 1.0 \text{ m}$. With these two changes, we find that the flux Φ_l through the left face is

$$\Phi_l = -12 \text{ N} \cdot \text{m}^2/\text{C}. \quad (\text{Answer})$$

Top face: The differential area vector $d\vec{A}$ points in the positive y direction and thus $d\vec{A} = dA\hat{j}$. The flux Φ_t through the top face is then

$$\begin{aligned} \Phi_t &= \int [(3.0 \text{ N/C} \cdot \text{m})x\hat{i} + (4.0 \text{ N/C})\hat{j}] \cdot (dA\hat{j}) \\ &= \int [(3.0 \text{ N/C} \cdot \text{m})(x dA)\hat{i} \cdot \hat{j} + (4.0 \text{ N/C})(dA)\hat{j} \cdot \hat{j}] \\ &= (0.0 \text{ N} \cdot \text{m}^2/\text{C}) + \int (4.0 \text{ N/C}) dA = (4.0 \text{ N/C}) \int dA \\ &= 16 \text{ N} \cdot \text{m}^2/\text{C}. \quad (\text{Answer}) \end{aligned}$$

24-4 Gauss' Law

Let's return for a moment to the consequence of Coulomb's law we presented in the first section, where we surrounded a single charge with a spherical Gaussian surface. We found that a flux-like quantity (namely, the product of the magnitude of the electric field at the sphere's surface multiplied by the area of the sphere's surface) is equal

to a constant times the enclosed charge. The surprising thing is this is true no matter what the radius of the sphere is, because the amount by which the surface area of the sphere increases just compensates for the amount by which the electric field magnitude decreases. This suggests that the net flux through a Gaussian surface of any shape enclosing a single charge will be proportional to the amount of charge enclosed.

Visualizing Flux through a Gaussian Surface

Since the relationship between flux and charge enclosed by a Gaussian surface is hard to visualize in three dimensions, let's consider the special case of an infinitely long rod that has a uniform charge density. While infinitely long rods do not exist, our result will be valid providing the Gaussian surfaces are far from the ends of the rod. Imagine a Gaussian surface that has the shape of a coin and surrounds a small segment of the rod. This is shown in Fig. 24-8.

FIGURE 24-8 (a) An infinitely long uniformly charged rod has a Gaussian surface that looks like a coin with front and back faces that are perpendicular to the rod and enclose a small charge. (b) An end view of the rod and Gaussian surface face can help us visualize flux at the surface's edges.

Because the charged rod is infinitely long it is symmetric about any point on it. As we showed in Section 23-5 (see Fig. 23-12), it turns out the electric field vectors created by a symmetric pair of charges point outward in a radial direction and have no components parallel to the line that the charges lie on (in this case, the line determined by the rod). We can also show that for a thin rod the field magnitude falls off as $1/r$ where r is the radial distance from the center of the rod. (Likewise, a similar negatively charged rod has electric field vectors pointing radially inward). The key factor in surrounding a piece of long rod with a coin-shaped closed surface is that all the flux at the surface will be at the edges and there will be no flux at the faces of the surface. For this reason, we can calculate and depict the “amount” of flux at elements of area on the edges of the surface by looking at an end view of the rod. This is true not only for coin-like closed surfaces that have circular faces but also for any shaped faces so long as the two faces are parallel to each other and perpendicular to the rod. End views depicting flux amounts as green rectangles are shown in Fig. 24-9 for three different imaginary Gaussian surfaces outlined in red.

FIGURE 24-9 Three imaginary Gaussian surfaces surround the same point charge. Here the red lines show only a two-dimensional cross section of three-dimensional surfaces. The contribution of electric flux at a series of small area elements is calculated and represented by rectangles. Note that whenever part of a surface is close to the charge, the flux elements are bigger but there are fewer of them. We can see visually that the net flux (which is proportional to the area occupied by all the outgoing flux (shown as green) minus the incoming flux (shown as pink)) is approximately the same in the three cases.

A small bundle of enclosed charge yields the same net electric flux at a Gaussian surface no matter what the shape of the surface. By superposition, if there are two charges enclosed by a Gaussian surface, each charge contributes its proportional share to the net flux no matter where each of the charges is located, provided both are *inside* the Gaussian surface. This leads us to a statement of Gauss' law that describes a plausible general relationship between the net flux through a Gaussian surface of any shape and the total enclosed charge no matter how it is distributed.

GAUSS' LAW: The net flux through any imaginary closed surface is directly proportional to the net charge enclosed by that surface.

Based on consideration of SI units, the constant of proportionality must be $1/\epsilon_0$ where ϵ_0 is the permittivity constant, so that the mathematical expression of Gauss' law is

$$\Phi^{\text{net}} = \frac{q^{\text{enc}}}{\epsilon_0} \quad (\text{Gauss' law}). \quad (24-6)$$

By substituting the definition of electric flux at a Gaussian surface, $\Phi^{\text{net}} \equiv \oint \vec{E} \cdot d\vec{A}$, we can also write Gauss' law as

$$\Phi^{\text{net}} = \oint \vec{E} \cdot d\vec{A} = \frac{q^{\text{enc}}}{\epsilon_0} \quad (\text{Gauss' law}). \quad (24-7)$$

Here, the circle on the integral sign indicates that the surface over which we integrate must be “closed.” The use of the permittivity constant for a vacuum, ϵ_0 , in Eqs. 24-6 and 24-7 indicates this form of Gauss' law only holds when the net charge is located in air or some other medium that doesn't polarize easily. In Section 28-6, we modify Gauss' law to include situations in which so-called dielectric materials that can polarize, such as paper, oil, or water, are present. In Fig. 24-10 we show how the net flux can have the same value for two different charge distributions involving the same amount of enclosed charge.

Gauss' law is useful for finding both charge and flux. That is, if we can calculate the net flux through a closed surface, we can deduce the amount of charge enclosed. On the other hand, if we know the amount of charge enclosed, we can use Gauss' law to deduce the net flux through any surface that encloses the charge.

Interpreting Gauss' Law

One use of Gauss' law is to calculate how much net charge is contained inside any closed surface. To make the calculation, you need know only the net electric flux at the surface enclosing the collection of charges. This net flux is related to the strength of the normal components of the electric field at all locations on the surface.

FIGURE 24-10 ■ Each Gaussian surface encloses a different charge distribution but encloses the same net charge. The electric flux calculated at the edges of the surface is represented by green rectangles (outward flux) or pink rectangles (inward flux). The total space covered by all of the green rectangles minus that occupied by the pink rectangles turns out to be the same for the two situations, which is compatible with the predictions of Gauss' law.

In Eqs. 24-6 and 24-7, the net charge q^{enc} is the algebraic sum of all the *enclosed* positive and negative charges, and it can be positive, negative, or zero. We include the sign, rather than just use the amount of enclosed charge, because the sign tells us something about the net flux at the Gaussian surface. Here we continue to use our convention that the normal area vectors representing the area elements of a closed surface point *outward*. If the net charge enclosed, q^{enc} , is positive, its electric field vectors point mostly outward too. This leads to a net flux that is *outward* and positive as shown in Fig. 24-11a. If q^{enc} is negative, the area vector still points outward but the electric field vector points inward. This leads to a net flux that is *inward* and negative, as shown in Fig. 24-11. Figure 24-11c shows how positive and negative charges inside a Gaussian surface can lead to zero net flux.

FIGURE 24-11 ■ Each of these Gaussian surfaces has the same shape. (a) One unit of enclosed positive charge causes a positive net outward flux shown in green. (b) One unit of enclosed negative charge causes a negative net inward flux shown in pink. Note that the amount of negative flux is the same as the amount of positive flux shown in the previous diagram. (c) If both the positive and negative charges are enclosed the net charge is zero and so is the net flux.

Charge outside a Gaussian surface, no matter how large or how close it may be, is not included in the term q^{enc} in Gauss' law. We expect this since there is no source of electric field inside the surface, and negative and positive flux elements will cancel each other, as shown in Fig. 24-12. The exact form or location of the charges inside the Gaussian surface is also of no concern; the only things that matter are the amount of the net charge enclosed and its sign. The quantity \vec{E} on the left side of Eq. 24-7, however, is the electric field resulting from *all* charges, both those inside and those outside the Gaussian surface. This may seem to be inconsistent, but keep in mind the electric field due to a charge outside the Gaussian surface contributes zero net flux on the surface (as shown in Fig. 24-12). This is the case even though a charge outside the surface does contribute to the actual values of the electric field at each point on the surface.

FIGURE 24-12 ■ A charge element along a rod is located *outside* a Gaussian surface. When the electric flux is calculated at each area element using Coulomb's law, its outward values are represented by green rectangles and the inward flux by pink rectangles. The net flux is zero because the negative inward flux at the portion of the surface near the charge just cancels the positive outward flux at the portions of the surface far away from the charge.

Let us apply these ideas to Fig. 24-13, which shows the electric field lines surrounding two point charges, equal in amount but opposite in sign. Four Gaussian surfaces are also shown, in cross section. Let us consider each in turn.

Surface S_1 (encloses only the positive charge): The electric field is dominated by the nearby positive charge and so points outward for the majority of the points on this surface. Thus, the flux of the electric field at this surface is positive, and so is the net charge within the surface, as Gauss' law requires. (That is, if Φ is positive, q^{enc} must be also.)

Surface S_2 (encloses only the negative charge): The electric field is dominated by the nearby negative charge and so points inward for the majority of the points on this surface. Thus, the flux of the electric field is negative and so is the enclosed charge, as Gauss' law requires.

FIGURE 24-13 ■ An idealization showing two point charges of equal amount and opposite sign are shown with the field lines that depict their net electric field as if all lines lie in a plane. The cross sections of four Gaussian surfaces are shown. Surface S_1 encloses the positive charge, S_2 encloses the negative charge, and S_3 encloses no charge. Since S_4 surrounds both charges, it encloses no net charge.

Surface S_3 (encloses no charges): Since $q^{\text{enc}} = 0$ and there are comparable contributions to the electric field at points on the surface from both charges, the field on some parts of the surface will point out and on other parts it will point in. Gauss' law (Eq. 24-7) requires the net electric flux through this surface to be zero. That is reasonable because in calculating the net flux, the inward and outward flux elements cancel each other.

Surface S_4 (encloses both charges): This surface encloses no *net* charge, because equal amounts of positive and negative charge are enclosed. Gauss' law requires the net flux of the electric field at this surface be zero. That is reasonable because in this case the field vectors point outward for the portion of the surface nearest to the positive charge (yielding positive flux) and inward for the portion of the surface near the negative charge (yielding negative flux). In calculating the net flux, the positive and negative flux elements cancel each other, even though the field is nonzero along most of the surface.

What would happen if we were to bring an enormous charge Q up close to (but still outside of) surface S_4 in Fig. 24-13? The pattern of the electric field would certainly change, but the net flux for the four Gaussian surfaces would not change. We can understand this because the inward and outward flux elements associated with the added Q at any of the four surfaces would cancel each other, making no contribution to the net flux at any of them. The value of Q would not enter Gauss' law in any way, because Q lies outside all four of the Gaussian surfaces that we are considering.

READING EXERCISE 24-2: The figure shows three situations in which a Gaussian cube sits in an electric field. The arrows indicate the directions of the electric field vectors for the top, front, and right faces of each cube. The flux at the six sides of each cube is listed in the table below. In which situations do the cubes enclose (a) a positive net charge, (b) a negative net charge, and (c) zero net charge?

Flux [$\text{N} \cdot \text{m}^2/\text{C}$]			
Face	Cube 1	Cube 2	Cube 3
Front	+2	-4	-7
Back	-3	-3	+8
Left	+7	+3	+2
Right	-4	+5	+5
Top	+5	+10	-6
Bottom	-7	-6	-5

24-5 Symmetry in Charge Distributions

Why go through all this trouble to develop a method of calculating electric fields that is equivalent to Coulomb's law? We suggested in the introduction to this chapter that it is because Gauss' law makes it possible to calculate the field for highly symmetric charge distributions. What we mean by symmetric charge distributions are

arrangements of charges that can be rotated about an axis or reflected in a mirror and still look the same. Figure 24-14 shows several examples of symmetric objects.

Why do charge distributions need to be symmetric in order for Gauss' law to be helpful in finding an electric field? Because we can use symmetry arguments to find the direction of the electric field and surfaces along which it is constant. This allows us to choose an imaginary Gaussian surface over which the electric field is constant. Then we can take the dot product and turn the vectors into scalar magnitudes. Finally, we know the electric field magnitude is constant at the surface we are integrating over, so we can pull the electric field vector outside of the integral sign. By following the steps we outlined, in some cases Gauss' law can be reduced to

$$\epsilon_0 \oint E \cos \theta \, dA = \epsilon_0 E \oint \cos \theta \, dA = |q^{\text{enc}}|.$$

Better still is to be able to find a Gaussian surface over which both the electric field and the angle between the field and area vectors, θ , are constant over the entire area. In that case, both the electric field and the cosine functions can be moved outside the integral and Gauss' law reduces to:

$$(\epsilon_0 E \cos \theta) \oint dA = |q^{\text{enc}}|.$$

This expression is very easy to evaluate because the integral of dA is simply the magnitude of the total area of the Gaussian surface, which we will denote as A . Hence, if we can find a Gaussian surface over which the field and angle θ are constant, Gauss' law allows us to calculate the electric field of an extended charge distribution without doing an integral. In those cases, Gauss' law tells us that the electric field magnitude is

$$E = \frac{|q^{\text{enc}}|}{\epsilon_0 A \cos \theta} \quad (\text{constant } E \text{ and } \theta), \quad (24-8)$$

where A is the area of the Gaussian surface, θ is the angle between the field and each area vector, and q^{enc} is the net charge *enclosed by the Gaussian surface*. In some cases where the angle, θ , has one value for some parts of a surface and another value for other parts of a surface, we can handle the calculation by breaking the surface integral into parts.

A word of caution: There are only a few charge distributions with sufficient symmetry for Gauss' law to be useful. These include single point charges and spherically symmetric ones. Charge distributions that work with Gauss' law also include the infinitely long cylinder, with cylindrical symmetry, and that of a uniformly charged slab with infinitely long sides with planar symmetry. Fortunately, there are many physical situations for which these geometries are important. Hence, Gauss' law is an extraordinarily useful tool.

However, for many charge distributions, we cannot use Gauss' law to find the field because the flux integral on the left-hand side of the expression

$$\epsilon_0 \oint \vec{E} \cdot d\vec{A} = q^{\text{enc}}$$

is too complicated to evaluate. In these cases, Gauss' law is still valid but not useful.

24-6 Application of Gauss' Law to Symmetric Charge Distributions

As we determined in the last section, Gauss' law is useful if we already know what the general shape of the vector electric field plot looks like. In some cases we can derive this knowledge from symmetry of the charge distribution without using equations or doing calculations. Only then can we choose an imaginary closed surface and use the

FIGURE 24-14 ■ Some symmetrically charged objects—a plane, a sphere, and a cylinder.

FIGURE 24-15 ■ A thin, charged, spherical shell with total charge q , in cross section. Two Gaussian surfaces S_1 and S_2 are also shown in cross section. Surface S_2 encloses the shell, and S_1 encloses only the empty interior of the shell.

mathematical form of Gauss' law to calculate the magnitude of the electric field at points on the surface. In this section we take this approach to determining the electric field for three highly symmetric charge distributions.

Spherical Symmetry for a Shell of Charge

Figure 24-15 shows a charged spherical shell of total positive charge q and radius R and two concentric spherical Gaussian surfaces, S_1 and S_2 . (Note that we chose the shape of the Gaussian surface to mirror the symmetry of the charge distribution.) Because the charge distribution is spherically symmetric no matter how we rotate the spherical shell around its center, the shell looks the same. This means that the electric field must have a spherical symmetry too. Thus, it must have the same magnitude at every point on the spherical Gaussian surface S_2 and it must point in a radial direction. Further, since the area vector points radially outward at all points on S_2 , the angle between the electric field \vec{E} and the area \vec{A} is constant. As a result of the spherical symmetry of the distributed charge, we know the electric field also points in a radial direction at all points on S_2 . Hence, the angle θ is not only constant but it is also 0° at all points on the surface. Applying Gauss' law to surface S_2 then comes down to evaluating the expression for the electric field magnitude that we derived in Eq. 24-8 for constant E and θ ,

$$E = \frac{|q^{\text{enc}}|}{\epsilon_0 A \cos \theta}.$$

Note that $\cos \theta = \cos 0 = 1$ and the area of a sphere (the Gaussian sphere) of radius r is $4\pi r^2$. Hence, for any $r \geq R$, we find that

$$E = \frac{1}{4\pi\epsilon_0} \frac{|q^{\text{enc}}|}{r^2} \quad (\text{spherical shell, field at } r \geq R). \quad (24-9)$$

What is surprising is that outside the shell the electric field is the same as if the shell of charge were replaced by a single point-like charge, q , provided that the single charge is placed where the center of the shell of charge was. Thus, if the charge on a shell is evenly distributed, a shell of total charge q would produce the same force on a small test charge placed anywhere *outside* the shell as a single point-like charge q would.

A shell with a uniform charge distribution attracts or repels a charged particle that is outside the shell as if all the shell's charge were concentrated at the center of the shell.

This shell theorem is identical to the one developed by Isaac Newton for gravitation in Section 14-2.

What happens to the electric field inside the shell of charge? Applying Gauss' law to surface S_1 , for which $r < R$, leads directly to

$$\vec{E} = 0 \text{ [N/C]} \quad (\text{spherical shell, field at } r < R), \quad (24-10)$$

because this Gaussian surface encloses no charge. Thus, when a small test charge is enclosed by a shell of uniform charge distribution, the shell exerts no net electrostatic force on it.

A shell of uniform charge exerts no electrostatic force on a charged particle that is located inside the shell.

A Spherically Symmetric Charge Distribution

Any spherically symmetric charge distribution, such as that of Fig. 24-16, can be constructed with a nest of concentric spherical shells. This is a good starting point for treating a wide variety of charged objects with nearly spherical distribution of charge such as nuclei and atoms. For purposes of applying the two shell theorems stated above, the volume charge density ρ , defined as the charge per unit volume, should have a single value for each shell but need not be the same from shell to shell. Thus, for the charge distribution as a whole, ρ , can vary only with r , the radial distance from the center of the sphere and not with direction. We can then examine the effect of the charge distribution “shell by shell.”

In Fig. 24-16a the entire charge lies within a Gaussian surface with $r > R$. The charge produces an electric field on the Gaussian surface as if the charge were a point charge located at the center, and Eq. 24-9 holds.

Figure 24-16b shows a Gaussian surface with $r < R$. To find the electric field at points on this Gaussian surface, we consider two sets of charged shells—one set inside the Gaussian surface and one set outside. The charge lying *outside* the Gaussian surface does not set up a net electric field on the Gaussian surface. Gauss' law tells us that the charge *enclosed* by the surface sets up an electric field as if that enclosed charge were concentrated at the center. Letting q' represent that enclosed charge, we can then write the electric field magnitude as

$$|\vec{E}| = \frac{1}{4\pi\epsilon_0} \frac{|q^{\text{enc}}|}{r^2} = \frac{1}{4\pi\epsilon_0} \frac{|q'(r)|}{r^2} \quad (\text{spherical distribution, field at } r < R), \quad (24-11)$$

where the term $q'(r)$ signifies that q' depends on r . (It is not the product of q' and r .)

Equation 24-11 is valid for any spherically symmetric charge distribution, even one that is not uniform. For example, Fig. 24-16 shows a situation in which the volume charge density is spherically symmetric but larger near the center of the sphere than further out. In other words, Eq. 24-11 is valid whenever $\rho = \rho(r)$ or ρ is a constant. But the equation is not useful unless we know how to use a knowledge of the volume charge density to determine the charge q' enclosed by a sphere of radius r .

Spherical Symmetry for a Uniform Volume Charge Distribution

Consider the simple case where the charge is distributed uniformly through the volume of a sphere of radius R containing an excess charge q . In this case it is possible to find the magnitude of the electric field at any location inside the sphere in terms of the total charge in the sphere.

Whenever the total charge q enclosed within a sphere of radius R is distributed uniformly, we can use the definition of volume charge density (presented in Table 23-2) and the knowledge that the volume of a sphere of radius R is given by $\frac{4}{3}\pi R^3$ to write

$$\rho \equiv \frac{q}{V} = \frac{q}{\frac{4}{3}\pi R^3}. \quad (24-12)$$

Since the charge density is a constant the amount of charge in a smaller sphere of radius r is proportional to its volume. Since its volume is $V' = \frac{4}{3}\pi r^3$ then $q' = \rho V' = \rho (\frac{4}{3}\pi r^3)$. Substituting Eq. 24-12 for ρ gives

$$q' = q \frac{r^3}{R^3}. \quad (24-13)$$

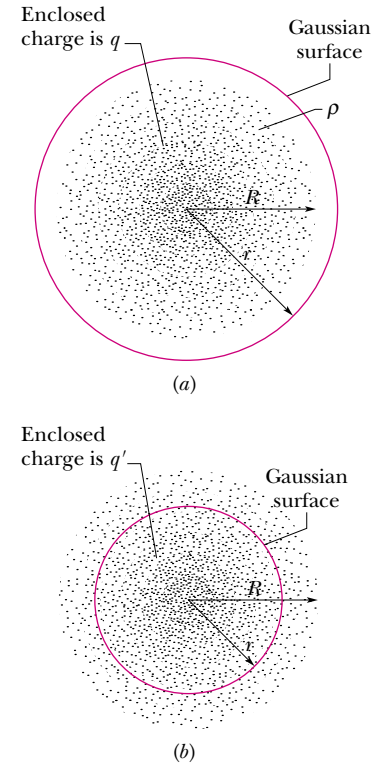

FIGURE 24-16 ■ Spherically symmetric distributions of charge of radius R , whose volume charge density ρ is a function only of distance from the center. The charged object is not a conductor, so the charge is assumed to be fixed in position. A cross-section of concentric spherical Gaussian surface with $r > R$ is shown in (a). A similar Gaussian surface with $r < R$ is shown in (b).

Substituting this into Eq. 24-11 gives us the electric field magnitude in terms of the total charge on the sphere.

$$E = \left(\frac{|q|}{4\pi\epsilon_0 R^3} \right) r \quad (\text{uniform volume charge density for } r \leq R). \quad (24-14)$$

FIGURE 24-17 ■ A Gaussian surface in the form of a closed cylinder surrounds a section of a very long, uniformly charged, cylindrical plastic rod.

Cylindrical Symmetry for a Uniform Line Charge Distribution

Figure 24-17 shows a section of a very long thin cylindrical plastic rod with a uniform distribution of positive charge, so that linear charge density λ (as defined in Table 23-2) is constant. Let us find an expression for the magnitude of the electric field \vec{E} outside of the rod at a distance r from its axis in terms of the linear charge density of the rod. In doing so, we assume that r is small compared to the length of the rod so that we can ignore the effect of the rod's ends.

We start by choosing a Gaussian surface that matches the cylindrical symmetry of the rod. So our imaginary surface is a circular cylinder of radius r and length h , coaxial with the rod. The Gaussian surface must be closed, so we include two end caps as part of the surface. We pick the end caps of the Gaussian surface so they are far from the end of the rod.

Imagine that, while you are not watching, someone rotates the plastic rod around its longitudinal axis or moves it a finite distance along the axis. When you look again at the rod, you will not be able to detect any change in either the appearance of the rod or the behavior of the electric field that surrounds it. Furthermore, when we experiment, we find that if the rod is flipped end for end we still detect no change in the rod's electric field. What does this tell us about the nature of the electric field? If the electric field has only a component that points radially inward or outward from the rod, then the field should be unaffected by the changes in orientation that we have discussed. If however, the field had any component tangent to the rod's surface, pointed toward or away from the rod, we would detect a change in the electric field as we rotated or flipped the rod. Hence, we conclude from these symmetry arguments that at every point on the cylindrical part of the Gaussian surface, the electric field must have the same magnitude $E = |\vec{E}|$ and must be directed radially outward (for a positively charged rod).

Since $2\pi r$ is the circumference of the cylinder and h is its height, the area A of the cylindrical surface is $2\pi rh$. The flux of \vec{E} at this cylindrical surface is then

$$\Phi = EA \cos \theta = E(2\pi rh) \cos 0 = E(2\pi rh).$$

There is no flux at the end caps because \vec{E} , being radially directed, is parallel to the end caps at every point, so \vec{E} is perpendicular to the normal and the dot product vanishes. Thus the flux through the cylindrical surface is equal to the net flux ($\Phi^{\text{net}} = \Phi$).

According to Gauss' law, shown in Eq. 24-6,

$$\Phi^{\text{net}} = \frac{q^{\text{enc}}}{\epsilon_0}.$$

We can find the enclosed charge in terms of the linear charge density, defined as the charge per unit length. If the charge enclosed by the surface that encompasses a length h of the rod has a uniform density λ , then $q^{\text{enc}} = \lambda h$. Thus, the previous two equations reduce to $E(2\pi rh) = |\lambda| h / \epsilon_0$, so that

$$E = \frac{|\lambda|}{2\pi\epsilon_0 r} \quad (\text{long line of uniformly distributed charge}). \quad (24-15)$$

This is the expression for the electric field magnitude due to a very long, straight line of uniformly distributed charge, at a point that is a radial distance r from the line. The direction of \vec{E} is radially outward from the line of charge if the charge is positive, and radially inward if it is negative. Equation 24-15 also approximates the field of a *finite* line of charge, at points that are not too near the ends (compared with the distance from the line).

A Sheet of Uniform Charge

Figure 24-18 shows a portion of a thin, very large, sheet with a uniform (positive) surface charge density σ (as defined in Table 23-2). A large sheet of thin plastic wrap, uniformly charged on one side, can serve as a simple example of a nonconducting sheet. A large sheet of aluminum foil serves as an example of a conducting sheet. Let us find the electric field \vec{E} a distance r from the uniformly charged sheet. Here we assume that we are far from the edges of the sheet and that the thickness of the sheet is much less than r .

Even though it doesn't have the same shape as a charged sheet, something called a Gaussian pillbox turns out to make a useful imaginary surface in this case. The pillbox is a closed cylinder with end caps of area A , arranged so that it is perpendicular to the sheet with each end cap located at the same distance from the sheet. This Gaussian pillbox is shown in Fig. 24-18*a*. Using symmetry (considerations like those used earlier in this section or those depicted in Fig. 23-12 and Fig. 23-13 in the previous chapter), \vec{E} must be perpendicular to the sheet and hence to the end caps. Furthermore, since the charge is positive, \vec{E} is directed *away* from the sheet, and thus the electric field vectors point in an outward direction from the two Gaussian end caps. Because the electric field vectors are perpendicular to the normal vectors on the curved surface, there is no flux at this portion of the Gaussian surface. Thus $\vec{E} \cdot d\vec{A}$ is simply $E dA$ —the product of the magnitudes of \vec{E} and $d\vec{A}$. In this case Gauss' law (Eq. 24-7) gives us

$$\oint \vec{E} \cdot d\vec{A} = q^{\text{enc}}/\epsilon_0.$$

Since there are two caps on our pillbox we need to break the integral into two parts so in terms of the area and electric field magnitudes,

$$EA + EA = \int_{\text{end caps}} E dA = |q^{\text{enc}}|/\epsilon_0.$$

Next we can find the amount of charge on the sheet enclosed by our Gaussian pillbox in terms of the surface charge density, σ , on the sheet. Since the surface charge is uniform and the surface charge density is defined as the ratio of the charge on a given surface to its area, we know that $\sigma = q^{\text{enc}}/A$. If we replace q^{enc} in the equation above with σA and solve it for the electric field magnitude we get

$$E = \frac{|\sigma|}{2\epsilon_0} \quad (\text{sheet of uniformly distributed charge}). \quad (24-16)$$

The equation holds whether the sheet is conducting or nonconducting as long as the layer of charge on the sheet is thin.

Equation 24-16 tells us that *the electric field has the same value for all locations outside a large uniformly charged sheet and points in a direction that is perpendicular to the sheet*. This result is quite surprising! The fact that the net field is perpendicular to the sheet can be explained using symmetry arguments. But how can it be that as you get farther away from the charged sheet the electric field doesn't decrease? The answer lies in considering the influences of the charges as we move away from the sheet. When a test charge is placed very close to the sheet, the

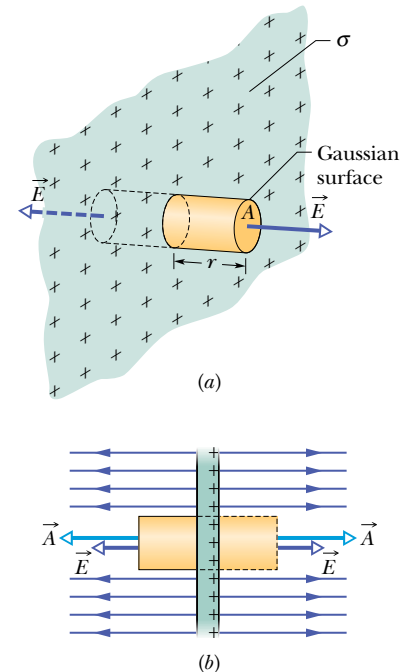

FIGURE 24-18 ■ Perspective view (a) and side view (b) of a portion of a very large, thin plastic sheet, uniformly charged with surface charge density σ . A closed cylindrical Gaussian surface passes through the sheet and is perpendicular to it.

influence on it by the charge closest to it dominates. If the test charge is moved farther from the sheet the influence of the nearest sheet charge gets weaker, but the normal components of the electric field vectors from neighboring sheet charges start to contribute and compensate for the loss of influence of the nearest sheet charge. If the test charge is moved even farther the influence of the nearest and nearby charges diminish but the components of additional surrounding charges come into play and so on.

Equation 24-16 agrees with what we would have found by integration of the electric field components that are produced by individual charges. That would be a very time-consuming and challenging integration, and note how much more easily we obtain the result using Gauss' law. This is one reason for devoting a whole chapter to Gauss' law. For certain symmetric arrangements of charge, it is much easier to use it than to integrate field components.

READING EXERCISE 24-3: Consider an array of 9 charges evenly distributed on a square insulating sheet as shown in the diagram. Use symmetry arguments to explain why the electric field vector anywhere on a line normal to the central charge and passing through it has no component that is parallel to the sheet.

■

TOUCHSTONE EXAMPLE 24-3: \vec{E} for Two Sheets of Charge

Figure 24-19a shows portions of two large, parallel, nonconducting sheets, each with a fixed uniform charge on one side. The amounts of the surface charge densities are $\sigma_{(+)} = 6.8 \mu\text{C}/\text{m}^2$ for the positively charged sheet and $\sigma_{(-)} = 4.3 \mu\text{C}/\text{m}^2$ for the negatively charged sheet.

Find the electric field \vec{E} (a) to the left of the sheets, (b) between the sheets, and (c) to the right of the sheets.

SOLUTION ■ The **Key Idea** here is that with the charges fixed in place, we can find the electric field of the sheets in Fig. 24-19a by (1) finding the field of each sheet as if that sheet were isolated and (2) adding the vector fields of the isolated sheets via the superposition principle. (The vector addition is simple here since the fields lie along the same axis. We can add the fields algebraically because they are parallel to each other.) From Eq. 24-16, the mag-

nitude $E_{(+)}$ of the electric field due to the positive sheet at any point is

$$|\vec{E}_{(+)}| = \frac{|\sigma_{(+)}|}{2\epsilon_0} = \frac{6.8 \times 10^{-6} \text{ C}/\text{m}^2}{(2)(8.85 \times 10^{-12} \text{ C}^2/\text{N} \cdot \text{m}^2)} = 3.84 \times 10^5 \text{ N/C}.$$

Similarly, the magnitude $|\vec{E}_{(-)}|$ of the electric field at any point due to the negative sheet is

$$|\vec{E}_{(-)}| = \frac{|\sigma_{(-)}|}{2\epsilon_0} = \frac{4.3 \times 10^{-6} \text{ C}/\text{m}^2}{(2)(8.85 \times 10^{-12} \text{ C}^2/\text{N} \cdot \text{m}^2)} = 2.43 \times 10^5 \text{ N/C}.$$

FIGURE 24-19 ■ (a) Two large, parallel insulating sheets, uniformly charged on one side. (b) The individual electric fields resulting from the two charged sheets. (c) The net field due to both charged sheets, found by superposition.

Figure 24-19b shows the fields set up by the sheets to the left of the sheets (L), between them (B), and to their right (R).

The resultant fields in these three regions follow from the superposition principle. To the left of the sheets, the field magnitude is

$$\begin{aligned} |\vec{E}_L| &= |\vec{E}_{(+)}| - |\vec{E}_{(-)}| \\ &= 3.84 \times 10^5 \text{ N/C} - 2.43 \times 10^5 \text{ N/C} \\ &= 1.4 \times 10^5 \text{ N/C.} \end{aligned} \quad (\text{Answer})$$

Because $|E_{(+)}|$ is larger than $|E_{(-)}|$, the net electric field \vec{E}_L in this region points to the left, as Fig. 24-19c shows. To the right of the

sheets, the electric field \vec{E}_R has the same magnitude but points to the right, as Fig. 24-19c shows.

Between the sheets, the two fields add and we have

$$\begin{aligned} |\vec{E}_B| &= |\vec{E}_{(+)}| + |\vec{E}_{(-)}| \\ &= 3.84 \times 10^5 \text{ N/C} + 2.43 \times 10^5 \text{ N/C} \\ &= 6.3 \times 10^5 \text{ N/C.} \end{aligned} \quad (\text{Answer})$$

The electric field \vec{E}_B points to the right.

24-7 Gauss' Law and Coulomb's Law

If Gauss' law and Coulomb's law are equivalent, we should be able to derive each from the other. Here we derive Coulomb's law from Gauss' law and some symmetry considerations.

Figure 24-20 shows a positive point charge q , around which we have drawn a concentric spherical Gaussian surface of radius r . Let us divide this surface into differential areas $d\vec{A}$. By definition, the area vector $d\vec{A}$ at any point is perpendicular to the surface and directed outward from the interior. From the symmetry of the situation, we know at any point the electric field \vec{E} is also perpendicular to the surface and directed outward from the interior. Thus, since the angle θ between \vec{E} and $d\vec{A}$ is zero, we can rewrite Gauss' law expressed in Eq. 24-7 as

$$\oint \vec{E} \cdot d\vec{A} = \oint E dA = q^{\text{enc}}/\epsilon_0. \quad (24-17)$$

Here $q^{\text{enc}} = q$. Although the magnitude of the vector \vec{E} varies radially with the distance from q , it has the same value everywhere on the spherical surface. Since the integral in this equation is taken over that surface, the electric field magnitude ($E = |\vec{E}|$) is a constant in the integration and can be brought out in front of the integral sign. That gives us

$$\epsilon_0 E \oint dA = |q^{\text{enc}}|. \quad (24-18)$$

The integral is now merely the sum of the magnitudes of all the differential area elements $d\vec{A}$ on the sphere and thus is just the surface area, $4\pi r^2$. Substituting this, we have

$$\epsilon_0 E(4\pi r^2) = |q^{\text{enc}}|,$$

or since $q = q^{\text{enc}}$

$$E = \frac{1}{4\pi\epsilon_0} \frac{|q^{\text{enc}}|}{r^2} = k \frac{|q|}{r^2}. \quad (24-19)$$

This is exactly the electric field due to a point charge (Eq. 23-8), which we found using Coulomb's law. Thus, we have shown that Gauss' law and Coulomb's law give us the same result for the electric field due to a single point-like charge. However, Gauss' law is also valid for complex arrays of charges. It can be shown using the principle of superposition that the information about electric fields obtained by using either Gauss' or Coulomb's law will yield the same results even for charge arrays. The difference between the two laws is this: It is easier to use Coulomb's law if we have an array of a few point-like charges, and it is easier to use Gauss' law if we have certain kinds

FIGURE 24-20 ■ A spherical Gaussian surface centered on a point charge q .

of highly symmetric charge distributions like those discussed in Section 24-6. In still other situations, it is quite difficult to use either law.

READING EXERCISE 24-4: There is a certain net flux Φ^{net} at a Gaussian sphere of radius r enclosing an isolated charged particle. Suppose the enclosing Gaussian surface is changed to (a) a larger Gaussian sphere, (b) a Gaussian cube with edge length equal to r , and (c) a Gaussian cube with edge length equal to $2r$. In each case, is the net flux at the new Gaussian surface greater than, less than, or equal to Φ^{net} ? ■

FIGURE 24-21 ■ (a) A lump of copper with a charge q hangs from an insulating thread. A Gaussian surface is placed within the metal, just inside the actual surface. (b) The lump of copper now has a cavity within it. A Gaussian surface lies within the metal, close to the cavity surface.

24-8 A Charged Isolated Conductor

Gauss' law permits us to prove an important theorem about isolated conductors:

If excess charges are placed on an isolated conductor, that amount of charge will move entirely to the surface of the conductor. Once the charges stop moving, none of the excess charge will be found within the body of the conductor.

This might seem reasonable, considering charges with the same sign repel each other. You might imagine that by moving to the surface, the added charges are getting as far away from each other as they can. We turn to Gauss' law for verification of this speculation.

Figure 24-21a shows, in cross section, an isolated lump of copper hanging from an insulating thread and having an excess charge q . We place a Gaussian surface just inside the actual surface of the conductor.

Once the excess charges stop moving, the electric field inside this conductor must be zero. If this were not so, the field would exert forces on the conduction (free) electrons, which are always present in a conductor such as copper, and thus current would always exist within a conductor. (That is, charge would flow from place to place within the conductor.) Of course, there are no such perpetual currents in an isolated conductor, and so we know that the internal electric field is zero.

An internal electric field *does* appear as a conductor is being charged. However, the added charge quickly distributes itself in such a way that the net internal electric field—the vector sum of the electric fields due to all the charges, both inside and outside—is zero. The movement of charge then ceases because there are drag forces known as *resistance* in conductors that dissipate the charges' kinetic energies and eventually bring them to rest. Since the net field is zero, the net force on each charge is zero. So, once the charges are stopped by resistance in the conductor, they remain at rest. Some special materials can be “superconductors” at very low temperatures and allow charges to move without resistance. Therefore, these materials can support long-lasting currents.

If \vec{E} is zero everywhere inside our copper conductor, it must be zero for all points on the Gaussian surface because that surface, though close to the surface of the conductor, is definitely inside the conductor. This means the flux at the Gaussian surface must be zero. Gauss' law then tells us the net charge inside the Gaussian surface must also be zero. Then because the excess charge is not inside the Gaussian surface, it must be outside that surface, which means it must lie on the actual surface of the conductor.

An Isolated Conductor with a Cavity

Figure 24-21b shows the same hanging conductor, but now with a cavity totally within the conductor. It is perhaps reasonable to suppose that when we scoop out the electrically neutral material to form the cavity we do not change the distribution of charge

or the pattern of the electric field that exists in Fig. 24-21*a*. Again, we can turn to Gauss' law for a quantitative proof.

We draw a Gaussian surface surrounding the cavity, close to its surface but inside the conducting body. Because $\vec{E} = 0$ inside the conductor, there can be no flux at this new Gaussian surface. Therefore, from Gauss' law, that surface can enclose no net charge. We conclude there is no net charge on the cavity walls; all the excess charge remains on the outer surface of the conductor, as in Fig. 24-21*a*.

The Conductor Removed

Consider now an object that has the same shaped surface, but consists of only a conducting shell of charge. This is equivalent to enlarging the cavity of Fig. 24-21*b* until it consumes the entire conductor, leaving only the charges. The electric field would not change at all; it would remain zero inside the thin shell of charge and would remain unchanged for all external points. This reminds us that the electric field is set up by the charges and not by the conductor. The conductor simply provides an initial pathway for the charges to take up their positions.

The External Electric Field

You have seen that the excess charge on an isolated conductor moves entirely to the conductor's surface. However, unless the conductor is spherical, the charge does not distribute itself uniformly. Put another way, the surface charge density σ (charge per unit area) varies over the surface of any nonspherical conductor. Generally, this variation makes the determination of the electric field set up by the surface charges very difficult.

Suppose we know the surface charge density, σ , on a region of a conductor. Then it is easy to use Gauss' law to calculate the electric field just outside the surface of a conductor. To do this, we consider a section of the surface small enough to permit us to neglect any curvature and thus to take the section to be flat. We then imagine a tiny cylindrical Gaussian surface to be embedded in the section as in Fig. 24-22: One end cap is fully inside the conductor, the other is fully outside, and the cylinder is perpendicular to the conductor's surface.

The electric field \vec{E} at and just outside the conductor's surface must also be perpendicular to that surface. If it were not, then it would have a component along the conductor's surface exerting forces on the surface charges, causing them to move. However, such motion would violate our implicit assumption that we are dealing with electrostatic equilibrium. Therefore, \vec{E} is perpendicular to the conductor's surface.

We now sum the flux at the Gaussian surface. There is no flux at the internal end cap, because the electric field within the conductor is zero. There is no flux at the curved surface of the cylinder, because internally (in the conductor) there is no electric field and externally the electric field is parallel to the curved portion of the Gaussian surface. The only flux at the Gaussian surface is at the external end cap, where \vec{E} is perpendicular to the plane of the cap. We assume the cap area A is small enough that the field magnitude $|\vec{E}|$ is constant over the cap. Then the amount of the flux at the cap is $|\vec{E}|A$, and that is the net amount of flux $|\Phi^{\text{net}}|$ at the Gaussian surface.

The charge q^{enc} enclosed by the Gaussian surface lies on the conductor's surface in an area A . If σ is the charge per unit area, then q^{enc} is equal to σA . When we substitute σA for q^{enc} and $|\vec{E}|A$ for $|\Phi^{\text{net}}|$, Gauss' law, $\epsilon_0 |\Phi^{\text{net}}| = |q^{\text{enc}}|$, becomes $\epsilon_0 |\vec{E}|A = |\sigma|A$, from which we find

$$|\vec{E}| = \frac{|\sigma|}{\epsilon_0} \quad (\text{conducting surface}). \quad (24-20)$$

FIGURE 24-22 ■ Perspective view (a) and side view (b) of a tiny portion of a large, isolated conductor with excess positive charge on its surface. A (closed) cylindrical Gaussian surface, embedded perpendicularly in the conductor, encloses some of the charge. Electric field lines pierce the external end cap of the cylinder, but not the internal end cap. The external end cap has area A and area vector \vec{A} .

Thus, the magnitude of the electric field at a location just outside a conductor is proportional to the surface charge density at that location on the conductor. If the charge on the conductor is positive, the electric field is directed away from the conductor as in Fig. 24-22. It is directed toward the conductor if the charge is negative.

The difference between Eq. 24-20 and Eq. 24-16 ($|\vec{E}| = |\sigma|/2\epsilon_0$) results from the fact that our conductor is no longer thin so that one of our Gaussian pillbox endcaps lies inside the conductor where the electric field is zero. Although the situation in Figs. 24-18 and 24-22 look similar, there is an important difference. There must be other charges in Fig. 24-22 that contribute to making the field zero inside the conductor. Even though these charges are outside the Gaussian surface and therefore do not contribute to the total flux, they change the values of the E field on the surface and therefore change the value we extract.

The field vectors in Fig. 24-22 point toward negative charges somewhere in the environment. If we bring those charges near the conductor, the charge density at any given location on the conductor's surface changes, and so does the magnitude of the electric field. However, the relation between the amount of the surface charge per unit area and the electric field magnitude is still given by Eq. 24-20,

$$E = \frac{|\sigma|}{\epsilon_0}.$$

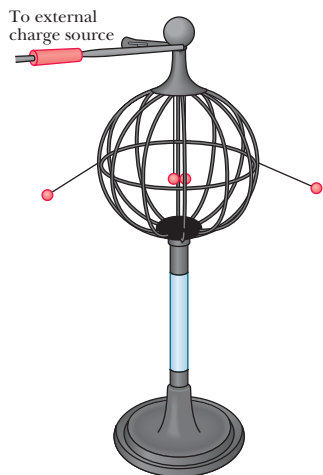

FIGURE 24-23 ■ A charged Faraday cage consisting of a sphere made of curved brass rods. Charges on the outside of the cage travel along conducting strings to the small balls causing them to be repelled from the cage. There is no charge inside the cage so the balls in the cage do not repel.

The Faraday Cage

The fact that an isolated conductor with a cavity has no electric field inside of it has led to the construction of a very valuable electrical device. Many research environments today involve the measurement of very low power electrical signals. This might occur when measuring the electrical signals from the neuron of a live mouse running a maze or while trying to measure the electrical properties of a microscopic device meant as part of a micro-miniaturized computer chip. In our modern world there are numerous electrical signals traveling through space, arising from everything from the 60 Hz power running in our walls to the radio signals from TV stations and cellular phones. These signals can interfere with sensitive electrical measurements.

To prevent these stray electric fields from ruining sensitive measurements, researchers often conduct their experiments inside a thin-walled metal cage known as a Faraday cage. Examples of Faraday cages are shown in the photo on the first page of this chapter as well as in Fig. 24-23. The Faraday cage in Fig. 24-23 is like the object shown in Fig. 24-21*b* except that now the “cavity” takes up almost the whole volume of the material. In addition, the thin metal shell in a Faraday cage is typically made of wire mesh. As long as the mesh is fairly fine, charge can spread out evenly on its surface. This type of cage can prevent even strong electrical signals from producing electric fields inside the cage. How? The external electric field induces charges on the surface of the Faraday cage to move so that the field they produce will precisely cancel the external field at points inside the surface. This rearrangement occurs naturally and is predictable by Gauss' law. This is why a demonstrator in a Faraday cage that is highly charged by a Van de Graaff generator can touch the inside of the cage and survive as shown in the opening photograph. The principle of the Faraday cage is also what makes it safe to be inside an automobile in a lightning storm. Even if lightning strikes your car, the effects inside the conductor are substantially reduced. This would not be the case if you were in a wooden crate, because the lightning could pass right through it. The crate could also catch on fire.

READING EXERCISE 24-5: Suppose a single positive charge is suddenly placed in the cavity shown in Fig. 24-21*b*. What has to happen in the conductor at the cavity walls to ensure that the electric field everywhere inside the conductor remains at zero? ■

TOUCHSTONE EXAMPLE 24-4: Spherical Metal Shell

Figure 24-24a shows a cross section of a spherical metal shell of inner radius R . A point charge of $-5.0\ \mu\text{C}$ is located at a distance $R/2$ from the center of the shell. If the shell is electrically neutral, what are the (induced) charges on its inner and outer surfaces? Are those charges uniformly distributed? What is the field pattern inside and outside the shell?

SOLUTION ■ Figure 24-24b shows a cross section of a spherical Gaussian surface within the metal, just outside the inner wall of the

FIGURE 24-24 ■ (a) A negative point charge is located within a spherical metal shell that is electrically neutral. (b) As a result, positive charge is nonuniformly distributed on the inner wall of the shell, and an equal amount of negative charge is uniformly distributed on the outer wall. The electric field lines are shown.

shell. One **Key Idea** here is that the electric field must be zero inside the metal (and thus on the Gaussian surface inside the metal). This means that the electric flux through the Gaussian surface must also be zero. Gauss' law then tells us that the *net* charge enclosed by the Gaussian surface must be zero. With a point charge of $-5.0\ \mu\text{C}$ within the shell, a charge of $+5.0\ \mu\text{C}$ must lie on the inner wall of the shell.

If the point charge were centered, this positive charge would be uniformly distributed along the inner wall. However, since the point charge is off-center, the distribution of positive charge is skewed, as suggested by Fig. 24-24b, because the positive charge tends to collect on the section of the inner wall nearest the (negative) point charge.

A second **Key Idea** is that because the shell is electrically neutral, its inner wall can have a charge of $+5.0\ \mu\text{C}$ only if electrons, with a total charge of $-5.0\ \mu\text{C}$, leave the inner wall and move to the outer wall. There they spread out uniformly, as is also suggested by Fig. 24-24b. This distribution of negative charge is uniform because the shell is spherical and because the skewed distribution of positive charge on the inner wall cannot produce an electric field in the shell to affect the distribution of charge on the outer wall.

The field lines inside and outside the shell are shown approximately in Fig. 24-24b. All the field lines intersect the shell and the point charge perpendicularly. Inside the shell the pattern of field lines is skewed owing to the skew of the positive charge distribution. Outside the shell the pattern is the same as if the point charge were centered and the shell were missing. In fact, this would be true no matter where inside the shell the point charge happened to be located.

Problems

SEC. 24-3 ■ NET FLUX AT A CLOSED SURFACE

1. Cube The cube in Fig. 24-25 has edge lengths of 1.40 m and is oriented as shown with its bottom face in the x - y plane at $z = 0.00$ m. Find the electric flux through the right face if the uniform electric field, in newtons per coulomb, is given by (a) $6.00\hat{i}$, (b) $-2.00\hat{j}$, and (c) $-3.00\hat{i} + 4.00\hat{k}$. (d) What is the total flux through the cube for each of these fields?

FIGURE 24-25 ■ Problems 1, 5, and 10.

2. Square Surface The square surface shown in Fig. 24-26 measures 3.2 mm on each side. It is immersed in a uniform electric field with magnitude $|\vec{E}| = 1800\ \text{N/C}$. The field lines make an angle of 35° with a normal to the surface, as shown. Take that normal to be directed “outward,” as though the surface were one face of a box. Calculate the electric flux through the surface.

FIGURE 24-26 ■ Problem 2.

SEC. 24-4 ■ GAUSS' LAW

3. Charge at Center of Cube A point charge of $1.8\ \mu\text{C}$ is at the center of a cubical Gaussian surface 55 cm on edge. What is the net electric flux through the surface?

4. Four Charges You have four point charges, $2q$, q , $-q$, and $-2q$. If possible describe how you would place a closed surface that encloses at least the charge $2q$ (and perhaps other charges) and through which the net electric flux is (a) 0 (b) $+3q/\epsilon_0$, and (c) $-2q/\epsilon_0$.

5. Flux Through Cube Find the net flux through the cube of Problem 1 and Fig. 24-25 if the electric field is given by (a) $\vec{E} = (3.00y\ \text{[N/(C}\cdot\text{m)]})\hat{j}$

and (b) $\vec{E} = -(4.00 \text{ N/C})\hat{i} + (6.00 \text{ N/C} + 3.00 y \text{ [N/(C}\cdot\text{m)]})\hat{j}$. (c) In each case, how much charge is enclosed by the cube?

6. Butterfly Net In Fig. 24-27, a butterfly net is in a uniform electric field of magnitude E . The rim, a circle of radius a , is aligned perpendicular to the field. Find the electric flux through the netting.

FIGURE 24-27 Problem 6.

7. Earth's Atmosphere It is found experimentally that the electric field in a certain region of Earth's atmosphere is directed vertically down. At an altitude of 300 m the field has magnitude 60.0 N/C; at an altitude of 200 m, the magnitude is 100 N/C. Find the net amount of charge contained in a cube 100 m on edge, with horizontal faces at altitudes of 200 and 300 m. Neglect the curvature of Earth.

8. Shower When a shower is turned on in a closed bathroom, the splashing of the water on the bare tub can fill the room's air with negatively charged ions and produce an electric field in the air as great as 1000 N/C. Consider a bathroom with dimensions of 2.5 m \times 3.0 m \times 2.0 m. Along the ceiling, floor, and four walls, approximate the electric field in the air as being directed perpendicular to the surface and as having a uniform magnitude of 600 N/C. Also, treat those surfaces as forming a closed Gaussian surface around the room's air. What are (a) the volume charge density ρ and (b) the number of excess elementary charges e per cubic meter in the room's air?

9. Point Charge A point charge q is placed at one corner of a cube of edge a . What is the flux through each of the cube faces? (*Hint:* Use Gauss' law and symmetry arguments.)

10. Surface of Cube At each point on the surface of the cube shown in Fig 24-25, the electric field is along the y -axis. The length of each edge of the cube is 3.0 m. On the right surface of the cube, $\vec{E} = (-34 \text{ N/C})\hat{j}$, and on the left face of the cube $\vec{E} = (+20 \text{ N/C})\hat{j}$. Determine the net charge contained within the cube.

SEC. 24-6 ■ APPLICATION OF GAUSS' LAW TO SYMMETRIC CHARGE DISTRIBUTIONS

11. Conducting Sphere A conducting sphere of radius 10 cm has an unknown charge. If the electric field 15 cm from the center of the sphere has the magnitude $3.0 \times 10^3 \text{ N/C}$ and is directed radially inward, what is the net charge on the sphere?

12. Charge Causes Flux A point charge causes an electric flux of $-750 \text{ N}\cdot\text{m}^2/\text{C}$ to pass through a spherical Gaussian surface of 10.0 cm radius centered on the charge. (a) If the radius of the Gaussian surface were doubled, how much flux would pass through the surface? (b) What is the value of the point charge?

13. Rutherford In a 1911 paper, Ernest Rutherford said: "In order to form some idea of the forces required to deflect an α particle through a large angle, consider an atom [as] containing a point positive charge Ze at its center and surrounded by a distribution of negative electricity $-Ze$ uniformly distributed within a sphere of radius R . The electric field $E \dots$ at a distance r from the center for a point inside the atom [is]

$$E = \frac{Ze}{4\pi\epsilon_0} \left(\frac{1}{r^2} - \frac{r}{R^3} \right)$$

Verify this equation.

14. Concentric Spheres Two charged concentric spheres have radii of 10.0 cm and 15.0 cm. The charge on the inner sphere is $4.00 \times 10^{-8} \text{ C}$, and that on the outer sphere is $2.00 \times 10^{-8} \text{ C}$. Find the electric field (a) at $r = 12.0 \text{ cm}$ and (b) at $r = 20.0 \text{ cm}$.

15. Proton A proton with speed $v = 3.00 \times 10^5 \text{ m/s}$ orbits just outside a charged sphere of radius $r = 1.00 \text{ cm}$. What is the charge on the sphere?

16. Charge at Center of Shell A point charge $+q$ is placed at the center of an electrically neutral, spherical conducting shell with inner radius a and outer radius b . What charge appears on (a) the inner surface of the shell and (b) the outer surface? What is the net electric field at a distance r from the center of the shell if (c) $r < a$, (d) $b > r > a$, and (e) $r > b$? Sketch field lines for those three regions. For $r > b$, what is the net electric field due to (f) the central point charge plus the inner surface charge and (g) the outer surface charge? A point charge $-q$ is now placed outside the shell. Does this point charge change the charge distribution on (h) the outer surface and (i) the inner surface? Sketch the field lines now. (j) Is there an electrostatic force on the second point charge? (k) Is there a net electrostatic force on the first point charge? (l) Does this situation violate Newton's Third Law?

17. Solid Nonconducting Sphere A solid nonconducting sphere of radius R has a nonuniform charge distribution of volume charge density $\rho = \rho_s r/R$, where ρ_s is a constant and r is the distance from the center of the sphere. Show (a) that the total charge on the sphere is $Q = \pi\rho_s R^3$ and (b) that

$$|\vec{E}| = k \frac{|Q|}{R^4} r^2$$

gives the magnitude of the electric field inside the sphere.

18. Hydrogen Atom A hydrogen atom can be considered as having a central point-like proton of positive charge $+e$ and an electron of negative charge $-e$ that is distributed about the proton according to the volume charge density $\rho = A \exp(-2r/a_1)$. Here A is a constant, $a_1 = 0.53 \times 10^{-10} \text{ m}$ is the *Bohr radius*, and r is the distance from the center of the atom. (a) Using the fact that hydrogen is electrically neutral, find A . (b) Then find the electric field produced by the atom at the Bohr radius.

19. Sphere of Radius a In Fig 24-28 an insulating sphere, of radius a and charge $+q$ uniformly distributed throughout its volume, is concentric with a spherical conducting shell of inner radius b and outer radius c . This shell has a net charge of $-q$. Find expressions for the electric field, as a function of the radius r , (a) within the sphere ($r < a$), (b) between the sphere and the shell ($a < r < b$), (c) inside the shell ($b < r < c$), and (d) outside the shell ($r > c$). (e) What are the charges on the inner and outer surfaces of the shell?

FIGURE 24-28 Problem 19.

20. Uniform Volume Charge Density Figure 24-29a shows a spherical shell of charge with uniform volume charge density ρ . Plot E due to the shell for distances r from the center of the shell ranging from zero to 30 cm. Assume that $\rho = 1.0 \times 10^{-6} \text{ C/m}^3$, $a = 10 \text{ cm}$, and $b = 20 \text{ cm}$.

FIGURE 24-29 ■ Problems 20 and 21.

21. Nonconducting Spherical Shell In Fig. 24-29b, a nonconducting spherical shell, of inner radius a and outer radius b , has a positive volume charge density $\rho = A/r$ (within its thickness), where A is a constant and r is the distance from the center of the shell. In addition, a positive point charge q is located at that center. What value should A have if the electric field in the shell ($a \leq r \leq b$) is to be uniform? (*Hint:* The constant A depends on a but not on b .)

22. Show That A nonconducting sphere has a uniform volume charge density ρ . Let \vec{r} be the vector from the center of the sphere to a general point P within the sphere. (a) Show that the electric field at P is given by $\vec{E} = \rho\vec{r}/3\epsilon_0$. (Note that the result is independent of the radius of the sphere.) (b) A spherical cavity is hollowed out of the sphere, as shown in Fig. 24-30. Using superposition concepts, show that the electric field at all points within the cavity is uniform and equal to $\vec{E} = \rho\vec{a}/3\epsilon_0$, where \vec{a} is the position vector from the center of the sphere to the center of the cavity. (Note that this result is independent of the radius of the sphere and the radius of the cavity.)

FIGURE 24-30 ■ Problem 22.

23. Spherically Symmetrical A spherically symmetrical but nonuniform volume distribution of charge produces an electric field of magnitude $|\vec{E}| = Kr^4$, directed radially outward from the center of the sphere. Here r is the radial distance from that center, and K is a positive constant. What is the volume density ρ of the charge distribution as a function of r ?

24. Long Metal Tube Figure 24-31 shows a section of a long, thin-walled metal tube of radius R , with a positive charge per unit length λ on its surface. Derive expressions for $|\vec{E}|$ in terms of the distance r from the tube axis, considering both (a) $r > R$ and (b) $r < R$. Plot your results for the range $r = 0$ to $r = 5.0$ cm, assuming that $\lambda = 2.0 \times 10^{-8}$ C/m and $R = 3.0$ cm. (*Hint:* Use cylindrical Gaussian surfaces, coaxial with the metal tube.)

FIGURE 24-31 ■ Problem 24.

25. Infinite Line of Charge An infinite line of charge produces a field magnitude of 4.5×10^4 N/C at a distance of 2.0 m. Calculate the amount of linear charge density $|\lambda|$.

26. Long Straight Wire A long, straight wire has fixed negative charge with a linear charge density of -3.6 nC/m. The wire is to be

enclosed by a thin, nonconducting cylinder of outside radius 1.5 cm, coaxial with the wire. The cylinder is to have positive charge on its outside surface with a surface charge density σ such that the net external electric field is zero. Calculate the required σ .

27. Cylindrical Rod A very long conducting cylindrical rod of length L with a total charge $+q$ is surrounded by a conducting cylindrical shell (also of length L) with total charge $-2q$, as shown in Fig. 24-32. Use Gauss' law to find (a) the electric field at points outside the conducting shell, (b) the distribution of charge on the shell, and (c) the electric field in the region between the shell and rod. Neglect end effects.

FIGURE 24-32 ■ Problem 27.

28. Solid Cylinder A long, nonconducting, solid cylinder of radius 4.0 cm has a nonuniform volume charge density ρ that is a function of the radial distance r from the axis of the cylinder, as given by $\rho = Ar^2$ with $A = 2.5 \mu\text{C}/\text{m}^5$. What is the magnitude of the electric field at a radial distance of (a) 3.0 cm and (b) 5.0 cm from the axis of the cylinder?

29. Two Concentric Cylinders Two long, charged, concentric cylinders have radii of 3.0 and 6.0 cm. Assume the outer cylinder is hollow. The charge per unit length is 5.0×10^{-6} C/m on the inner cylinder and -7.0×10^{-6} C/m on the outer cylinder. Find the electric field at (a) $r = 4.0$ cm and (b) $r = 8.0$ cm, where r is the radial distance from the common central axis.

30. Geiger Counter Figure 24-33 shows a Geiger counter, a device used to detect ionizing radiation (radiation that causes ionization of atoms). The counter consists of a thin, positively charged central wire surrounded by a concentric, circular, conducting cylinder with an equal negative charge. Thus, a strong radial electric field is set up inside the cylinder. The cylinder contains a low-pressure inert gas. When a particle of radiation enters the device through the cylinder wall, it ionizes a few of the gas atoms. The resulting free electrons (labelled e) are drawn to the positive wire. However, the electric field is so intense that, between collisions with other gas atoms, the free electrons gain energy sufficient to ionize these atoms also. More free electrons are thereby created, and the process is repeated until the electrons reach the wire. The resulting "avalanche" of electrons is collected by the wire generating a signal that is used to record the passage of the original particle of radiation. Suppose that the radius of the central wire is $25 \mu\text{m}$, the radius of the cylinder 1.4 cm, and the length of the tube 16 cm. If the electric field component E_r at the cylinder's inner wall is $+2.9 \times 10^4$ N/C, what is the total positive charge on the central wire?

FIGURE 24-33 ■ Problem 30.

31. Charge Is Distributed Uniformly Charge is distributed uniformly throughout the volume of an infinitely long cylinder of

radius R . (a) Show that, at a distance r from the cylinder axis (for $r < R$),

$$|\vec{E}| = \frac{|\rho|r}{2\epsilon_0},$$

where $|\rho|$ is the amount of volume charge density. (b) Write an expression for $|\vec{E}|$ when $r > R$.

32. Parallel Sheets Figure 24-34 shows cross sections through two large, parallel, nonconducting sheets with identical distributions of positive charge with area charge density σ . What is \vec{E} at points (a) above the sheets, (b) between them, and (c) below them?

FIGURE 24-34 ■ Problem 32.

33. Square Metal Plate A square metal plate of edge length 8.0 cm and negligible thickness has a total charge of 6.0×10^{-6} C. (a) Estimate the magnitude E of the electric field just off the center of the plate (at, say, a distance of 0.50 mm) by assuming that the charge is spread uniformly over the two faces of the plate. (b) Estimate E at a distance of 30 m (large relative to the plate size) by assuming that the plate is a point charge.

34. Thin Metal Plates Two large, thin metal plates are parallel and close to each other. On their inner faces, the plates have excess surface charge of opposite signs. The amount of charge per unit area is given by $|\sigma| = 7.0 \times 10^{-22}$ C/m², with the negatively charged plate on the left. What are the magnitude and direction of the electric field \vec{E} (a) to the left of the plates, (b) to the right of the plates, and (c) between the plates?

FIGURE 24-35 ■ Problem 35.

35. Ball on Thread In Fig. 24-35, a small, nonconducting ball of mass $m = 1.0$ mg and charge $q = 2.0 \times 10^{-8}$ C (distributed uniformly through its volume) hangs from an insulating thread that makes an angle $\theta = 30^\circ$ with a vertical, uniformly charged nonconducting sheet (shown in cross section). Considering the gravitational force on the ball and assuming that the sheet extends far vertically and into and out of the page, calculate the surface charge density σ of the sheet.

36. Large Metal Plates Two large metal plates of area 1.0 m² face each other. They are 5.0 cm apart and have equal but opposite charges on their inner surfaces. If the magnitude $|\vec{E}|$ of the electric field between the plates is 55 N/C, what is the amount of charge on each plate? Neglect edge effects.

37. An Electron Is Shot An electron is shot directly toward the center of a large metal plate that has excess negative charge with surface charge density -2.0×10^{-6} C/m². If the initial kinetic energy of the electron is 1.60×10^{-17} J and if the electron is to stop (owing to electrostatic repulsion from the plate) just as it reaches the plate, how far from the plate must it be shot?

38. Planar Slab A planar slab of thickness d has a uniform volume charge density ρ . Find the magnitude of the electric field at all points in space both (a) within and (b) outside the slab, in terms of x , the distance measured from the central plane of the slab.

SEC. 24-8 ■ A CHARGED ISOLATED CONDUCTOR

39. Photocopying Machine The electric field just above the surface of the charged drum of a photocopying machine has a magnitude $|\vec{E}|$ of 2.3×10^5 N/C. What is the surface charge density on the drum, assuming that the drum is a conductor?

40. Space Vehicles Space vehicles traveling through Earth's radiation belts can intercept a significant number of electrons. The resulting charge buildup can damage electronic components and disrupt operations. Suppose a spherical metallic satellite 1.3 m in diameter accumulates -2.4 μ C of charge in one orbital revolution. (a) Find the resulting surface charge density. (b) Calculate the magnitude of the electric field just outside the surface of the satellite due to the surface charge.

41. Charged Sphere A uniformly charged conducting sphere of 1.2 m diameter has a surface charge density of 8.1 μ C/m². (a) Find the net charge on the sphere. (b) What is the total electric flux leaving the surface of the sphere?

42. Arbitrary Shape Conductor An isolated conductor of arbitrary shape has a net charge of $+10 \times 10^{-6}$ C. Inside the conductor is a cavity within which is a point charge $q = +3.0 \times 10^{-6}$ C. What is the charge (a) on the cavity wall and (b) on the outer surface of the conductor?

Additional Problems

43. If/Can If the electric field in a region of space is zero, can you conclude there are no electric charges in that region? Explain.

44. If/Than If there are fewer electric field lines leaving a Gaussian surface than there are entering the surface, what can you conclude about the net charge enclosed by that surface?

45. Net Flux What is the net electric flux through each of the closed surfaces in Fig. 24-36 if the value of q is $+1.6 \times 10^{-19}$ C?

46. Net Flux Two What is the net electric flux through each of the closed surfaces in Fig. 24-37 if the value of q is 8.85×10^{-12} C? Explain the reasons for your answers.

FIGURE 24-36 ■ Problem 45.

FIGURE 24-37 ■ Problem 46.

47. Fair Weather During fair weather, an electric field of about 100 N/C points vertically downward into Earth's atmosphere. Assuming that this field arises from charge distributed in a spherically symmetric manner over the surface of Earth, determine the *net* charge of Earth and its atmosphere if the radius of Earth and its atmosphere is 6.37×10^6 m.

48. Hollow Sphere Suppose a charge is located at the center of a hollow sphere as shown in Fig. 24-38.

(a) Are the intersections of the field lines with the surface of the sphere uniformly distributed throughout? In other words, is the density of lines passing through the surface of the sphere uniform? Explain why or why not.

(b) Consider surface elements A and B , which have exactly the same area. Is the number of field lines passing through surface element A greater than, less than, or equal to the number of field lines through surface element B ? Explain.

(c) Is the flux through surface element A greater than, less than, or equal to the flux through surface element B ? Explain.

49. Center of Cube Suppose a charge is located at the center of the cube shown in Fig. 24-39.

(a) Are the intersections of the field lines with a side of the cube uniformly distributed across the side? In other words, is the density of lines passing through the box uniform? Explain why or why not.

(b) Is the number of field lines through surface element A greater than, less than, or equal to the number of field lines through surface element B ? Explain.

(c) Is the flux through surface element A greater than, less than, or equal to the flux through surface element B ? Explain.

50. Using Gauss' Law Gauss' law is usually written as an equation in the form

$$\oint \vec{E} \cdot d\vec{A} = q_{\text{enc}}/\epsilon_0.$$

(a) For this equation, specify what each term in this equation means and how it is to be calculated when doing some specific (but arbitrary—not a special case) calculation.

FIGURE 24-38 ■ Problem 48.

FIGURE 24-39 ■ Problem 49.

A long thin cylindrical shell like that shown in Fig. 24-40 has length L and radius R with $L \gg R$ and is uniformly covered with a charge Q . If we look for the field near the cylinder somewhere about the middle, we can treat the cylinder as if it were an infinitely long cylinder. Using this assumption, we can calculate the magnitude and direction of the field at a point a distance d from the *axis* of the cylinder (outside the cylindrical shell; i.e., $L \gg d > R$ but d not very close to R) using Gauss' law. Do so by explicitly following the steps below.

FIGURE 24-40 ■ Problem 50.

(b) Select an appropriate Gaussian surface. Explain why you chose it.

(c) Carry out the integral on the left side of the equation, expressing it in terms of the unknown value of the magnitude of the E field.

(d) What is the relevant value of q for your surface?

(e) Use your results in (c) and (d) in the equation and solve for the magnitude of E .

51. Interpreting Gauss Gauss' law states

$$\oint_A \vec{E} \cdot d\vec{A} = q_A/\epsilon_0,$$

where A is a surface and q_A is a charge.

(a) Which of the following statements are true about the surface A appearing in Gauss' law for the equation to hold? You may list any number of these statements including all or none.

- i. The surface A must be a closed surface (must cover a volume).
- ii. The surface A must contain all the charges in the problem.
- iii. The surface A must be a highly symmetrical surface like a sphere or a cylinder.
- iv. The surface A must be a conductor.
- v. The surface A is purely imaginary.
- vi. The normals to the surface A must all be in the same direction as the electric field on the surface.

(b) Which of the following statements are true about the charge q_A appearing in Gauss' law? You may list any number of these statements including all or none.

- i. The charge q_A must be all the charge lying on the Gaussian surface.
- ii. The charge q_A must be the charge lying within the Gaussian surface.
- iii. The charge q_A must be all the charge in the problem.
- iv. The charge q_A flows onto the Gaussian surface once the surface is established.
- v. The electric field E in the integral on the left of Gauss' law is due only to the charge q_A .
- vi. The electric field E in the integral on the left on Gauss' law is due to all charges in the problem.

25

Electric Potential

At more than 115 years old, the Eiffel Tower is arguably the world's most famous landmark. Among other things, the tower is an engineering feat, a work of art, a scenic lookout, and a radio tower. Less well known is the tower's ability to protect people, trees, and other buildings from being struck by lightning that might emanate from thunderheads behind it.

How can the Eiffel Tower protect people from lightning?

The answer is in this chapter.

25-1 Introduction

In the last few chapters we have explored the nature of interaction forces between charged particles. We have developed the concept of electric field as a way to represent the forces a point charge would experience at any point in the space surrounding a collection of charges.

In certain situations it is difficult to understand the motions of charges in terms of an electric field. This difficulty is analogous to problems encountered in describing the motion of an object in the presence of gravitational forces. We developed the concepts of work and energy in Chapters 9 and 10 to deal with these problems. We will now investigate the application of the concepts of work and energy to situations in which the forces involved are electrostatic forces. In this chapter we develop the concept of electric potential—commonly referred to as voltage. We then explore some of its properties, including how charges are distributed on a metal conductor placed in an electric field.

Since the concept of potential or voltage is essential to an understanding of electric circuits, we will use the concept of electric potential in the next chapter to help us understand the role that batteries play in maintaining currents.

25-2 Electric Potential Energy

Newton's law for the gravitational force and Coulomb's law for the electrostatic force are mathematically similar. In Section 14-2 we saw that the gravitational force between two particle-like masses depends directly on the product of the masses and inversely with the square of the distance between them (Eq. 14-2). In like manner, the electrostatic forces between two point charges depend directly on the product of the charges and inversely with the square of the distance between them (Eq. 22-4). This similarity gives us a starting point in our search for additional useful concepts related to the interactions between charged objects. In this chapter, we consider whether some of the general features we have established for the gravitational force apply to the electrostatic force as well.

For example, the gravitational force is a *conservative force*. The work done by it is independent of the path along which an object moves. In experimental tests the work done by the electrostatic force has also been found to be *path independent*. If a charged particle moves from point i to point f while an electrostatic force is acting on it, the work W done by the force is the same for all paths between points i and f . Hence, we can infer that the electrostatic force is a conservative force as well.

Definition of Electric Potential Energy

In Chapter 10 we defined potential energy as the energy associated with the configuration of a system of objects that interact and hence exert forces on each other. We then proceeded to define gravitational potential energy as the negative of the amount of gravitational work objects in the system do on each other when their positions relative to one another change. From Eq. 10-5, $\Delta U \equiv -W^{\text{cons}}$ or $\Delta U^{\text{grav}} = -W^{\text{grav}}$ (Eq. 10-6). This general definition of work can be applied to a system of charges that interact by means of electrostatic forces.

Since electrostatic forces, like gravitational forces, are conservative, then it makes sense to assign an **electric potential energy change** ΔU to a system of interacting charges in a similar manner. If we cause or allow a system to change its configuration from an initial potential energy state U_1 to a different final state U_2 , the internal electrostatic forces do a total amount of work W^{elec} on the particles in the system. As in

FIGURE 25-1 (a) A system of three charges is in an initial configuration in which the charges are separated and have an electric potential energy U_1 associated with them. (b) Since both of the negative charges will be attracted to the positive charge, they will coalesce into a final configuration with potential energy U_2 . The net electrostatic work the charges do on each other is positive so the system loses potential energy. Thus $U_2 < U_1$ so that $\Delta U < 0$.

Chapter 10, we define the potential energy change ΔU as the negative of the work the system does on itself when it undergoes the reconfiguration. This can be expressed symbolically as

$$\Delta U = U_2 - U_1 \equiv W^{\text{ext}} = -W^{\text{elec}}. \quad (25-1)$$

Figure 25-1 shows a system of charges losing electrostatic potential energy as a result of a natural reconfiguration. Figure 25-2 shows the same system gaining electrostatic potential energy as an external agent (doing positive work) causes the system to reconfigure. This results in the system doing negative work on itself.

FIGURE 25-2 (a) A system of three charges is in an initial configuration in which the charges are close together and have an electric potential energy U_1 associated with them. (b) Since q_1 and q_3 are both attracted to q_2 , it will take positive external work, W^{ext} , to pull the charges apart. The net electrostatic work the charges do on each other is negative so the system gains potential energy. Thus $U_2 > U_1$ so that $\Delta U > 0$.

As you may recall, we determined that only differences in gravitational potential energy were physically significant. In Chapter 10 the system of masses we considered consisted of the Earth and a single object near its surface. We chose a convenient height at which to set the gravitational potential energy to zero. For example, we may have defined an Earth–object system as having zero potential energy when an object is at floor level or at the level of a tabletop. In doing so, we set the absolute scale for gravitational potential energy differently in different situations. This is legitimate since only potential energy *differences* are meaningful.

Potential energy difference is also of primary importance in keeping track of electric potential energy. Typically, we *define the electric potential energy of a system of charges to be zero when the particles are all infinitely separated from each other*, just as we did in Chapter 14 with the general form of gravitational potential energy. Using this zero of electric potential energy makes sense because the charges making up such a system have no interaction forces in that configuration. Using a standard reference potential (instead of moving it around as we typically do for Earth–object systems) allows us to find unique values of U_1 and U_2 . For example suppose several charged particles come together from initially infinite separations (state 1) to form a system of nearby particles (state 2). Then using the conventional reference configuration, the initial potential energy U_1 is zero. If W^{elec} represents the internal work done by the electrostatic forces between particles during the move in from infinity, then from Eq. 25-1,

$$\Delta U = U_2 - U_1 = U_2 = -W^{\text{elec}}. \quad (25-2)$$

Since U_1 is zero, the final potential energy U_2 of the system can simply be denoted as U . Then, in terms of symbols,

$$U \equiv -W^{\text{elec}} \quad (\text{for initial potential energy} = 0). \quad (25-3)$$

As usual, the use of the symbol “ \equiv ” signifies that the expression is a definition.

External Forces and Energy Conservation

Since opposite charges attract, they will come together naturally if they are free to move. In these cases the charges “fall together” and the potential energy of the system of charges will be reduced. Similarly, like charges that are free will move apart and their potential energy will also be reduced. However, we can raise the potential energy of a system of charges by using energy from another system. Two common examples of external agents that can raise the potential energy of a system of charges are the Van de Graaff generator and the battery. Van de Graaff generators (see Fig. 25-3) use mechanical energy to force charges of like sign onto metal conductors. Batteries use chemical potential energy (which is actually a combination of electric and quantum effects) to force charges onto an electrode having the same sign charges.

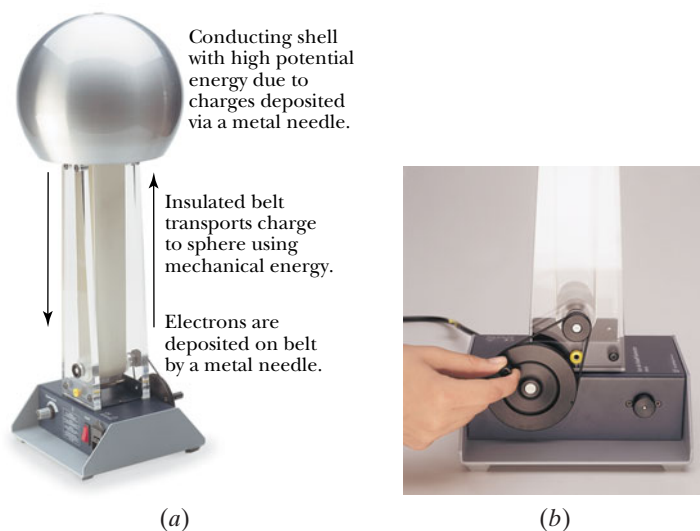

FIGURE 25-3 ■ A Van de Graaff generator uses mechanical energy from either (a) a motor or (b) a hand crank to transport charge to a conducting sphere, raising its potential energy. (Photo courtesy of PASCO scientific.)

Suppose an *external force* outside of the system under consideration causes a test particle of charge q to move from an initial location to a final location in the presence of an unchanging electric field generated by the source charges in the system. As the test charge moves, our outside force does work W^{ext} on the charge. At the same time, the electric field does work W^{elec} on it. By the work-kinetic energy theorem, the change ΔK in the kinetic energy of the particle is

$$\Delta K = K_2 - K_1 = W^{\text{ext}} + W^{\text{elec}}.$$

But since $W^{\text{elec}} = -\Delta U$,

$$\Delta K + \Delta U = W^{\text{ext}}. \quad (25-4)$$

Now suppose the particle is stationary before and after the move. Then K_2 and K_1 are both zero, and this reduces to

$$\Delta U = W^{\text{ext}} \quad (\text{for no kinetic energy change}). \quad (25-5)$$

FIGURE 25-4 ■ A 1.5 V D-cell can act as an external agent that does the work needed to move electrons through a wire from a metal plate with excess positive charges to one with excess negative charges.

That is, the work, W^{ext} , done by our external force during the move is equal to the change in electric potential energy—provided there is no change in kinetic energy.

So in what direction will a positive or negative charge move if released? Will the charge move to raise or lower the potential energy of the system? The expression above can be used to determine this. For example, let the external force (perhaps the push or pull of your hand) do positive work. Recall from Section 9-4 the sign convention associated with work in general. If W^{ext} is positive, then ΔU must also be positive (by the equation above) and so we know that $U_2 > U_1$. In other words, the motion of a charge from a lower potential energy to a higher potential energy requires positive work to be done on the system. This motion would not happen if the particle were simply released. Spontaneous or naturally occurring motion is associated with reduced potential energy. This is very similar to the situations encountered in Section 9-8, where we considered an object under the influence of the Earth's attractive gravitational force. Often a battery does this work in a circuit, as in Fig. 25-4.

READING EXERCISE 25-1: Why is a configuration with charges separated by an infinite distance a good choice for our reference (zero) potential energy? Would a zero separation be equally good? Why or why not? ■

READING EXERCISE 25-2: In the figure, a proton moves from point 1 to point 2 in a uniform electric field directed as shown. (a) Does the electric field do positive or negative work on the proton? (b) Does the electric potential energy of the proton increase or decrease? (c) In this case we don't choose the potential energy to be zero at infinity. Why not? ■

25-3 Electric Potential

When considering gravitational potential energy we dealt primarily with a system consisting of the Earth and a single object much smaller than the Earth. If the object were to fall toward the Earth the interaction forces between them would be equal in magnitude, but as the object moves toward the Earth, the Earth's motion would be negligibly small. Thus the change in the system's gravitational potential energy would simply be the change in potential energy of the falling object. Similarly, as we did in Section 23-2, we can consider systems in which a small “test” charge moves in the presence of an electric field but does not change the electric field significantly. In these systems, the electric potential energy of the system can be calculated as the negative of work done by the electric field on a single test charge as we bring it to a location of interest from infinity.

In the next several chapters we will focus primarily on systems in which the change in potential energy of a single test charge moving in an electric field is for all practical purposes the same as the change in potential energy of the entire system of charges.

This situation applies if the only charge that moves is our test charge. In this case, the electric field generated by the fixed source charges remains the same, so that the change in the system's potential energy will be proportional to the magnitude of the test charge. (This will not be true if other charges move.)

Defining Electric Potential

Recall that we defined and used the concept of electric field as the *electric force per unit charge* so we could easily analyze the forces experienced by a charge of any

sign or magnitude. It is advantageous to develop an analogous concept for the determination of the electric potential energy of a system associated with the change in location of a test charge of any reasonable sign or magnitude. We will do that now, defining **electric potential** as a potential energy *per unit charge*. Once we have chosen a reference configuration with zero energy, our electric potential (potential energy per unit charge) has a unique value at any point in space. For example, suppose we move a test particle of positive charge $q_t = 1.60 \times 10^{-19} \text{ C}$ from a location at infinity where the electric potential energy is defined as zero to a location in an electric field where the particle has an electric potential energy of $2.40 \times 10^{-17} \text{ J}$. Then the change in electric potential, ΔV , of the system associated with the change in location of a test charge can be calculated as

$$\Delta V = V_2 - V_1 = \frac{2.40 \times 10^{-17} \text{ J}}{1.60 \times 10^{-19} \text{ C}} - 0 = 150 \text{ J/C}.$$

Next, suppose we replace that test particle with one having twice as much positive charge, $3.20 \times 10^{-19} \text{ C}$. We would find that, at the same point, the second particle has an electric potential energy of $4.80 \times 10^{-17} \text{ J}$, twice that of the first particle. However, the potential energy per unit charge or electric potential would be the same, still 150 J/C.

Thus, the system potential energy per unit charge, which can be symbolized as U/q_t , is independent of the charge q_t of the test particle we happen to be considering (Fig. 25-5). It is *characteristic only of the electric field* that is present. The potential energy per unit charge at a point in an electric field is defined as the electric potential V (or simply the **potential**) at that point. Thus V is defined as

$$V \equiv \frac{U}{q}. \quad (25-6)$$

Note that potential energy and charge are both scalar quantities, so the electric potential is also a scalar, not a vector.

The *electric potential difference*, ΔV , associated with moving a charge q between any two points 1 and 2 in an electric field is equal to the difference between the potential energy per unit charge at the two points:

$$\Delta V = V_2 - V_1 = \frac{U_2}{q} - \frac{U_1}{q} = \frac{\Delta U}{q}. \quad (25-7)$$

Using $\Delta U = U_2 - U_1 = -W^{\text{elec}}$ (Eq. 25-1) to substitute the work done by electrostatic forces $-W^{\text{elec}}$ for ΔU in the equation above, we can define the potential difference between points 1 and 2 as

$$\Delta V = V_2 - V_1 \equiv -\frac{W^{\text{elec}}}{q} \quad (\text{potential difference defined}). \quad (25-8)$$

That is, the potential difference between two points is the negative of the work done by the electrostatic force to move a unit charge from one point to the other. A potential difference can be positive, negative, or zero, depending on the signs and magnitudes of the charge q and the electrostatic work W^{elec} .

As we already mentioned, we have set $U_1 = 0$ infinitely far from any charges as our reference potential energy. So since $V \equiv U/q$ (Eq. 25-6), the electric potential

FIGURE 25-5 ■ A test charge moves in an electric field created by a stable configuration of source charges. If the test charge doesn't affect the electric field significantly as it changes location, the change in electric potential, ΔV , of the system (consisting of the source charges and the test charge) is due entirely to the work per unit charge done on the test charge by the electric field.

must also be zero there. Then using Eq. 25-8, we can define the electric potential V (measured relative to infinity) at any point in an electric field to be

$$V = -\frac{W_{\infty}^{\text{elec}}}{q} \quad (\text{potential defined relative to infinity}), \quad (25-9)$$

where W_{∞}^{elec} is the work done by the electrostatic force on a charged particle as that particle moves in from infinity to point f . As was the case with potential difference ΔV , a potential V can be positive, negative, or zero, depending on the signs and magnitudes of q and W_{∞}^{elec} .

The SI unit for electric potential that follows from Eq. 25-9 is the joule per coulomb. This combination occurs so often that a special unit, the *volt* (abbreviated V) is used to represent it. Thus,

$$1 \text{ volt} \equiv 1 \text{ joule/coulomb}. \quad (25-10)$$

Although the terms electric potential energy and electric potential are very similar, they are not the same thing. This is probably one of the reasons why it is so common to refer to electric potential as **voltage** after its unit—the volt.

This new unit called the volt allows us to adopt a more conventional unit for the electric field \vec{E} , which we have measured up to now in newtons per coulomb. With two unit conversions, we obtain

$$1 \text{ N/C} = \left[1 \frac{\text{N}}{\text{C}} \right] \left[\frac{1 \text{ V}}{1 \text{ J/C}} \right] \left[\frac{1 \text{ J}}{1 \text{ N} \cdot \text{m}} \right] = 1 \text{ V/m}. \quad (25-11)$$

The conversion factor in the second set of parentheses comes from Eq. 25-10, and that in the third set of parentheses is derived from the definition of the joule. From now on, we shall express values of the electric field in volts per meter rather than in newtons per coulomb.

The Electron Volt

Because we often have situations in which the charges involved are very small (a few times the charge of an electron), we define an energy unit that is a convenient one for energy measurements in the atomic and subatomic domain. One *electron-Volt* (eV) is the energy equal to the work required to move a single positive elementary charge e (the charge magnitude of the electron or the proton) through a potential difference of exactly one volt. Equation 25-8,

$$\Delta V = V_2 - V_1 = -\frac{W^{\text{elec}}}{q} = \frac{-W^{\text{elec}}}{e},$$

tells us that the magnitude of this work is $e \Delta V$, so

$$\begin{aligned} 1 \text{ eV} &= e(1 \text{ V}) \\ &= (1.60 \times 10^{-19} \text{ C})(1 \text{ J/C}) = 1.60 \times 10^{-19} \text{ J}, \end{aligned} \quad (25-12)$$

where the units for electron volt are joules because it is actually a unit of energy rather than electric potential.

READING EXERCISE 25-3: In the figure shown in Reading Exercise 25-2, we moved a proton from point i to point f in a uniform electric field directed as shown. (a) Does our external force do positive or negative work? (b) Does the proton move to a point of higher or lower potential? ■

TOUCHSTONE EXAMPLE 25-1: Electron Motion

An electron starts from rest at a point in space at which the electric potential is 9.0 V. If the only force acting on the electron is that associated with the electric potential, how fast will the electron be moving when it passes a second point in space where the electric potential is 10.0 V?

SOLUTION ■ First we need to convince ourselves that this problem describes a physical situation that is even possible. Equation 25-4 tells us that $\Delta K + \Delta U = W^{\text{ext}}$. Since $W^{\text{ext}} = 0$ here and since ΔK must be positive if the electron speeds up, this means that ΔU must be negative. But is it? After all, ΔV is positive here since $V_2 - V_1 = +1.0$ V. However, the charge of the electron is negative, so Eq. 25-7 tells us that:

$$\Delta U = q\Delta V = (-e)\Delta V = (-e)(+1.0 \text{ V}) = -1.0 \text{ eV},$$

so that $\Delta K = -\Delta U = -(-1.0 \text{ eV}) = +1.0 \text{ eV}$,

which is positive.

The **Key Idea** here is that a negative charge *loses* potential energy and *gains* kinetic energy when it moves from a region of *lower* potential to a region of *higher* potential. This is just the opposite of what would happen to a positive charge!

Now that we know the electron has 1.0 eV of kinetic energy, we need to determine how fast it is going. The **Key Idea** here is that $1 \text{ eV} = 1.60 \times 10^{-19} \text{ J}$ (Eq. 25-12). Then

$$\Delta K = K_2 - K_1 = \left(\frac{1}{2}\right)mv_2^2 - 0,$$

which gives us

$$\begin{aligned} v_2 &= \sqrt{2\Delta K/m} \\ &= \sqrt{2(1.0 \text{ eV})(1.60 \times 10^{-19} \text{ J/eV})/(9.1 \times 10^{-31} \text{ kg})} \\ &= 5.9 \times 10^5 \text{ m/s.} \end{aligned} \quad (\text{Answer})$$

25-4 Equipotential Surfaces

We are interested in what our knowledge of electric potential can tell us about how small test charges might move. We can infer from the discussion above that charged particles will not spontaneously move from one point to another point of equal potential. This is quite analogous to movement of mass in a gravitational field. A skier on a flat surface with no kinetic energy will not spontaneously move from one part of the surface to another. On the other hand, if the skier is on a slope and is free to move, the skier will spontaneously start moving down the slope, from higher to lower potential energy. Thus, it would be useful to know where all the points of equal potential energy are in a given region of space. That way, we can easily infer the directions of the forces on each of the charges. An **equipotential surface** is defined as a surface having the same potential at all points on it. Topographical maps show equipotential surfaces (lines on a two-dimensional map) in regard to gravitational potential energy.

Let's consider the electric field associated with a source consisting of a single fixed point charge we designate as the source charge. What happens if we place a test charge at a distance r from the source charge and move it around? If we move the charge anywhere on the surface of a sphere of radius r , no electrostatic work is done on the test charge as it is always moving perpendicular to the electric field vectors. However, we cannot move our test charge from one distance from the source charge to another distance without the electric field doing work on it. This is illustrated in Fig. 25-6. Thus, any sphere centered on the source charge is an equipotential surface. If our source charge is positive, then the potential decreases as the distance from the source charge increases. We know this because from $\Delta U = -W^{\text{elec}}$ (Eq. 25-1) a charge naturally moves from high potential energy to low. Thus the equipotential surfaces

FIGURE 25-6 ■ All of the electric field vectors created by the presence of a single charge point radially outward in three dimensions. If a test charge moves around on a sphere that is centered on the charge (where the dashed circle shows a cross section of the sphere), no work is done on it by the electric field since all the electric field vectors on surface elements of the sphere are normal to the sphere. If the charge is moved from one radius to the other (black squiggly line) it has to move parallel to the field vectors some of the time, and work is done on it.

associated with a positive point charge consist of an infinite family of concentric spheres centered on the source charge. Each sphere has a different potential.

An equipotential surface can be either imaginary, such as a mathematical sphere, or a real, physical surface such as the outside of a wire. The set of all equipotential surfaces fills all of space, since every point in space has some value of electric potential associated with it. We could draw an equipotential surface through any one of these points, just like we can draw a field line through every point in space. However, in order to simplify illustrations and diagrams, we typically show just a few of the surfaces.

No work W^{elec} is done on a charged particle by an electric field when the particle moves between two points i and f on the same equipotential surface. This follows from Eq. 25-8,

$$\Delta V = V_2 - V_1 = -\frac{W^{\text{elec}}}{q},$$

which tells us W^{elec} must be zero if $V_2 = V_1$. Because of the path independence of work (and thus of potential energy and potential), $W^{\text{elec}} = 0$ for *any* path connecting points 1 and 2, regardless of whether that path lies entirely on the equipotential surface. In other words, if the charge moves away from the equipotential surface during the motion, the work done (positive or negative) is exactly canceled by the work done (negative or positive) in moving back onto the surface.

Figure 25-7 shows a *family* of equipotential surfaces associated with the electric field due to some distribution of charges. The work done by the electrostatic force on a charged particle as the particle moves from one end to the other of paths I and II is zero because each of these paths begins and ends on the same equipotential surface. The work done as the charged particle moves from one end to the other of paths III and IV is not zero but has the same value for both these paths because the initial and final potentials are identical for the two paths; that is, paths III and IV connect the same pair of equipotential surfaces.

As we already noted, the equipotential surfaces produced by a point charge or a spherically symmetrical charge distribution are a family of concentric spheres. For a uniform electric field it is not difficult to see that the equipotential surfaces are a family of planes perpendicular to the field lines.

The fact that the value of the potential is constant along an equipotential surface implies that the electric field must always be perpendicular to the equipotential surfaces. Why? Because, if \vec{E} were *not* perpendicular to an equipotential surface, it would have a component lying along that surface. This component would then do work on a

FIGURE 25-7 ■ Portions of four equipotential surfaces at electric potentials $V_1 = 100 \text{ V}$, $V_2 = 80 \text{ V}$, $V_3 = 60 \text{ V}$, and $V_4 = 40 \text{ V}$. Four paths along which a test charge may move are shown. Two electric field lines are also indicated.

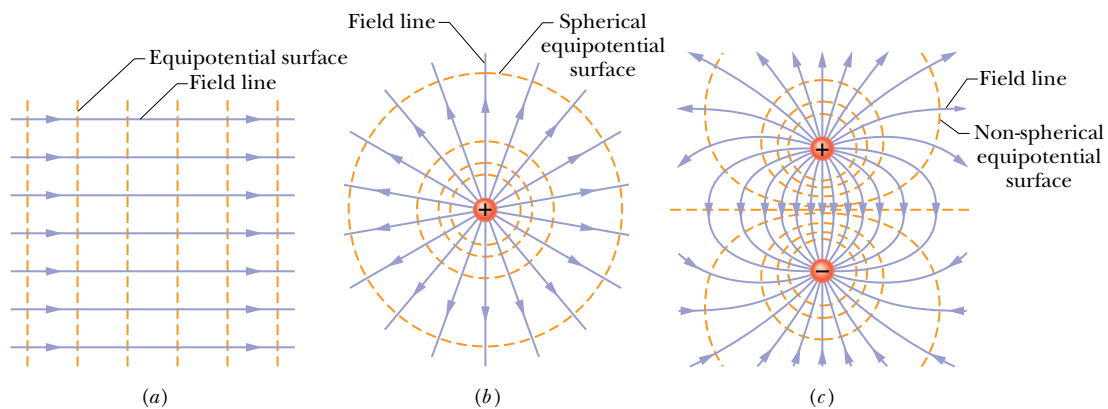

FIGURE 25-8 ■ Electric field lines (solid purple lines with arrows) and cross sections of equipotential surfaces (dashed gold lines) for (a) a uniform field with planar equipotential surfaces, (b) the field of a point charge with spherical equipotential surfaces, and (c) the field of an electric dipole with distorted equipotential surfaces that are not quite spherical.

charged particle as it moved along the surface. However, to prove that work cannot be done if the surface is truly an equipotential surface we use Eq. 25-8 once again,

$$\Delta V = V_2 - V_1 = -\frac{W^{\text{elec}}}{q}.$$

The only possible conclusion is that the electric field lines must be perpendicular to the surface everywhere along it.

If electric field lines are perpendicular to an equipotential surface, then conversely the equipotential surface must be perpendicular to the field lines. Thus, equipotential surfaces are always perpendicular to the direction of the electric field \vec{E} , which is tangent to the field lines. Figure 25-8 shows electric field lines and cross sections of the equipotential surfaces for a uniform electric field and for the field associated with a point charge and with an electric dipole.

25-5 Calculating Potential from an E -Field

Can we calculate the potential difference between any two points 1 and 2 in an electric field if we know the electric field vector \vec{E} all along any path connecting those points? We can if we can find the work done on a charge by the field as the charge moves from 1 to 2, and then use Eq. 25-8 again,

$$\Delta V = V_2 - V_1 = -\frac{W^{\text{elec}}}{q}.$$

For example, consider an arbitrary electric field, represented by the field lines in Fig. 25-9, and a positive test charge q_t moving along the path shown from point 1 to point 2. At any point on the path, an electrostatic force $q_t\vec{E}$ acts on the charge as it moves through an infinitesimally small differential displacement $d\vec{s}$. From Chapter 9, we know the differential work dW done on a particle by a force \vec{F} during a displacement $d\vec{s}$ is

$$dW = \vec{F} \cdot d\vec{s}. \quad (25-13)$$

For the situation of Fig. 25-9, $\vec{F} = q_t\vec{E}$, and Eq. 25-13 becomes

$$dW^{\text{elec}} = q_t\vec{E} \cdot d\vec{s}. \quad (25-14)$$

To find the total work W^{elec} done on the particle by the field as the particle moves from point 1 to point 2, we sum—via integration—the differential work done on the charge as it moves through all the differential displacements $d\vec{s}$ along the path:

$$W^{\text{elec}} = q_t \int_1^2 \vec{E} \cdot d\vec{s}. \quad (25-15)$$

If we substitute the total electrical work W^{elec} from Eq. 25-15 into Eq. 25-8, $\Delta V = V_2 - V_1 = -W^{\text{elec}}/q$, we find

$$V_2 - V_1 = -\int_1^2 \vec{E} \cdot d\vec{s}. \quad (25-16)$$

Thus, the potential difference $V_2 - V_1$ between any two points 1 and 2 in an electric field is equal to the negative of the *line integral* (meaning the integral along a particular path) of $\vec{E} \cdot d\vec{s}$ from 1 to 2. However, because the electrostatic force is conservative,

FIGURE 25-9 ■ A test charge q_t moves from point 1 to point 2 along the path shown in a nonuniform electric field represented by curved electric field lines. During a displacement $d\vec{s}$, an electrostatic force $q_t\vec{E}$ acts on the test charge. This force points in the direction of the field line at the location of the test charge.

all paths (whether easy or difficult to use) yield the same result. So, choose an easy-to-use path.

If the electric field is known throughout a certain region, Eq. 25-16 allows us to calculate the difference in potential between any two points in the field. If we choose the potential V_1 at point 1 to be zero, then Eq. 25-16 becomes

$$V = -\int_1^2 \vec{E} \cdot d\vec{s} \quad (\text{for } V_1 = 0), \quad (25-17)$$

where we have dropped the subscript 2 on V_2 . Equation 25-17 gives us the potential V at any point 2 in the electric field *relative to the zero potential* at point 1. If we let point 1 be at infinity, then Eq. 25-17 gives us the potential V at any point 2 relative to the zero potential at infinity.

READING EXERCISE 25-4: The figure shows a family of parallel equipotential surfaces (in cross section) and five paths along which we shall move an electron from one surface to another. (a) What is the direction of the electric field associated with the surfaces? (b) For each path, is the work we do positive, negative, or zero? (c) Rank the paths according to the work we do, greatest first.

TOUCHSTONE EXAMPLE 25-2: Finding the Potential Difference

(a) Figure 25-10a shows two points 1 and 2 in a uniform electric field \vec{E} . The points lie on the same electric field line (not shown) and are separated by a distance d . Find the potential difference $V_2 - V_1$ by moving a positive test charge q_t from 1 to 2 along the path shown, which is parallel to the field direction.

FIGURE 25-10 (a) A test charge q_t moves in a straight line from point 1 to point 2, along the direction of a uniform electric field. (b) Charge q_t moves along path 1-3-2 in the same electric field.

SOLUTION ■ The **Key Idea** here is that we can find the potential difference between any two points in an electric field by integrating $\vec{E} \cdot d\vec{s}$ along a path connecting those two points according to Eq. 25-16. We do this by mentally moving a test charge q_t along that path, from initial point 1 to final point 2. As we move such a test charge along the path in Fig. 25-10a, its differential displacement $d\vec{s}$ always has the same direction as \vec{E} . Thus, the angle ϕ between \vec{E} and $d\vec{s}$ is zero and the dot product in Eq. 25-16 is

$$\vec{E} \cdot d\vec{s} = |\vec{E}| |d\vec{s}| \cos \phi = |\vec{E}| |d\vec{s}|. \quad (25-18)$$

Equations 25-16 and 25-18 then give us

$$V_2 - V_1 = -\int_1^2 \vec{E} \cdot d\vec{s} = -\int_1^2 |\vec{E}| |d\vec{s}|. \quad (25-19)$$

Since the field is uniform, E is constant over the path and can be moved outside the integral, giving us

$$V_2 - V_1 = -|\vec{E}| \int_1^2 |d\vec{s}| = -|\vec{E}| |d|,$$

in which the integral is simply the length d of the path. The minus sign in the result shows that the potential at point 2 in Fig. 25-10a is lower than the potential at point 1. This is a general result: The potential always decreases along a path that extends in the direction of the electric field lines.

(b) Now find the potential difference $V_2 - V_1$ by moving the positive test charge q_t from 1 to 2 along the path 1-3-2 shown in Fig. 25-10b.

SOLUTION ■ The **Key Idea** of (a) applies here too, except now we move the test charge along a path that consists of two lines: 1-3 and 3-2. At all points along line 1-3, the displacement $d\vec{s}$ of the test charge is perpendicular to \vec{E} . Thus, the angle ϕ between \vec{E} and $d\vec{s}$ is 90° , and the dot product $\vec{E} \cdot d\vec{s}$ is 0. Equation 25-16 then tells us that points 1 and 3 are at the same potential: $V_3 - V_1 = 0$.

For line 3-2 we have $\phi = 45^\circ$ and, from Eq. 25-16,

$$\begin{aligned} V_2 - V_1 = V_2 - V_3 &= -\int_3^2 \vec{E} \cdot d\vec{s} = -\int_3^2 |\vec{E}|(\cos 45^\circ) |d\vec{s}| \\ &= -|\vec{E}|(\cos 45^\circ) \int_3^2 |d\vec{s}|. \end{aligned}$$

The integral in this equation is just the length of line 3-2; from Fig. 25-10b, that length is $d/\sin 45^\circ$. Thus,

$$V_2 - V_1 = -|\vec{E}|(\cos 45^\circ) \frac{|d|}{\sin 45^\circ} = -|\vec{E}||d|. \quad (\text{Answer})$$

This is the same result we obtained in (a), as it must be; the potential difference between two points does not depend on the path connecting them. Moral: When you want to find the potential difference between two points by moving a test charge between them, you can save time and work by choosing a path that simplifies the use of Eq. 25-16.

25-6 Potential Due to a Point Charge

Imagine a single point charge in space. What would the value of the potential be at a distance of 3 m away from the charge? Consider a point P at a distance R from a fixed particle of positive charge q as in Fig. 25-11. To use Eq. 25-16,

$$V_2 - V_1 = -\int_1^2 \vec{E} \cdot d\vec{s},$$

we imagine that we move a positive test charge q_t from infinity to its final location at point P . We need to bring our test charge from infinity to a point P that is a distance R from the source charge. Because the path we choose will not change our final result, we are free to choose it. Mathematically, the simplest path between infinity and point P involves traveling along the same line that the electric field vectors lie along so no nonradial vector components of the electric field have to be considered.

We must then evaluate the dot product

$$\vec{E} \cdot d\vec{s} = |\vec{E}| \cos \phi |d\vec{s}| = (E)(ds) \cos \phi. \quad (25-20)$$

The electric field \vec{E} in Fig. 25-11 is directed radially outward from the fixed particle. So the differential displacement $d\vec{s}$ of the test particle along our chosen path is radially inward and has the opposite direction as \vec{E} . That means that the angle $\phi = 180^\circ$ and $\cos \phi = -1$. Because the path is radial, let us write ds as dr . Then, substituting the limits ∞ and R , we can write Eq. 25-16,

$$V_2 - V_1 = -\int_1^2 \vec{E} \cdot d\vec{s},$$

as
$$V_2 - V_1 = -\int_\infty^R E_r dr, \quad (25-21)$$

where E_r is the component of the electric field in the radial direction. Next we set $V_1 = 0$ (at ∞) and $V_2 = V$ (at R). Then, for the magnitude of the electric field at the site of the test charge, we substitute from Chapter 23:

$$E = k \frac{|q|}{r^2}. \quad (25-22)$$

FIGURE 25-11 ■ The positive point charge q produces an electric field \vec{E} and an electric potential ΔV at point P . We find the potential by moving a test charge q_t from its initial location at infinity to a point P . The test charge is shown at distance r from the point charge undergoing differential displacement $d\vec{s}$.

With these changes, Eq. 25-21 then gives us

$$\begin{aligned} V - 0 &= -k|q| \int_{\infty}^R \frac{1}{r^2} dr = k|q| \left[\frac{1}{r} \right]_{\infty}^R \\ &= k \frac{|q|}{R} \quad (\text{for positive } q). \end{aligned} \quad (25-23)$$

We want to generalize finding the potential relative to infinity for any distance, not just distance R . So, switching from R to r , we have an expression for potential at a distance r from a source charge of

$$V = k \frac{|q|}{r} \quad (\text{for positive } q).$$

Although we have derived this expression above for a positively charged particle, the derivation also holds for a negatively charged particle as well. However, if q in Fig. 25-11 were a negative charge, the electric field vectors would point in the same direction as the path (radially inward). Thus, the differential displacement $d\vec{s}$ of the test particle along our chosen path has the same direction as \vec{E} . That means the angle $\phi = 0^\circ$ and so $\cos \phi = +1$. This introduces a negative sign that remains throughout the derivation and results in a negative final result for the potential. So, we conclude that *the sign of V is the same as the sign of q* . This gives us

$$V = k \frac{q}{r} \quad (\text{relative to infinity for either sign of charge}), \quad (25-24)$$

as the electric potential V relative to infinity due to a particle of charge q at any radial distance r from the particle.

A positively charged particle produces a positive electric potential. A negatively charged particle produces a negative electric potential.

Figure 25-12 shows a computer-generated plot of Eq. 25-24 for a positively charged particle; the magnitude of V is plotted vertically. Note that the magnitude increases as $r \rightarrow 0$. In fact, according to the expression above, V is infinite at $r = 0$, although Fig. 25-12 shows a finite, smoothed-off value there.

Equation 25-24 also gives the electric potential *outside or on the external surface of a spherically symmetric charge distribution*. We can prove this by using an

FIGURE 25-12 (a) A computer-generated plot of the electric potential $V(r)$ due to a positive point charge located at the origin of an x - y plane. The potentials at points in that plane are plotted vertically. (Curved lines have been added to help you visualize the plot.) The infinite value of V predicted by Eq. 25-24 for $r = 0$ is not plotted. (b) The same plot of electric potential is shown for a negative charge.

electrostatic analogy to the shell theorem we found so useful in our study of gravitation (Section 14-2). This theorem allows us to replace the actual spherical charge distribution with an equal charge concentrated at its center. Then the derivation leading to Eq. 25-24 follows, provided we do not consider a point within the actual distribution.

TOUCHSTONE EXAMPLE 25-3: Near a Proton

The nucleus of a hydrogen atom consists of a single proton, which can be treated as a particle (or point charge).

(a) With the electric potential equal to zero at infinite distance, what is the electric potential V due to the proton at a radial distance $r = 2.12 \times 10^{-10}$ m from it?

SOLUTION ■ The **Key Idea** here is that, because we can treat the proton as a particle, the electric potential V it produces at distance r is given by Eq. 25-24,

$$V = k \frac{q}{r}.$$

Here charge q is $e (= 1.6 \times 10^{-19}$ C). Substituting this and the given value for r , we find

$$\begin{aligned} V &= \frac{(8.99 \times 10^9 \text{ N} \cdot \text{m}^2/\text{C}^2)(1.60 \times 10^{-19} \text{ C})}{2.12 \times 10^{-10} \text{ m}} \\ &= 6.78 \text{ V}. \end{aligned} \quad (\text{Answer})$$

(b) What is the electric potential energy U in electron-volts of an electron at the given distance from the nucleus? (The potential

energy is actually that of the electron–proton system—the hydrogen atom.)

SOLUTION ■ The **Key Idea** here is that when a particle of charge q is located at a point where the electric potential due to other charges is V , the electric potential energy U is given by Eq. 25-6 ($V = U/q$). Using the electron's charge $-e$, we find

$$\begin{aligned} U &= qV = (-1.60 \times 10^{-19} \text{ C})(6.78 \text{ V}) \\ &= -1.0848 \times 10^{-18} \text{ J} = -6.78 \text{ eV}. \end{aligned} \quad (\text{Answer})$$

(c) If the electron moves closer to the proton, does the electric potential energy increase or decrease?

SOLUTION ■ The **Key Ideas** of parts (a) and (b) apply here also. As the electron moves closer to the proton, the electric potential V due to the proton at the electron's position increases because r decreases). Thus, the value of V in part (b) increases. Because the electron is negatively charged, this means that the value of U becomes more negative. Hence, the potential energy U of the electron (that is, of the system or atom) decreases.

25-7 Potential and Potential Energy Due to a Group of Point Charges

Now let's consider what happens when there are lots of charges. First we will look at the case where we only move a small test charge while all the other charges remain fixed. In this case, the changes in the system's potential energy as the test charge moves lead us to the same definition of electric potential, V , as we already developed. At the end of this section we consider the situation in which many charges move and find that the total potential energy of the system changes. In this case, even though the system has a potential energy associated with it, we cannot define an electric potential.

We found in Chapter 23 that the electric field arising from a group of point charges satisfies a superposition principle. That is, the total electric field is the sum of the individual electric fields arising from each individual point charge. Since the potential V is the line integral of the electric field and the integral of a sum of terms is the sum of the integrals, the superposition principle also holds for electrostatic potential.

Hence, we use the principle of superposition to find the electric potential at a particular location due to a group of point charges. We calculate the potential resulting from the influence of each charge in the system one at a time, using Eq. 25-24 with the

sign of the charge included. Then we sum the potentials. For n charges, the net potential (measured relative to a zero at infinity) is

$$V = \sum_{i=1}^n V_i = k \sum_{i=1}^n \frac{q_i}{r_i} \quad (\text{potential due to } n \text{ point charges}). \quad (25-25)$$

Here q_i is the value of the i th charge, and r_i is the radial distance of the given point from the i th charge. The sum in Eq. 25-25 is an *algebraic sum*, not a vector sum like the sum used to calculate the electric field resulting from a group of point charges. Herein lies an important computational advantage of potential over electric field: it is a lot easier to sum several scalar quantities than to sum several vector quantities whose directions and components must be considered.

In Section 25-2, we discussed the electric potential energy of a charged particle as an electrostatic force does work on it. In that section, we assumed that the charges that produced the force were fixed in place, so that neither the force nor the corresponding electric field could be influenced by the presence of the test charge. If we consider a system with charges that move when a test charge moves around, there is no logical way to determine a charge-independent electric potential for it. The electric field will keep changing due to the presence of the test charge. But we can take a broader view and find the electric potential energy of the entire *system* of charges due to the electric field produced *by* those same charges.

We can start simply by pushing two bodies that have charges of like sign into the same vicinity. For example, imagine that we have one excess electron on the conducting shell of the Van de Graaff generator shown in Fig. 25-3 and we want to put a second electron in place. Our second electron is sprayed on the insulated belt and the generator motor does work as it forces the second electron toward the conducting shell in the presence of the first one. The first electron is no doubt relocating and acting on the second electron during the forcing process. Nonetheless, we can keep track of the work the motor does. This work is stored as electric potential energy in the two-body system (provided the kinetic energy of the bodies does not change). As we bring up a third electron we can measure the work we have to bring it up to the shell in the presence of the other two electrons, which are relocating as a result of the interactions of all three electrons. The work needed to bring the third electron to the conducting shell adds to the work needed to bring up the second electron. The total work is stored as the potential energy of the three-body system. This process of doing more work and causing the excess electrons on the shell to relocate goes on until there are billions and billions of electrons on the conducting shell. If you later release the charges but touch the shell with a conductor attached to the ground, you can recover this stored energy, in whole or in part, as the kinetic energy of the charged bodies as they rush away from each other.

We define the electric potential energy *of a system of point charges* in terms of the final locations of all the charges as follows:

The electric potential energy of a system of point charges that are not moving is equal to the work that must be done by an external agent to assemble the system one charge at a time.

We assume that the charges are stationary both in their initial infinitely distant positions and in their final assembled configuration. In equation form, the total electric potential energy of the system is given by the sum of the potential energies of all the possible pairs in the system so that

$$U = \sum_{\text{all pairs}} k \frac{q_i q_j}{|\vec{r}_i - \vec{r}_j|} \quad (\text{system potential energy of } n \text{ point charges}). \quad (25-26)$$

READING EXERCISE 25-5: So far in this chapter, we have discussed two ways to calculate the electric potential V . Describe how one would calculate the electric potential given information about the charge distribution (the magnitudes of the charges and where they are located). Describe how one would calculate the electric potential given information regarding the electric field \vec{E} .

READING EXERCISE 25-6: The figure shows three arrangements of two protons. Rank the arrangements according to the net electric potential produced at point P by the protons, greatest first.

TOUCHSTONE EXAMPLE 25-4: A Square of Charges

What is the electric potential at point P , located at the center of the square of point charges shown in Fig. 25-13a? The distance d is 1.3 m, and the charges are

$$\begin{aligned} q_1 &= +12 \text{ nC}, & q_3 &= +31 \text{ nC}, \\ q_2 &= -24 \text{ nC}, & q_4 &= +17 \text{ nC}. \end{aligned}$$

SOLUTION ■ The **Key Idea** here is that the electric potential V at P is the algebraic sum of the electric potentials contributed

FIGURE 25-13 (a) Four point charges are held fixed at the corners of a square. (b) The closed curve is a cross section, in the plane of the figure, of the equipotential surface that contains point P . (The curve is only roughly drawn.)

by the four point charges. (Because electric potential is a scalar, the orientations of the point charges do not matter.) Thus, from Eq. 25-25, we have

$$V = \sum_{i=1}^4 V_i = k \left(\frac{q_1}{r} + \frac{q_2}{r} + \frac{q_3}{r} + \frac{q_4}{r} \right).$$

The distance r is $d/\sqrt{2}$, which is 0.919 m, and the sum of the charges is

$$\begin{aligned} q_1 + q_2 + q_3 + q_4 &= (12 - 24 + 31 + 17) \times 10^{-9} \text{ C} \\ &= 36 \times 10^{-9} \text{ C}. \end{aligned}$$

$$\begin{aligned} \text{Thus, } V &= \frac{(8.99 \times 10^9 \text{ N} \cdot \text{m}^2/\text{C}^2)(36 \times 10^{-9} \text{ C})}{0.919 \text{ m}} \\ &\approx 350 \text{ V}. \end{aligned} \quad (\text{Answer})$$

Close to any of the three positive charges in Fig. 25-13a, the potential has very large positive values. Close to the single negative charge, the potential has very large negative values. Therefore, there must be points within the square that have the same intermediate potential as that at point P . The curve in Fig. 25-13b shows the intersection of the plane of the figure with the equipotential surface that contains point P . Any point along that curve has the same potential as point P .

TOUCHSTONE EXAMPLE 25-5: A Dozen Electrons

(a) In Fig. 25-14a, 12 electrons (of charge $-e$) are equally spaced and fixed around a circle of radius R . Relative to $V = 0$ at infinity, what are the electric potential and electric field at the center C of the circle due to these electrons?

SOLUTION ■ The **Key Idea** here is that the electric potential V at C is the algebraic sum of the electric potentials contributed

by all the electrons. (Because electric potential is a scalar, the orientations of the electrons do not matter.) Because the electrons all have the same negative charge $-e$ and are all the same distance R from C , Eq. 25-25 gives us

$$\Delta V = -12k \frac{e}{R}. \quad (\text{Answer}) \quad (25-27)$$

FIGURE 25-14 (a) Twelve electrons uniformly spaced around a circle. (b) Those electrons are now nonuniformly spaced along an arc of the original circle.

For the electric field at C , the **Key Idea** is that electric field is a vector quantity and thus the orientation of the electrons is important. Because of the symmetry of the arrangement in Fig. 25-14a, the electric field vector at C due to any given electron is canceled by the field vector due to the electron that is diametrically opposite it. Thus, at C ,

$$\vec{E} = 0. \quad (\text{Answer})$$

(b) If the electrons are moved along the circle until they are nonuniformly spaced over a 120° arc (Fig. 25-14b), what then is the potential at C ? How does the electric field at C change (if at all)?

SOLUTION ■ The potential is still given by Eq. 25-27, because the distance between C and each electron is unchanged and orientation is irrelevant. The electric field is no longer zero, because the arrangement is no longer symmetric. There is now a net field that is directed toward the charge distribution.

25-8 Potential Due to an Electric Dipole

Electrically neutral matter is made of equal amounts of positive and negative charges. Electric forces pull in opposite directions on those charges. Thus, an electric field can cause a small separation of the positive and negative charges in matter (called polarization). In addition, many molecules distribute their electrons throughout their volume in a nonuniform way. This results in their having more positive charge on one end and one negative charge on the other end. For example, the water molecule shown in Fig. 23-22 has a nonuniform charge distribution.

A small separation produces an electric field very similar to that of a pair of equal and opposite charges separated by a small distance. If the charges were right on top of each other, their electric fields would cancel and they would appear neutral. But if they are a bit separated, their fields don't cancel perfectly, leaving a field pattern known as an electric dipole. The electric dipole fields produced by molecules play an essential role in a large number of processes in chemistry and biology, as well as in determining the electrical properties of matter such as color and transparency.

Now let us apply Eq. 25-25,

$$V = \sum_{i=1}^n V_i = \frac{1}{4\pi\epsilon_0} \sum_{i=1}^n \frac{q_i}{r_i},$$

to an electric dipole to find the potential at an arbitrary point P in Fig. 25-15a. At P , the positive point charge (at distance $r_{(+)}$) sets up potential $V_{(+)}$ and the negative point charge (at distance $r_{(-)}$) sets up potential $V_{(-)}$. Then the net potential at P is given by Eq. 25-25 as

$$\begin{aligned} V &= \sum_{i=1}^2 V_i = V_{(+)} + V_{(-)} = \frac{1}{4\pi\epsilon_0} \left(\frac{q}{r_{(+)}} + \frac{-q}{r_{(-)}} \right) \\ &= \frac{q}{4\pi\epsilon_0} \frac{r_{(-)} - r_{(+)}}{r_{(-)}r_{(+)}}. \end{aligned} \quad (25-28)$$

Naturally occurring dipoles—such as those possessed by many molecules—are quite small, so we are usually interested only in points that are relatively far from the

FIGURE 25-15 (a) Point P is a distance r from the midpoint O of a dipole. The line OP makes an angle θ with the dipole axis. (b) If P is far from the dipole, the lines of lengths $r_{(+)}$ and $r_{(-)}$ are approximately parallel to the line of length r , and the dashed line is approximately perpendicular to the line of length $r_{(-)}$.

dipole, such that $r \gg d$, where d is the distance between the charges. Under those conditions, the approximations that follow from Fig. 25-15b are

$$r_{(-)} - r_{(+)} \approx d \cos \theta \quad \text{and} \quad r_{(-)}r_{(+)} \approx r^2.$$

If we substitute these quantities into Eq. 25-28, we can approximate V to be

$$V \approx \frac{q}{4\pi\epsilon_0} \frac{d \cos \theta}{r^2} \quad (\text{for } r \gg d).$$

Here θ is measured from the dipole axis as shown in Fig. 25-15a. We can now write V as

$$V \approx k \frac{p \cos \theta}{r^2} \quad (\text{electric dipole for } r \gg d), \quad (25-29)$$

in which $p(=qd)$ is the magnitude of the electric dipole moment \vec{p} defined in Section 23-7. The vector \vec{p} is directed along the dipole axis, from the negative to the positive charge. (Thus, θ is measured from the direction of \vec{p} .)

Induced Dipole Moment

Many molecules such as water have *permanent* electric dipole moments. In other molecules (called nonpolar molecules) and in every isolated atom, the centers of the positive and negative charges coincide (Fig. 25-16a) and thus no dipole moment is set up. However, if we place an atom or a nonpolar molecule in an external electric field, the field affects the locations of the electrons relative to the nuclei and separates the

FIGURE 25-16 (a) An atom, showing the positively charged nucleus (green) and a cloud of negatively charged electrons (gold shading). The centers of positive and negative charge coincide. (b) If the atom is placed in an external electric field \vec{E} , the electron orbits are distorted so that the centers of positive and negative charge no longer coincide. An induced dipole moment \vec{p} appears. The distortion is exaggerated here by many orders of magnitude.

centers of positive and negative charge (Fig. 25-16*b*). Because the electrons are negatively charged, they tend to be shifted in a direction opposite the field. This shift sets up a dipole moment \vec{p} pointing in the direction of the field. This dipole moment is said to be induced by the field, and the atom or molecule is then said to be polarized by the field (it has a positive side and a negative side). When the field is removed, the induced dipole moment and the polarization disappear.

READING EXERCISE 25-7: Suppose three points are set at equal (large) distances r from the center of the dipole in Fig. 25-15: Point a is on the dipole axis above the positive charge, point b is on the axis below the negative charge, and point c is on a perpendicular bisector through the line connecting the two charges. Rank the points according to the electric potential of the dipole there, greatest (most positive) first. ■

25-9 Potential Due to a Continuous Charge Distribution

When a charge distribution q is continuous (as on a uniformly charged thin rod or disk), we cannot use a summation to find the potential V at a point P . Instead, we must choose a differential element of charge dq . A differential element of charge is a very small bit of charge, small enough so we can treat it as if it were a point charge. We can then determine the potential dV at P due to dq , and then integrate over the entire charge distribution.

Let us again take the zero of potential to be at infinity. If we treat the element of charge dq as a point charge, then we can use Eq. 25-24,

$$V = k \frac{q}{r},$$

to express the potential dV at point P due to dq :

$$dV = k \frac{dq}{r} \quad (\text{positive or negative } dq). \quad (25-30)$$

Here r is the distance between P and dq . To find the total potential V at P , we integrate to sum the potentials due to all the charge elements:

$$V = \int dV = k \int \frac{dq}{r}. \quad (25-31)$$

The integral must be taken over the entire charge distribution. Note that because the electric potential is a scalar, there are *no vector components* to consider in the equation above.

We now examine a continuous charge distribution, a line of charge.

Line of Charge

In Fig. 25-17*a*, a thin, nonconducting rod of length L has a positive charge of uniform linear density λ . Let us determine the electric potential V due to the rod at point P , a perpendicular distance d from the left end of the rod.

We consider a differential element dx of the rod as shown in Fig. 25-17*b*. This (or any other) element of the rod has a differential charge of

$$dq = \lambda dx. \quad (25-32)$$

This element produces a potential dV at point P , which is a distance $r = (x^2 + d^2)^{1/2}$ from the element. Treating the element as a point charge, we can use Eq. 25-30,

$$dV = k \frac{dq}{r},$$

to write the potential dV as

$$dV = k \frac{dq}{r} = k \frac{\lambda dx}{(x^2 + d^2)^{1/2}}. \quad (25-33)$$

Since the charge on the rod is positive and we have taken $V = 0$ at infinity, we know dV in this expression must be positive.

We now find the total potential V (measured relative to a zero at infinity) produced by the rod at point P by integrating along the length of the rod, from $x = 0$ to $x = L$. We evaluate the integral using an integral table or a symbolic manipulation program like Mathcad or Maple. We then find

$$\begin{aligned} V &= \int dV = \int_0^L k \frac{\lambda}{(x^2 + d^2)^{1/2}} dx \\ &= k\lambda \int_0^L \frac{dx}{(x^2 + d^2)^{1/2}} \\ &= k\lambda [\ln(x + (x^2 + d^2)^{1/2})]_0^L \\ &= k\lambda [\ln(L + (L^2 + d^2)^{1/2}) - \ln d]. \end{aligned}$$

We can simplify this result by using the general relation $\ln A - \ln B = \ln(A/B)$. We then find

$$V = k\lambda \ln \left[\frac{L + (L^2 + d^2)^{1/2}}{d} \right]. \quad (25-34)$$

Because V is the sum of positive values of dV , it should be positive—but does this expression give a positive V ? Since the argument of the logarithm is greater than one, the logarithm is a positive number and V is indeed positive.

25-10 Calculating the Electric Field from the Potential

In Section 25-5, you saw how to find the potential at a point f if you know the electric field along a path from a reference point to point f . In this section, we propose to go the other way—that is, to find the electric field when we know the potential. As Fig. 25-8 shows, graphically finding the direction of the field is easy: If we know the potential V at all points near an assembly of charges, we can draw in a family of equipotential surfaces. The electric field lines, sketched perpendicular to those surfaces, reveal the direction of \vec{E} . What we are seeking here is the mathematical equivalent of this graphical procedure.

Figure 25-18 shows cross sections of a family of closely spaced equipotential surfaces, the potential difference between each pair of adjacent surfaces being dV . As the figure suggests, the field \vec{E} at any point P is perpendicular to the equipotential surface through P .

Suppose a positive test charge q_t moves through a displacement $d\vec{s}$ from one equipotential surface to the adjacent surface. From Eq. 25-8, we can relate the change

FIGURE 25-17 (a) A thin, uniformly charged rod produces an electric potential V at point P . (b) A differential element of charge produces a differential potential dV at P .

FIGURE 25-18 A test charge q_t undergoes a displacement $d\vec{s}$ from one equipotential surface to another. (The separation between the surfaces has been exaggerated for clarity.) The displacement $d\vec{s}$ makes an angle θ with the direction of the electric field \vec{E} .

in electric potential to the work done by the electric field on our test charge

$$\Delta V = V_2 - V_1 = -\frac{W^{\text{elec}}}{q_t}.$$

Let's consider the potential difference associated with an infinitesimally small displacement denoted by $d\vec{s}$. We see that the electric field does an infinitesimal amount of work on the test charge during the move. Using Eq. 25-8, we can denote this as $-q_t dV$. From Eq. 25-14, $dW = q_t \vec{E} \cdot d\vec{s}$, and Fig. 25-18, we see that the infinitesimal work done by the force may also be written as $(q_t \vec{E}) \cdot d\vec{s}$ or $q_t |\vec{E}| (\cos \phi) |d\vec{s}|$, where ϕ is the angle between the electric field and displacement vectors as shown in Fig. 25-18. Equating these two expressions for the work yields

$$-q_t dV = q_t |\vec{E}| (\cos \phi) |d\vec{s}|, \quad (25-35)$$

or
$$\vec{E} (\cos \phi) = -\frac{dV}{ds}. \quad (25-36)$$

Since $E_s = |\vec{E}| \cos \phi$ is the component of \vec{E} in the direction of $d\vec{s}$, the equation above becomes

$$E_s = -\frac{\partial V}{\partial s}. \quad (25-37)$$

We have added a subscript to the component of \vec{E} and switched to the partial derivative symbols to emphasize that this expression involves only the variation of ΔV along a specified axis (here called the s axis) and only the component of \vec{E} along that axis. In words, Eq. 25-37 is essentially the inverse of Eq. 25-16,

$$V_2 - V_1 = -\int_1^2 \vec{E} \cdot d\vec{s},$$

and states:

The component of \vec{E} in any direction is the negative of the rate of change of the electric potential with distance in that direction. Hence, \vec{E} points in the direction of decreasing electric potential V .

If we take the s axis to be, in turn, the x , y , and z axes, we find that the x -, y -, and z -components of \vec{E} at any point are

$$E_x = -\frac{\partial V}{\partial x}; \quad E_y = -\frac{\partial V}{\partial y}; \quad E_z = -\frac{\partial V}{\partial z}. \quad (25-38)$$

Thus, if we know V for all points in the region around a charge distribution—that is, if we know the function $V(x, y, z)$ —we can find the components of \vec{E} , and thus \vec{E} itself, at any point by taking partial derivatives. Each component of the electric field is simply the negative of the slope of the curve representing the electric potential vs. distance along each chosen axis.

For the simple situation in which the electric field \vec{E} is uniform, the equipotential surfaces are a set of parallel planes that lie perpendicularly to the direction of the electric field. In addition, for a given potential difference, the distance between any two equipotential planes is the same. So, when the component of the electric field along the direction of $d\vec{s}$ is uniform, we can rewrite Eq. 25-37 ($E_s = -\partial V/\partial s$) in terms

of the magnitude of the electric field $E = |\vec{E}|$ as

$$E = \left| \frac{\Delta V}{\Delta s} \right|, \quad (25-39)$$

where Δs is the component of displacement perpendicular to the equipotential surfaces. Equation 25-36 tells us that whenever the potential is constant along a surface so that $\Delta V = 0$, the electric field is zero. The component of the electric field is zero in any direction parallel to the equipotential surfaces. Thus, for a given potential difference ΔV , the magnitude of the electric field is given by the magnitude of the potential difference divided by the distance between any two equipotential surfaces.

READING EXERCISE 25-8: The figure shows three pairs of parallel plates with the same separation, and the electric potential of each plate. The electric field between the plates is uniform and perpendicular to the plates. (a) Rank the pairs according to the magnitude of the electric field between the plates, greatest first. (b) For which pair is the electric field pointing rightward? (c) If an electron is released midway between the third pair of plates, does it remain there, move rightward at constant speed, move leftward at constant speed, accelerate rightward, or accelerate leftward?

READING EXERCISE 25-9: In what ways is the superposition principle for energy discussed above the same as, and different from, the superposition principle for electric field? ■

TOUCHSTONE EXAMPLE 25-6: Obtaining \vec{E} from V

The electric potential at any point on the axis of a uniformly charged disk is given by

$$V = \frac{\sigma}{2\epsilon_0} (\sqrt{z^2 + R^2} - z).$$

Starting with this expression, derive an expression for the electric field at any point on the axis of the disk.

SOLUTION ■ We want the electric field \vec{E} as a function of distance z along the axis of the disk. For any value of z , the direction

of \vec{E} must be along that axis because the disk has circular symmetry about that axis. Thus, we want the component E_z of \vec{E} in the direction of z . Then the **Key Idea** is that this component is the negative of the rate of change of the electric potential with distance z . Thus, from the last of Eqs. 25-38, we can write

$$\begin{aligned} E_z &= -\frac{\partial V}{\partial z} = -\frac{\sigma}{2\epsilon_0} \frac{d}{dz} (\sqrt{z^2 + R^2} - z) \\ &= \frac{\sigma}{2\epsilon_0} \left(1 - \frac{z}{\sqrt{z^2 + R^2}} \right). \end{aligned} \quad (\text{Answer})$$

25-11 Potential of a Charged Isolated Conductor

In Section 24-8, we concluded $\vec{E} = 0$ for all points inside an electrically isolated conductor. We then used Gauss' law to prove that an excess charge placed on an isolated conductor lies entirely on its surface. (This is true even if the conductor has an empty internal cavity.) Here we use the first of these facts to prove an extension of the second:

An excess charge placed on an isolated conductor will distribute itself on the surface of that conductor so that all points of the conductor—whether on the surface or inside—come to the same potential. This is true even if the conductor has an internal cavity and even if that cavity contains a net charge.

This fact is rather obvious since any potential difference inside a conductor requires an electric field inside it. The nonzero electric field would, in turn, cause the free conduction electrons to redistribute themselves until the potential difference disappears.

The mathematical proof that an electrically isolated conductor is an equipotential region follows directly from Eq. 25-16,

$$V_2 - V_1 = - \int_1^2 \vec{E} \cdot d\vec{s}.$$

Since $\vec{E} = 0$ for all points within a conductor, it follows directly that $V_2 = V_1$ for all possible pairs of points i and f in the conductor.

A Spherical Shell with No External Electric Field

Figure 25-19a shows a plot of potential against radial distance r from the center for an isolated spherical conducting shell of 1.0 m radius, having a net excess charge of $1.0 \mu\text{C}$. In the absence of an external field, we know by symmetry the surface charges will be uniformly distributed over the surface of the shell. For points outside the shell, we can calculate $V(r)$, the electric potential. Obviously this potential also has a spherical symmetry and can be given by Eq. 25-24,

$$V = k \frac{q}{r},$$

because the total charge on the shell, denoted as q , behaves for external points as if it were concentrated at the center of the shell. That equation holds right up to the surface of the shell. Now let us push a small test charge through the shell—assuming a small hole exists—to its center. No extra work is needed to do this because no net electric force acts on the test charge once it is inside the shell. Thus, the potential at all points inside the shell has the same value as on the surface, as shown in the Fig. 25-19a graph.

The Fig. 25-19b graph shows the variation of electric field with radial distance for the same shell. Note that $\vec{E} = 0$ everywhere inside the shell. The curves of Fig. 25-19b can be derived from the curve of Fig. 25-19a by differentiating with respect to r , using Eq. 25-37 (the derivative of a constant, recall, is zero). The curve of Fig. 25-19a can be derived from the curves of Fig. 25-19b by integrating

$$E_s = - \frac{\partial V}{\partial s}.$$

The Charge Distribution on a Nonspherical Conductor

Consider a nonspherical charged conductor. Assume the conductor is electrically isolated and there is no external electric field in its vicinity. It turns out its surface charges do not distribute themselves uniformly. When compared to the uniform density of excess charge on a spherical conductor, the charges redistribute themselves so there is a higher charge density when the radius of curvature is convex and small and a lower charge density where the radius of curvature is concave and small (Fig. 25-20). Why? We can use the characteristics of equipotential surfaces to develop a qualitative explanation for this phenomenon.

FIGURE 25-19 (a) A plot of $V(r)$ both inside and outside a charged spherical shell of radius 1.0 m. (b) A plot of the electric field magnitude, $E(r)$, for the same shell.

FIGURE 25-20 The magnitude of the charge density on a conductor is greatest on a convex surface with a small radius of curvature (A) and least on a concave surface having small radius of curvature (D). The ranking of the magnitude of the charge density is $A > B > C > D$.

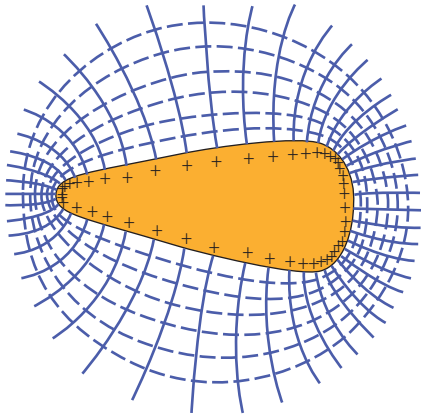

FIGURE 25-21 ■ The net positive charge on an odd-shaped isolated conductor distributes itself on the conductor's surface so the electric field generated by it is zero inside and normal to the surface elements of the conductor. This requires the equipotential surfaces (shown with dotted lines) to be closest together on the left where the conductor's convex radius of curvature is smallest. The electric field lines (shown with solid lines) and the excess charges also have the greatest density on the left where the curvature of the conductor's surface is smallest.

The explanation is as follows: There is no electric field inside the conductor, and the electric field at each point on the surface of the conductor must be normal (in other words perpendicular) to the surface. This requirement is obvious since any component of electric field parallel to the surface would cause free electrons to reconfigure themselves until all tangential components along the surface disappear. This also means the entire surface of our conductor is an equipotential surface no matter what its shape is. However, if we are far away from our charged conductor, the equipotential surfaces look more and more like those of a point charge. Thus, the family of equipotential surfaces that are each ΔV apart from the previous one become more and more spherical in shape. As the successive equipotential surfaces morph (change shape) slowly from that of our odd-shaped surface to that of a sphere, the parts of the equipotential surfaces near small-radius convex surface elements must be closer together than those elements having large radii of curvature. This is shown in Fig. 25-21. Now, equipotential surfaces more closely spaced occur where the electric field is the strongest and can do the most work on test charges, but the electric field is largest where the charge density that is its source is largest. The implication is that:

On an isolated conductor the concentration of charges and hence the strength of the electric field is greater near sharp points where the curvature is large.

An Isolated Conductor in an External Electric Field

Suppose an *uncharged* isolated conductor is placed in an *external electric field*, as in Fig. 25-22. The electric field at the conductor's surface must have the same characteristics as it does when no external field is present. However, this doesn't mean its charges will be distributed in the same way as if no external electric field were present. All points of the conductor still come to a single potential regardless of whether the conductor is electrically neutral or has an excess charge. The free conduction electrons distribute themselves on the surface in such a way that the electric field they produce at interior points cancels the external electric field that would otherwise be there. Furthermore, the electron distribution causes the net electric field at all points on the surface to be normal to the surface. If the conductor in Fig. 25-22 could somehow be removed, leaving the surface charges frozen in place, the pattern of the electric field would remain absolutely unchanged for both exterior and interior points.

One common natural source of an external electric field that can affect isolated metal objects are excess negative charges at the bases of clouds contributing to the onset of thunderstorms. Such an external electric field can cause charge separation in conducting objects at the Earth's surface such as golf clubs and rock hammers. Since

FIGURE 25-22 ■ An uncharged conductor is suspended in an external electric field. The free electrons in the conductor distribute themselves on the surface as shown, so as to reduce the net electric field inside the conductor to zero and make the net field outside normal to each surface element.

FIGURE 25-23 ■ This enhanced photograph shows the result of an overhead cloud system creating a strong electric field \vec{E} near a woman's head. Many of the hair strands extended along the field, which was perpendicular to the equipotential surfaces and greatest where those surfaces were closest, near the top of her head.

these objects have points where the curvature is high, the surface charge density—and thus the external electric field, which is proportional to it—may reach very high values. The air around sharp points may become ionized, producing the corona discharge that golfers and mountaineers see on their tools when thunderstorms threaten. Such corona discharges, like hair that stands on end, are often the precursors of lightning strikes.

The cells and blood inside a human body contain salt water that acts as a conductor. The natural oil found on hair is also conductive. A person placed in a strong electric field can act like an uncharged conductor. For example, the woman shown in Fig. 25-23 was standing on a platform connected to the mountainside, and was at about the same potential as the mountainside. Overhead, a cloud system that had a high degree of charge separation with excess negative charges at its base moved in and created a strong electric field around her and the mountainside. Electrostatic forces due to this field drove some of the conduction electrons in the woman downward through her body, leaving her head and strands of her hair positively charged. The magnitude of this electric field was apparently large, but less than the value of about 3×10^6 V/m needed to cause electrical breakdown of the air molecules. (That value was exceeded when lightning struck the platform shortly after the picture was taken.)

As we just discussed, the surface charges on a nonspherical conductor concentrate in regions where the curvature is greatest. Thus, we expect the electric field to be greatest near the top of the woman's head—an equipotential surface. This suspicion is confirmed because the strands of her hair, containing excess positive charge, are pulled out most strongly where her head has the most curvature. Also, the strands of hair are extended along the direction of \vec{E} perpendicular to her head. Since the magnitude of \vec{E} was greatest just above her head, this is where the equipotential surfaces were most closely spaced. A sketch showing this close spacing is shown in Fig. 25-23.

The lesson here is simple. If an electric field causes the hairs on your head to stand up, you'd better run for shelter rather than pose for a snapshot.

What If Lightning Might Strike?

Speaking of lightning, what is the best way to protect yourself if lightning strikes? There are two ways to protect yourself using your knowledge of how conductors behave in electric fields. One is to enclose yourself in a relatively spherical conducting shell. The other is to use a lightning rod.

Using a Spherical Shell: If you enclose yourself inside a more or less spherical cavity, the electric field inside the cavity is guaranteed to be zero. A car (unless it is a convertible) is almost ideal (Fig. 25-24) because it protects the passengers from the effects of lightning for the same reason that the Faraday cage shown in Chapter 24 protects the demonstrator from the high voltage caused by the transfer of charge to the cage by a Van de Graaff generator.

Using a Lightning Rod: If you live in an area where thunderstorms are common, you can embed the base of a tall metal lightning rod in the ground. Recall that the bottoms of thunderclouds have an excess of negative charge that creates strong electric fields at the Earth's surface. What happens if a conducting rod, like the Eiffel Tower, has a sharp point *and* is taller than its immediate surroundings? A couple of factors come into play. First, the distance $|\Delta s|$ between the cloud bases and the top of a lightning rod is smaller than the distance to the ground, even though the electric field strength near the top of a tall rod is not really uniform. Equation 25-39 ($E = |\Delta V/\Delta s|$) tells us that the magnitude of the electric field between the cloud bases and the top of the rod is greater than that between the clouds and the ground. Second, as we discussed earlier in this section the magnitude of the electric field near a conductor that has a sharp point is quite strong compared to that on level

FIGURE 25-24 ■ A large spark jumps to a car's body and then exits by moving across the insulating left front tire, leaving the person inside unharmed because the electric potential difference remains zero inside the car.

ground. This means that the free electrons at the top of a lightning rod (such as the Eiffel Tower) will move toward the ground leaving a large accumulation of positive metal ions at the sharp point at the top of the tower. The tip of the rod will attract electrons from the atmosphere to it and down to the ground in a corona discharge process that can serve to prevent a major discharge or lightning strike in the vicinity of the tower. Lightning is shown hitting the Eiffel Tower in Fig. 25-25.

READING EXERCISE 25-10: The figure below shows the region in the neighborhood of a negatively charged conducting sphere and a large positively charged conducting plate extending far beyond the region shown. Someone claims lines *A* through *F* are possible field lines describing the electric field lying in the region between the two conductors. (a) Examine each of the lines and indicate whether it is a correctly drawn field line. If a line is not correct, explain why. (b) Redraw the diagram with a pattern of field lines that is more nearly correct. (Based on Arnold Arons' *Homework and Test Questions*, Wiley, New York, 1994.)

READING EXERCISE 25-11: Why are the equipotential surfaces shown in Fig. 25-23 closer together just above the woman's head than they are at the side of her head? ■

FIGURE 25-25 ■ In this historic 1902 postcard photo, bolts of lightning are shown converging at the top of the Eiffel Tower. The tower is acting as a “lightning rod” protecting people, trees, and other buildings from being struck by lightning.

Problems

SEC. 25-3 ■ ELECTRIC POTENTIAL

1. Car Battery A particular 12 V car battery can send a total charge of 3.0×10^5 C through a circuit, from one terminal to the other. (a) How many coulombs of charge does this represent? (b) If this entire charge undergoes a potential difference of 12 V, how much energy is involved?

2. Ground and Cloud The electric potential difference between the ground and a cloud in a particular thunderstorm is 1.2×10^9 V. What is the magnitude of the change in the electric potential energy (in multiples of the electron-volt) of an electron that moves between the ground and the cloud?

3. Lightning Flash In a given lightning flash, the potential difference between a cloud and the ground is 1.0×10^9 V and the quantity of charge transferred is 30 C. (a) What is the decrease in energy of that transferred charge. (b) If all that energy could be used to accelerate a 1000 kg automobile from rest, what would be the automobile's final speed? (c) If the energy could be used to melt ice, how much ice would it melt at 0°C ? The heat of fusion of ice is 3.33×10^5 J/kg.

SEC. 25-5 ■ CALCULATING THE POTENTIAL FROM AN *E*-FIELD

4. From *A* to *B* When an electron moves from *A* to *B* along an electric field line in Fig. 25-26, the electric field does $3.94 \times$

10^{-19} J of work on it. What are the electric potential differences (a) $V_B - V_A$, (b) $V_C - V_A$, and (c) $V_C - V_B$?

5. Infinite Sheet An infinite non-conducting sheet has a surface charge density $\sigma = 0.10 \mu\text{C}/\text{m}^2$ on one side. How far apart are equipotential surfaces whose potentials differ by 50 V?

6. Parallel Plates Two large, parallel, conducting plates are 12 cm apart and have charges of equal magnitude and opposite sign on their facing surfaces. An electrostatic force of 3.9×10^{-15} N acts on an electron placed anywhere between the two plates. (Neglect fringing.) (a) Find the electric field at the position of the electron. (b) What is the potential difference between the plates?

7. Geiger Counter A Geiger counter has a metal cylinder 2.00 cm in diameter along whose axis is stretched a wire 1.30×10^{-4} cm in diameter. If the potential difference between the wire and the cylinder is 850 V, what is the electric field at the surface of (a) the wire and (b) the cylinder? (*Hint*: Use the result of Problem 30 of Chapter 24.)

FIGURE 25-26 ■ Problem 4.

8. Field Inside The electric field inside a nonconducting sphere of radius R , with charge spread uniformly throughout its volume, is radially directed and has magnitude

$$E(r) = |\vec{E}(r)| = \frac{|q|r}{4\pi\epsilon_0 R^3}.$$

Here q (positive or negative) is the total charge within the sphere, and r is the distance from the sphere's center. (a) Taking $V = 0$ at the center of the sphere, find the electric potential $V(r)$ inside the sphere. (b) What is the difference in electric potential between a point on the surface and the sphere's center? (c) If q is positive, which of those two points is at the higher potential?

9. Uniformly Distributed A charge q is distributed uniformly throughout a spherical volume of radius R . (a) Setting $V = 0$ at infinity, show that the potential at a distance r from the center, where $r < R$, is given by

$$V = \frac{q(3R^2 - r^2)}{8\pi\epsilon_0 R^3}.$$

(Hint: See Section 24-6.) (b) Why does this result differ from that in (a) of Problem 8? (c) What is the potential difference between a point on the surface and the sphere's center? (d) Why doesn't this result differ from that of (b) of Problem 8?

10. Infinite Sheet Two Figure 25-27 shows, edge-on, an infinite nonconducting sheet with positive surface charge density σ on one side. (a) Use Eq. 25-16 and Eq. 24-16 to show that the electric potential of an infinite sheet of charge can be written $V = V_0 - (\sigma/2\epsilon_0)z$, where V_0 is the electric potential at the surface of the sheet and z is the perpendicular distance from the sheet. (b) How much work is done by the electric field of the sheet as a small positive test charge q_0 is moved from an initial position on the sheet to a final position located a distance z from the sheet?

FIGURE 25-27 Problem 10.

11. Thick Spherical Shell A thick spherical shell of charge Q and uniform volume charge density ρ is bounded by radii r_1 and r_2 , where $r_2 > r_1$. With $V = 0$ at infinity, find the electric potential ΔV as a function of the distance r from the center of the distribution, considering the regions (a) $r > r_2$, (b) $r_2 > r > r_1$, and (c) $r < r_1$. (d) Do these solutions agree at $r = r_2$ and $r = r_1$? (Hint: See Section 24-6.)

SEC. 25-7 ■ POTENTIAL AND POTENTIAL ENERGY DUE TO A GROUP OF POINT CHARGES

12. Space Shuttle As a space shuttle moves through the dilute ionized gas of Earth's ionosphere, its potential is typically changed by -1.0 V during one revolution. By assuming that the shuttle is a sphere of radius 10 m, estimate the amount of charge it collects.

13. Diametrically Opposite Consider a point charge $q = 1.0 \mu\text{C}$, point A at distance $d_1 = 2.0$ m from q , and point B at distance $d_2 = 1.0$ m. (a) If these points are diametrically opposite each other, as in

Fig. 25-28a, what is the electric potential difference $V_A - V_B$? (b) What is that electric potential difference if points A and B are located as in Fig. 25-28b?

FIGURE 25-28 Problem 13.

14. Field Lines and Equipotentials

Figure 25-29 shows two charged particles on an axis. Sketch the electric field lines and the equipotential surfaces in the plane of the page for (a) $q_1 = +q$ and $q_2 = +2q$ and (b) $q_1 = +q$ and $q_2 = -3q$.

FIGURE 25-29 Problems 14, 15, 16.

15. In Terms of d In Fig. 25-29, set $V = 0$ at infinity and let the particles have charges $q_1 = +q$ and $q_2 = -3q$. Then locate (in terms of the separation distance d) any point on the x axis (other than at infinity) at which the net potential due to the two particles is zero.

16. E-Field Is Zero Two particles, of charges q_1 and q_2 , are separated by distance d in Fig. 25-29. The net electric field of the particles is zero at $x = d/4$. With $V = 0$ at infinity, locate (in terms of d) any point on the x axis (other than at infinity) at which the electric potential due to the two particles is zero.

17. Spherical Drop of Water A spherical drop of water carrying a charge of 30 pC has a potential of 500 V at its surface (with $V = 0$ at infinity). (a) What is the radius of the drop? (b) If two such drops of the same charge and radius combine to form a single spherical drop, what is the potential at the surface of the new drop?

18. Charge and Charge Density What are (a) the charge and (b) the charge density on the surface of a conducting sphere of radius 0.15 m whose potential is 200 V (with $V = 0$ at infinity)?

19. Field Near Earth An electric field of approximately 100 V/m is often observed near the surface of Earth. If this were the field over the entire surface, what would be the electric potential of a point on the surface? (Set $V = 0$ at infinity.)

20. Center of Rectangle

In Fig. 25-30, point P is at the center of the rectangle. With $V = 0$ at infinity, what is the net electric potential at P due to the six charged particles?

FIGURE 25-30 Problem 20.

21. Potential at P In Fig. 25-31, what is the net potential at point P due to the four point charges, if $V = 0$ at infinity?

22. Potential Energy (a) What is the electric potential energy of two electrons separated by 2.00 nm? (b) If the separation increases,

does the potential energy increase or decrease?

23. Work Required Derive an expression for the work required to set up the four-charge configuration of Fig. 25-32, assuming the charges are initially infinitely far apart.

24. Electric Potential Energy What is the electric potential energy of the charge configuration of Fig. 25-13a? Use the numerical values provided in Touchstone Example 25-4.

25. The Rectangle In the rectangle of Fig. 25-33, the sides have lengths 5.0 cm and 15 cm, $q_1 = -5.0 \mu\text{C}$, and $q_2 = +2.0 \mu\text{C}$. With $V = 0$ at infinity, what are the electric potentials (a) at corner A and (b) at corner B ? (c) How much work is required to move a third charge $q_3 = +3.0 \mu\text{C}$ from B to A along a diagonal of the rectangle? (d) Does this work increase or decrease the electric energy of the three-charge system? Is more, less, or the same work required if q_3 is moved along paths that are (e) inside the rectangle but not on a diagonal and (f) outside the rectangle?

26. How Much Work In Fig. 25-34, how much work is required to bring the charge of $+5q$ in from infinity along the dashed line and place it as shown near the two fixed charges $+4q$ and $-2q$? Take distance $d = 1.40$ cm and charge $q = 1.6 \times 10^{-19}$ C.

27. A Particle of Positive Charge A particle of positive charge Q is fixed at point P . A second particle of mass m and negative charge $-q$ moves at constant speed in a circle of radius r_1 , centered at P . Derive an expression for the work W that must be done by an external agent on the second particle to increase the radius of the circle of motion to r_2 .

28. How Much Energy Calculate (a) the electric potential established by the nucleus of a hydrogen atom at the average distance ($r = 5.29 \times 10^{-11}$ m) of the atom's electron (take $V = 0$ at infinite distance), (b) the electric potential energy of the atom when the electron is at this radius, and (c) the kinetic energy of the electron, assuming it to be moving in a circular orbit of this radius centered on the nucleus. (d) How much energy is required to ionize the hydrogen atom (that is, to remove the electron from the nucleus so that the separation is effectively infinite)? Express all energies in electron-volts.

29. Fixed at Point P A particle of charge q is fixed at point P , and a second particle of mass m and the same charge q is initially held a distance r_1 from P . The second particle is then released. Determine

FIGURE 25-31 Problem 21.

FIGURE 25-32 Problem 23.

FIGURE 25-33 Problem 25.

FIGURE 25-34 Problem 26.

its speed when it is distance r_2 from P . Let $q = 3.1 \mu\text{C}$, $m = 20$ mg, $r_1 = 0.90$ mm, and $r_2 = 2.5$ mm.

30. Thin Plastic Ring A charge of -9.0 nC is uniformly distributed around a thin plastic ring of radius 1.5 m that lies in the yz plane with its center at the origin. A point charge of -6.0 pC is located on the x axis at $x = 3.0$ m. Calculate the work done on the point charge by an external force to move the point charge to the origin.

31. Tiny Metal Spheres Two tiny metal spheres A and B of mass $m_A = 5.00$ g and $m_B = 10.0$ g have equal positive charges $q = 5.00 \mu\text{C}$. The spheres are connected by a massless nonconducting string of length $d = 1.00$ m, which is much greater than the radii of the spheres. (a) What is the electric potential energy of the system? (b) Suppose you cut the string. At that instant, what is the acceleration of each sphere? (c) A long time after you cut the string, what is the speed of each sphere?

32. Conducting Shell on Support A thin, spherical, conducting shell of radius R is mounted on an isolating support and charged to a potential of $-V$. An electron is then fired from point P at distance r from the center of the shell ($r \gg R$) with initial speed v_1 and directly toward the shell's center. What value of v_1 is needed for the electron to just reach the shell before reversing direction?

33. Two Electrons Two electrons are fixed 2.0 cm apart. Another electron is shot from infinity and stops midway between the two. What is its initial speed?

34. Charged, Parallel Surfaces Two charged, parallel, flat conducting surfaces are spaced $d = 1.00$ cm apart and produce a potential difference $\Delta V = 625$ V between them. An electron is projected from one surface directly toward the second. What is the initial speed of the electron if it stops just at the second surface?

35. An Electron Is Projected An electron is projected with an initial speed of 3.2×10^5 m/s directly toward a proton that is fixed in place. If the electron is initially a great distance from the proton, at what distance from the proton is the speed of the electron instantaneously equal to twice the initial value?

SEC. 25-8 ■ POTENTIAL DUE TO AN ELECTRIC DIPOLE

36. Ammonia The ammonia molecule NH_3 has a permanent electric dipole moment equal to 1.47 D, where $1 \text{ D} = 1$ debye unit $= 3.34 \times 10^{-30}$ C · m. Calculate the electric potential due to an ammonia molecule at a point 52.0 nm away along the axis of the dipole. (Set $V = 0$ at infinity.)

37. Three Particles Figure 25-35 shows three charged particles located on a horizontal axis. For points (such as P) on the axis with $r \gg d$, show that the electric potential $V(r)$ is given by

$$V(r) = \frac{kq}{r} \left(1 + \frac{2d}{r} \right).$$

FIGURE 25-35 Problem 37.

(Hint: The charge configuration can be viewed as the sum of an isolated charge and a dipole.)

SEC. 25-9 ■ POTENTIAL DUE TO A CONTINUOUS CHARGE DISTRIBUTION

38. Plastic Rod (a) Figure 25-36a shows a positively charged plastic rod of length L and uniform linear charge density λ . Setting $V = 0$ at infinity and considering Fig. 25-17 and Eq. 25-34, find the electric potential at point P without written calculation. (b) Figure 25-36b shows an identical rod, except that it is split in half and the right half is negatively charged; the left and right halves have the same magnitude λ of uniform linear charge density. With V still zero at infinity, what is the electric potential at point P in Fig. 25-36b?

FIGURE 25-36 ■ Problem 38.

39. Nonlinear Charge Density The plastic rod shown in Fig. 25-37 has length L and a nonuniform linear charge density $\lambda = cx$, where c is a positive constant. With $V = 0$ at infinity, find the electric potential at point P_1 on the axis, at distance d from one end.

FIGURE 25-37 ■ Problems 39, 40, 44, 45.

40. Rod of Length L Figure 25-37 shows a plastic rod of length L and uniform positive charge Q lying on an x axis. With $V = 0$ at infinity, find the electric potential at point P_1 on the axis, at distance d from one end of the rod.

SEC. 25-10 ■ CALCULATING THE ELECTRIC FIELD FROM THE POTENTIAL

41. Points in the xy Plane The electric potential at points in an xy plane is given by $V = (2.0 \text{ V/m}^2)x^2 - (3.0 \text{ V/m}^2)y^2$. What are the magnitude and direction of the electric field at the point (3.0 m, 2.0 m)?

42. Parallel Metal Plates Two large parallel metal plates are 1.5 cm apart and have equal but opposite charges on their facing surfaces. Take the potential of the negative plate to be zero. If the potential halfway between the plates is then +5.0 V, what is the electric field in the region between the plates?

43. Show That (a) Using Eq. 25-31, show that the electric potential at a point on the central axis of a thin ring of charge of radius R and a distance z from the ring is

$$V = \frac{kq}{\sqrt{z^2 + R^2}}.$$

(b) From this result, derive an expression for the E -field magnitude

$|\vec{E}| = E$ at points on the ring's axis; compare your result with the calculation of E in Section 23-7

44. Why Not The plastic rod of length L in Fig. 25-37 has the nonuniform linear charge density $\lambda = cx$, where c is a positive constant. (a) With $V = 0$ at infinity, find the electric potential at point P_2 on the y axis, a distance y from one end of the rod. (b) From that result, find the electric field component E_y at P_2 . (c) Why cannot the field component E_x at P_2 be found using the result of (a)?

45. Find Component (a) Use the result of Problem 39 to find the electric field component E_x at point P_1 in Fig. 25-37 (*Hint*: First substitute the variable x for the distance d in the result.) (b) Use symmetry to determine the electric field component E_y at P_1 .

SEC. 25-11 ■ POTENTIAL OF A CHARGED ISOLATED CONDUCTOR

46. Hollow Metal Sphere An empty hollow metal sphere has a potential of +400 V with respect to ground (defined to be at $V = 0$) and has a charge of 5.0×10^{-9} C. Find the electric potential at the center of the sphere.

47. Excess Charge What is the excess charge on a conducting sphere of radius $r = 0.15$ m if the potential of the sphere is 1500 V and $V = 0$ at infinity?

48. Widely Separated Consider two widely separated conducting spheres, 1 and 2, the second having twice the diameter of the first. The smaller sphere initially has a positive charge q , and the larger one is initially uncharged. You now connect the spheres with a long thin wire. (a) How are the final potentials V_1 and V_2 of the spheres related? (b) What are the final charges q_1 and q_2 on the spheres, in terms of q ? (c) What is the ratio of the final surface charge density of sphere 1 to that of sphere 2?

49. Two Metal Spheres Two metal spheres, each of radius 3.0 cm, have a center-to-center separation of 2.0 m. One has a charge of $+1.0 \times 10^{-8}$ C; the other has a charge of -3.0×10^{-8} C. Assume that the separation is large enough relative to the size of the spheres to permit us to consider the charge on each to be uniformly distributed (the spheres do not affect each other). With $V = 0$ at infinity, calculate (a) the potential at the point halfway between their centers and (b) the potential of each sphere.

50. Charged Metal Sphere A charged metal sphere of radius 15 cm has a net charge of 3.0×10^{-8} C. (a) What is the electric field at the sphere's surface? (b) If $V = 0$ at infinity, what is the electric potential at the sphere's surface? (c) At what distance from the sphere's surface has the electric potential decreased by 500 V?

51. Surface Charge Density (a) If Earth had a net surface charge density of 1.0 electron per square meter (a very artificial assumption), what would its potential be? (Set $V = 0$ at infinity.) (b) What would be the electric field due to the Earth just outside its surface?

52. Concentric Spheres Two thin, isolated, concentric conducting spheres of radii R_1 and R_2 (with $R_1 < R_2$) have charges q_1 and q_2 . With $V = 0$ at infinity, derive expressions for the electric field magnitude $E(r)$ and the electric potential $V(r)$, where r is the distance from the center of the spheres. Plot $E(r)$ and $V(r)$ from $r = 0$ to $r = 4.0$ m for $R_1 = 0.50$ m, $R_2 = 1.0$ m, $q_1 = +2.0 \mu\text{C}$, and $q_2 = +1.0 \mu\text{C}$.

Additional Problems

53. Work Done Consider a charge $q = -2.0 \mu\text{C}$ that moves from A to B or C to D along the paths shown in Fig. 25-38. This charge is moving in the presence of a uniform electric field of magnitude $E = 100 \text{ N/C}$.

FIGURE 25-38 ■ Problem 53.

(a) What is the total work done on the charge if the distance between A and B is 0.62 m ?

(b) What is the total work done on the charge if the distance between C and D is 0.58 m ?

54. Orienteering an Electric Potential. (a) Figure 25-39 shows a contour plot of part of a range of hills in Virginia. The outer part of the figure is at sea level (marked 0). Each contour line from the region marked 0 shows a level 10 m higher than the previous line. The maximum height is 70 m and is shown by the number 70.

Answer the following questions by giving the pair of grid markers (a letter and a number) closest to the point being requested.

- i. Where is there a steep cliff?
- ii. Where is there a pass between two hills?
- iii. Where is the easiest climb up the hill?

(b) Now suppose the figure represents a plot of the electric equipotentials for the surface of a glass plate, and the numbers now represent voltage. The maximum is 70 V and each contour line from the region marked 0 shows a level 10 V higher than the previous line.

- i. Where would a test charge placed on the glass feel the strongest electric force? In what direction would the force point?
- ii. Is there a place on the glass where a charge could be placed so it feels no electric force? Where?

FIGURE 25-39 ■ Problem 54.

26

Current and Resistance

When the zeppelin *Hindenburg* was built, it was the pride of Germany. Almost three football fields long, it was the largest flying machine ever built. Although the zeppelin was kept aloft by 16 cells of highly flammable hydrogen gas, it made many uneventful trans-Atlantic trips. However, on May 6, 1937, the *Hindenburg* burst into flames while landing at a U.S. naval air station in New Jersey during a rainstorm. While its handling ropes were being let down to a ground crew, ripples were sighted on the outer fabric near the rear of the ship. Seconds later, flames erupted from that region and 32 seconds after that the Hindenburg fell to the ground.

After so many successful flights of hydrogen zeppelins, why did this one burst into flames?

The answer is in this chapter.

26-1 Introduction

The interpretation of electrostatics experiments (described in Chapters 22 through 25) is that matter consists of two kinds of electrical charges, positive and negative. At least some negative charge can be moved from one object to another, leaving the first positively charged (with a deficit of negative charge) and the second negatively charged (with an excess of negative charge). Once the charges stopped moving we explored the electrostatic forces between them.

It turns out that the electrical devices we encounter most often in modern life such as computers, lights, and telephones are not purely electrostatic but involve moving charges which we will come to call *electric currents*. In addition, natural phenomena such as lightning, the flow of protons between the Earth's magnetic poles, and cosmic ray currents involve electric currents.

In this chapter we explore electric currents, or charge flow, with a primary focus on how current passes through conductors in electric circuits. We will see that the critical idea is to understand that a potential difference across a conductor causes a flow of charge (a current) through that conductor.

26-2 Batteries and Charge Flow

By the end of the 18th century, Alessandro Volta had discovered that when two metal plates were placed in contact with a moist piece of metal, they seemed to have electrical properties like those of rubbed amber and glass. To magnify this effect, Volta piled up pairs of unlike metals. When he grasped the plates (terminals) at each end of the pile with his hands, he claimed to feel electric charges move through his body on a continuous basis. Volta had invented the battery, and his experience with early batteries is an indication that there is a connection between electric charges, as discussed in Chapters 22–25, and the continuous flow of electricity created by batteries and other power sources. However, it is not obvious without further investigation that there is actually a connection between the sensation of electric flow that Volta experienced and the electric charges we believe exist based on the electrostatic observations discussed in Chapter 22.

In order to investigate this further, let's examine the results of several experiments involving a metal wire connected to oppositely charged conducting plates as shown in Fig. 26-1*a* and the same wire connected to a battery instead as shown in Fig. 26-1*b*.

Experiment 1 (Electrostatic Discharge): Suppose we use glass and amber rods that have been rubbed to transfer electrons to or from conducting plates. We can use a hanging amber or glass rod shown in Fig. 22-2 to verify that we have excess electric charge on each plate. Since it is easier to add excess electrons to a conductor than remove electrons from a conductor, the negatively charged plate will tend to have a

FIGURE 26-1 ■ (a) When a conducting wire connects two oppositely charged plates, charge flows from the negatively charged plate to the positively charged plate until both plates have the same number of excess electrons. As a result the wire becomes hot. (b) When a battery is placed between the ends of the wire instead, the wire also becomes hot, indicating that charge is also flowing.

FIGURE 26-2 ■ If there is a complete conducting loop between the two terminals of a battery, a bulb will stay lit until the battery runs down.

greater magnitude of charge. Initially the negative electrons on the left plate repel each other and spread out but cannot leave the plate. Since a positive test charge placed between the plates will be repelled from the positive plate (on the right) and attracted to the negative plate (on the left), we know there is an electric field between the plates. So, Eq. 25-17 tells us there will be a potential difference between the plates.

If we connect the two plates with a piece of thread nothing happens. But when a conducting wire is connected across the two plates, (Fig. 26-1a) we observe that excess electrons on the left-hand plate will flow to the right-hand plate until both plates have the same number of excess electrons on them. This is not surprising since we expect the repulsive forces between the electrons on the left plate to push the charges through the wire while the attractive forces on the right plate pull on the charges. If we have enough excess charge on the plates, the wire will feel hot just after the discharge and then cool down again. If the wire has a properly connected small bulb in the middle of it, the bulb will light up briefly and then go out. We conclude from these observations that charge is flowing through the wire for a short time.

Experiment 2 (Battery Current): As we mentioned in Chapter 25, a battery is capable of doing work on electric charges and increasing their potential energy. So there must be a potential difference across its terminals. If we connect a piece of thread between the terminals of a battery nothing happens. On the other hand, if we connect a wire between the terminals of a battery, we observe that the wire gets very hot and stays that way for a long time as shown in Fig. 26-1b. If we also properly connect a bulb to the middle of the wire, as shown in Fig. 26-2, the bulb stays continuously lit until the battery eventually runs down. (In the next section we discuss how to connect a bulb to a battery properly, so that it lights.)

Because, at first, the electrostatic charging in Experiment 1 has the same result as the battery in Experiment 2, we infer that the underlying electric effects are the same in both cases. The hot wires and the lighting of bulbs lead us to conclude that charge is flowing through the wires. We call this flow of charge **electric current**.

READING EXERCISE 26-1: Although you were not provided with any details, what sensations might Volta have felt that led him to believe that electric charge was flowing through his body? ■

26-3 Batteries and Electric Current

There are some additional observations that help us understand the nature of electric current. Suppose we want to use a battery and perhaps a wire to light a flashlight bulb. By fiddling around we discover that many of the possible arrangements for lighting a bulb *do not work*. For example, none of the arrangements shown in Fig. 26-3 work.

To understand why these arrangements do not work, we need to examine a flashlight bulb much more carefully. The flashlight bulb consists of a piece of thin conducting “filament” wire encapsulated in glass that has no air inside. This wire glows and so gives off light when electric current passes through it. One end of the filament wire is in contact with a conductor that surrounds the bottom part of the bulb. The other end is connected to another conductor at the bulb’s base. These conductors are separated by an insulator. A cutaway diagram of the bulb is shown in Fig. 26-4.

FIGURE 26-3 ■ Three of many arrangements of a battery and bulb and wire that do not cause the bulb to light.

FIGURE 26-4 ■ A cutaway diagram of a flashlight bulb.

After some more fiddling we discover that all of the arrangements of wires, bulb, and battery that cause the bulb to light have one thing in common. They all have a continuous, complete loop or **circuit** for current to pass from one terminal of a battery through conductors back to other terminal of the battery. In addition to the arrangement shown in Fig. 26-2, another of the many arrangements that forms a complete loop and causes a bulb to light is shown in Fig. 26-5.

When bulb filaments get old they sometimes break. In this case the circuit is incomplete and our “burned out” bulb does not light. Another requirement is that the battery must have a potential difference between its terminals. When a battery loses its potential difference after much use we refer to it as a “dead battery.”

What Is Stored in a Battery?

It is commonly (and wrongly) believed that batteries store excess charge that can be “used up” in a circuit, and that a battery is “dead” when this excess charge is used up. The fact that people often refer to “charging” and “discharging” batteries is evidence of this belief. Careful observation tells us that this idea is wrong. The excess charge a fresh alkaline flashlight battery would have to store to keep a flashlight bulb lit as long as it does is more than 20 000 coulombs. This is a hundred million times the amount of charge we can typically place on a light metal-coated ball on a string. Yet, we observe no forces between such a charged ball and a fresh battery. There are also no forces between a charged ball and the wires carrying current in a circuit.

Observations indicate that both batteries and any current-carrying wires connected to them are *electrically neutral*.

We conclude from these observations that batteries do not store charge. Batteries store energy. The energy in the battery is transformed to mechanical energy, light energy, and thermal energy as it pushes charges through wires and bulbs. Thus our observations support the idea that a battery acts as a pump that absorbs electrons at the negative terminal and releases higher potential energy electrons from the positive terminal. We discuss how chemical reactions can create a charge pump in more detail in Section 27-6.

If we connect two identical bulbs to the same battery as shown in Fig. 26-5, they shine with the same brightness. Based on this observation we conclude that the same current is passing through both bulbs.

When wires and other conducting elements such as bulbs are placed between the battery terminals to make a continuous loop or circuit, the battery acts as a pump that pushes charge carriers already available in the wires around the loop. The battery is not a source of charge and electrical elements like bulbs do not use up charge.

Figure 26-6a shows a very simplified representation of a small segment of wire made up of electrically neutral atoms. In Fig. 26-6b the ends of the wire segment are

FIGURE 26-5 ■ When two identical bulbs in holders are connected in a row to a battery, they have the same brightness as each other. We conclude that the same current is passing through both bulbs. This indicates that the battery is not a source of excess charge used up by the bulbs.

FIGURE 26-6 (a) A representation of many electrically neutral atoms in a wire. (b) A diagram that shows a potential difference across the ends of the wire so a very small fraction of the electrons surrounding atoms start moving and a few ions with missing conduction electrons are present. These ions have excess positive charge. *Note:* The neutral atoms are still present but are not shown.

connected to a battery (not shown). A few of the conduction electrons in the metal start moving, but the stationary charges, consisting of neutral atoms and ions (with missing conduction electrons) still exist in the wire. The stationary ions neutralize the moving conduction electrons. To reduce clutter, Fig. 26-6b shows the stationary ions but not the neutral atoms. In other figures in this chapter we just show moving electrons and not the stationary ions. This type of depiction can give the false impression that there is excess charge in the wire. This is not so. Conducting wires are electrically neutral.

Defining Current Mathematically

Figure 26-2 shows a complete circuit with a battery (or other power source) that maintains a constant potential difference across its terminals. In this case, charge pushed through the circuit by the battery flows through a conducting wire, and then through the filament of a bulb, which is usually a very thin wire. In order to think more carefully about the current, we need to develop a mathematical definition for current.

Figure 26-7 shows a section of a conducting loop with different cross-sectional areas in which a current has been established. If net charge dq passes through a hypothetical plane (such as a) in time dt , then the current through that plane is defined as

$$i \equiv \frac{dq}{dt} \quad (\text{definition of current}). \quad (26-1)$$

Regardless of the details of the geometry of the charge flow, we can find the net charge passing through any plane in a time interval extending from 0 to t by integration:

$$q = \int dq = \int_0^t i dt. \quad (26-2)$$

Measurements of current through various locations in a single loop circuit show that the current is the same in all parts of a circuit where there are no junctions or alternate paths for the current to take. The current or rate of charge flow is the same passing through the imaginary planes a , b , and c shown in Fig. 26-7. Indeed, the current is the same for any plane that passes completely through the conducting elements in a continuous circuit with no branches, no matter what their locations or orientations. That is, a charge carrier must pass through plane a for every charge carrier that passes through plane c .

The unit for current is called the *ampere* (A), and it can be related to the coulomb by the expression

$$1 \text{ ampere} = 1 \text{ A} = 1 \text{ coulomb/second} = 1 \text{ C/s}.$$

The Directions of Currents

How can we tell whether there are positive or negative charges moving when a current is established in electrically neutral conductors? When we place a conducting wire between the plates shown in Fig. 26-8, charge carriers flow until the plates are neutralized.

FIGURE 26-7 The current i or charge per unit time through the conductor has the same value at imaginary planes a , b , and c as long as the planes cut through the entire conductor at the points of intersection.

It is not possible for us to design an experiment based on macroscopic observations that will allow us to tell whether the charge carriers are positive or negative because the end result (neutralized plates) will be the same in either case. Early experimenters with electricity had no knowledge of atomic structure and could only use macroscopic observations of electrical effects to guide them. They assumed that charge carriers were positive. Even though we now know that negatively charged electrons are the charge carriers in conductors, for historical reasons we will stick with the assumption that the charge carriers are positive. This historical assumption makes it easier to use traditional references on electricity, and all the characteristics of circuits we will study on a macroscopic level will be exactly the same. Furthermore, this early assumption would have been correct if Benjamin Franklin had decided to designate the excess charges on rubber rods as positive and those on glass as negative instead of the other way around!

Although the charge carriers in conductors are negative, other currents, for example, protons streaming out of our Sun, create positive currents. Also charge carriers in fluids can be either positive ions (atoms with missing electrons) or negative electrons or ions (atoms with extra electrons). In fact, the movement of charge within most batteries is due to the migration of positive ions that undergo chemical reactions. Also, currents in biological systems are carried by sodium and potassium ions, which are positive charge carriers.

Current arrows show only a direction (or sense) of flow of charge carriers along the connected conductors as they bend and turn between battery terminals, not a fixed direction in space. Since current is actually a flux, which is a scalar quantity, *these current arrows do not represent vectors with magnitude and direction.*

A current arrow, although not a mathematical vector, is drawn in the direction in which positive charge carriers would move through wires and circuit elements from a higher potential to a lower (more negative) potential, even though the actual charge carriers are usually negative and move in the opposite direction.

Charge Conservation at Junctions

So far we have only considered circuits like the one shown in Fig. 26-9a, ones for which there is only one path for charge carriers to follow. Such circuits are called **series** circuits. However, it is also common to find circuits or portions of circuits in which charge carriers encounter a junction where they can take either of two (or more) paths as shown in Fig. 26-9b. We call this type of circuit a **parallel** circuit. Although we introduce the terms “series” and “parallel” here, we will focus on the quantitative evaluation of series and parallel circuits in Chapter 27.

Figure 26-9b shows the moving charge carriers splitting up at a junction and then moving in parallel. If the bulbs are *identical*, how do the currents split at junction 1?

FIGURE 26-9 ■ We use a lightbulb as an example of a circuit element. (a) A series connection involves two or more circuit elements that are connected together so that the same current that passes through one element must pass through the other element. The potential differences across the elements is the sum of the drops across each element. (b) A parallel connection requires that one terminal of each two or more elements are connected together at one point and then the other terminal of each of the elements is connected together at another point. These points of connection are called junctions. Because of the connections at the junctions the potential difference across each element is the same when the parallel network is placed in a circuit.

FIGURE 26-8 ■ No macroscopically-oriented experiment will allow us to detect whether the charge carriers in a conducting wire are (a) positive or (b) negative. So we define the current flow to be from right to left in both cases. Although stationary charges are not depicted, the conducting wires are neutral.

FIGURE 26-10 ■ To verify what we think would happen to current at the junctions, four identical lightbulbs and a battery are connected in a circuit having both series and parallel elements. Observations tell us that the brightness of bulb *A* is the same as that in bulb *D*. Bulbs *B* and *C* have the same brightness as each other but share the battery's current, so they are much dimmer than *A* and *D*. Note that even though they are not adjacent, bulbs *A* and *D* are in series.

FIGURE 26-11 ■ The relation $i = i_1 + i_2$ is true at junction *a* no matter what the orientation of the three wire segments is.

What happens when they come back together at junction 2? Since the bulbs are identical, we expect that the current coming into junction 1 will divide equally so half takes the left path and half the right. If charge is conserved, when the currents combine at junction 2, they should add up to the original current. We can verify this by making a very simple observation with a couple of flashlight batteries in series and four bulbs as shown in Fig. 26-10. Bulbs *A* and *D* have the same brightness as each other. This fact indicates that the amount of current through bulb *A* is the same amount of current passing through bulb *D* and back through the battery. The fact that bulbs *B* and *C* have the same brightness as each other but are dimmer than *A* and *D* suggests that the current is splitting in half at the junction. We conclude

$$i = i_1 + i_2 = \frac{i}{2} + \frac{i}{2} \quad (\text{special case with identical parallel elements}), \quad (26-3)$$

where i is the total current and i_1 and i_2 are the currents in the two branches.

If charge is conserved, the magnitudes of the currents in two parallel branches *must* add to yield the magnitude of the current in the original conductor even when the branches have different circuit elements. This statement, called Kirchhoff's current law, states that in general

$$i = i_1 + i_2 \quad (\text{three-way junction of Fig. 26-11a}). \quad (26-4)$$

We treat Kirchhoff's circuit laws in more detail in Chapter 27.

Experiments indicate that bending or reorienting the wires in space does not change the validity of Eq. 26-4. The fact that current is not affected by wire orientation can be explained by the accumulation of static surface charges. These charges keep the electric field associated with a potential difference pointing along a wire, regardless of how the wire twists. The lack of influence of bending is depicted in Fig. 26-11.

READING EXERCISE 26-2: Explain why the word “circuit,” as used in everyday speech, is an appropriate term for application to electrical situations. ■

READING EXERCISE 26-3: Suppose a battery sets up a flow of charges through wires and a bulb. (a) Will the overall circuit, consisting of the battery, bulb, and wires, remain electrically neutral, become positive, or become negative? Explain. (b) Will the wires remain electrically neutral, become positive, or become negative? (c) What ordinary observations would support your answers? ■

READING EXERCISE 26-4: Apply your understanding of the concept of flux, the nature of electrical charge, and the definition of current presented to explain why a flow of equal amounts of opposite charge in the same direction would not be considered a current. That is, explain why there must be a net flow of charge through a surface for there to be a current. ■

READING EXERCISE 26-5: The figure below shows a portion of a circuit. What are the magnitude and direction of the current i in the lower right-hand wire? ■

TOUCHSTONE EXAMPLE 26-1: Charged Fuel

If you've ever gone to a gas station to fill a gas can with fuel for your lawn mower, you may have noticed the sign that tells you to take the gas can out of your car and place it on the ground before you fill it with gasoline. Why is this important? As fuel is pumped from its underground storage tank, it can acquire a net electrical charge. If so, as you pump fuel into a container, the can will build up a net electrical charge if it is electrically isolated from its surroundings. If this charge builds up to a sufficient level, it can create a spark, igniting the fumes around your container with very unfortunate consequences.

Suppose the maximum safe charge that can be deposited on your 5.0 gal gas can is $1.0 \mu\text{C}$.

(a) What is the maximum safe charge per liter that the fuel you are pumping can have?

SOLUTION ■ The **Key Idea** here is simply that the maximum safe “charge density” is

$$(1.0 \mu\text{C})/(5.0 \text{ gal}) = (0.20 \mu\text{C}/\text{gal})(264 \text{ gal}/\text{m}^3)(1 \text{ m}^3/1000 \text{ L}) \\ = 0.0528 \mu\text{C}/\text{L}. \quad (\text{Answer})$$

(b) If the pump delivers fuel at a rate of 8.0 gallons per minute, what is the maximum safe electrical current associated with the flow of the fuel into the can?

SOLUTION ■ The **Key Idea** here is that the fuel delivery rate is

$$(8.0 \text{ gal}/\text{min})(1 \text{ L}/0.264 \text{ gal})(1 \text{ min}/60 \text{ s}) = 0.50505 \text{ L}/\text{s}.$$

Since each liter of fuel can deliver no more than $0.0528 \mu\text{C}$ safely, the maximum safe electrical current is just $(0.0528 \mu\text{C}/\text{L})(0.50505 \text{ L}/\text{s}) = 0.027 \mu\text{C}/\text{s} = 27 \text{ nA}$.

26-4 Circuit Diagrams and Meters

As we move into the remaining sections in this chapter and the next, we will be drawing electric circuits with elements such as batteries, bulbs, wires, and switches. We will also be introducing new elements such as resistors and meters for measuring current and voltage.

Symbols for Basic Circuit Elements

Before proceeding with our study of current and resistance, we pause and introduce a few of the symbols scientists and engineers have created to represent circuit elements. Figure 26-12 shows the common symbols used to make the circuits we discuss in this chapter easier to draw.

Using these symbols, the circuit shown in Fig. 26-2 with a switch added can be represented as shown in Fig. 26-13.

Meters

Current and potential differences are very important properties of electrical circuits, and we have well-established convenient

FIGURE 26-12 ■ Some circuit symbols.

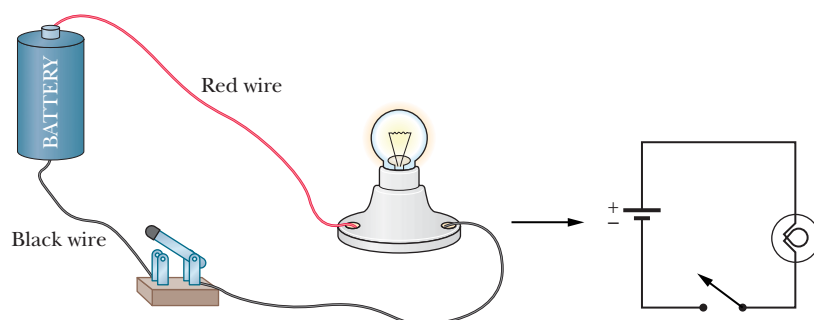

FIGURE 26-13 ■ A circuit sketch and corresponding diagram.

FIGURE 26-14 ■ An analog ammeter for measuring current and an analog voltmeter for measuring potential difference (or “voltage”), along with their circuit symbols.

Current measurements

Voltmeter symbol

FIGURE 26-15 ■ Three analog ammeters measure the same current flowing through three locations in a series circuit consisting of two #14 flashlight bulbs.

ways to measure these quantities using meters. The device with which one measures current is called an **ammeter**. Potential difference is measured with a device called a **voltmeter**. An ammeter and voltmeter along with their circuit symbols are depicted in Fig. 26-14.

Since an ammeter measures current *through* a circuit (or a branch of a more complex circuit), it is placed in *series* with circuit elements. A voltmeter measures the potential difference between two locations (or points) in a circuit, so a voltmeter is placed *across* or in *parallel* with the two points of interest. This is shown in Fig. 26-15.

Often ammeters and voltmeters are combined in a device used to measure either potential difference or current. When the two or more meters are combined, the meter is typically called a **multimeter**. A digital multimeter is shown in Fig. 26-16. Many modern digital multimeters are also capable of measuring other quantities we will discuss, such as resistance and capacitance.

FIGURE 26-16 ■ The digital multimeter pictured can be configured to act as an ammeter to measure current *through* a given part of a circuit, a voltmeter to measure potential difference *across* any two points in a circuit, or the resistance of any circuit element.

FIGURE 26-17 ■ A basic circuit for measuring the current flowing *through* a circuit element as a function of potential difference *across* it.

READING EXERCISE 26-6: In Fig. 26-17, the voltmeter is attached across the bulb and the ammeter is inserted into the circuit. Why are these devices connected this way? How would the ammeter reading change if it were inserted in the circuit before the bulb instead of after it? ■

26-5 Resistance and Ohm's Law

In professional applications of physics like designing electronic devices, we often need to know what effect adding more circuit elements will have on the flow of current. Given devices like ammeters and voltmeters, with which we can measure current and potential difference, we can do quantitative studies of the relationship between current and potential difference. For example, what will happen to the current in a circuit

element, such as a bulb, that is part of a circuit if we add more batteries in series with our original battery? What will happen to the current in a conducting wire as voltage increases? The experimental setup for this investigation is shown in Fig. 26-17. The results are presented in Fig. 26-18 as graphs of applied potential difference ΔV and the resulting current i in two different circuit elements.

We can draw several interesting conclusions from looking at the two graphs in Fig. 26-18. First, we see in both graphs that as the potential difference increases, the amount of current through a given device increases. Second, it is not possible to tell how much current exists just by knowing the potential difference across a circuit element. For instance, when 1.0 V is placed across the lightbulb, the current through it is greater than the current in the Nichrome wire with the same potential difference

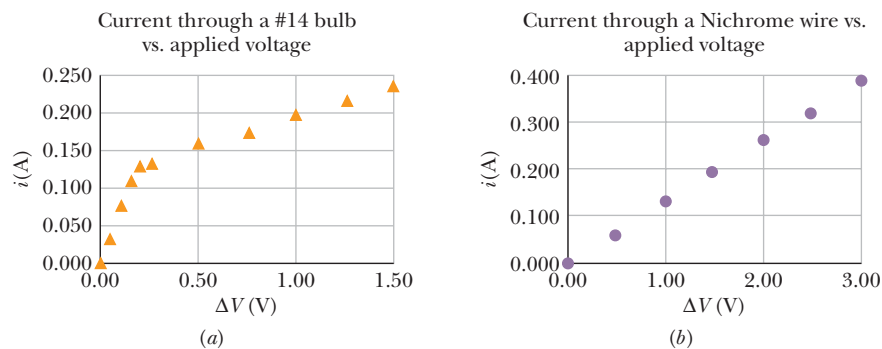

FIGURE 26-18 ■ Graph (a) shows ammeter data for current passing through a #14 lightbulb as a function of potential difference between the terminals of the lightbulb. Graph (b) shows ammeter data for the current through a length of cylindrical Nichrome wire as a function of potential difference between the ends of the wire.

across it. Third, for the length of Nichrome wire, the current is directly proportional to the potential difference, ΔV , across it. Thus, if we know the slope of the line, we can predict the current associated with any value of ΔV . Because of this direct proportionality, we refer to the Nichrome wire as a **linear** device. For the lightbulb, there is no convenient direct proportionality, so it is called a **nonlinear** device.

Definition of Resistance

In both the small bulb and the Nichrome wire, once we measure a specific potential difference, ΔV , across a circuit element and the corresponding current through it we have a measure of the *resistance* of the element to current but only at that ΔV . The **resistance** of a given circuit element is defined as the ratio of the potential difference across the element to the current through the element. When a small potential difference causes a relatively large current, the circuit element has a small resistance to flow of charge. Conversely, when the same potential difference produces a current that is small, we say the resistance is large. For example, in the data presented in Fig. 26-18, a potential difference of 1V across the bulb causes a current of 0.19A to flow, while the same potential difference across that Nichrome wire causes only 0.13A to flow. So we say that at the specific potential difference of 0.25V, the Nichrome wire has more resistance than the bulb.

We define resistance as the ratio of potential difference applied to the current that results:

$$R \equiv \frac{\Delta V}{i} \quad (\text{definition of } R). \quad (26-5)$$

Here we use the notation ΔV to emphasize we are dealing with the *difference* in potential between two locations in a circuit, which changes the potential energy of the charges as they flow. When discussing circuits, potential difference is often referred to by an alternate name of **voltage**.

The SI unit for resistance that follows from Eq. 26-5 is the volt per ampere. This combination occurs so often that we give it a special name, the **ohm** (symbol Ω); that is,

$$\begin{aligned} 1 \text{ ohm} &= 1 \Omega = 1 \text{ volt/ampere} \\ &= 1 \text{ V/A.} \end{aligned} \quad (26-6)$$

If we rewrite Eq. 26-5 as

$$i = \frac{\Delta V}{R},$$

it emphasizes the fact that the potential difference across a device with resistance R produces an electric current. The most common way to express the definition of resistance in Eq. 26-5 is

$$\Delta V = iR. \quad (26-7)$$

For a linear device like Nichrome wire we will get the same value for R no matter what potential difference we impress across the device. However, we must be *careful* in the case of a nonlinear device like a light bulb to specify at what potential difference we are measuring the current, i , in order to determine its resistance.

Ohm's Law

As we just pointed out, our Nichrome wire has the same resistance no matter what the value of the applied potential difference (as shown in Fig. 26-18*b*). Other conducting devices, such as lightbulbs, have resistances that change with the applied potential difference (as shown in Fig. 26-18*a*). Although both the Nichrome wire and the bulb contain metallic conductors, the wire in the bulb is so thin that its temperature rises noticeably as the potential difference increases, and the bulb's resistance increases.

In 1827, George Simm Ohm, a Bavarian, reported that he had observed a linear relationship between current and potential difference for metallic conductors kept at a fairly constant temperature. Because of this, linear devices such as the length of Nichrome wire are sometimes referred to as **ohmic**.

A device is said to obey Ohm's law whenever the current through it is *always* directly proportional to the potential difference applied. That is, the device's resistance is constant in the $\Delta V = iR$ relation.

Many elements used in electric circuits, whether they are conductors like copper or semiconductors like pure silicon or silicon containing special impurities, obey Ohm's law within some range of values of potential difference. If the current in a resistive device is large enough to cause significant temperature changes in it, then Ohm's law often breaks down.

It is sometimes contended that $R = \Delta V/i$ (or $\Delta V = iR$) is a statement of Ohm's law. That is not true! This equation is the defining equation for resistance, and it applies to all conducting devices, whether they obey Ohm's law or not. If we measure the potential difference ΔV across and the current i through any device, even a bulb or other non-ohmic device, we can find its resistance *at that value of ΔV* as $R \equiv \Delta V/i$. The essence of Ohm's law, however, is a plot of i versus ΔV that is a straight line, so that the value of R is independent of the value of ΔV .

Resistors

A conductor whose function in a circuit is to obey Ohm's law so that it provides a specified resistance to the flow of charge independent of the potential difference impressed across it is called a **resistor** (see Fig. 26-19). Carbon resistors are the most standard sources of ohmic resistance used in electrical circuits for several reasons. Unlike a lightbulb, a resistor has a resistance that remains constant as current changes. Carbon resistors are inexpensive to manufacture, and they can be produced with a large range of resistances. The circuit diagram symbol for a resistor is shown in Fig. 26-20.

A typical carbon resistor contains graphite, a form of carbon, suspended in a hard glue binder. It usually is surrounded by a plastic case with a color code painted on it as shown in Fig. 26-21.

READING EXERCISE 26-7: The following table gives the current i (in amperes) through three devices for several values of potential difference ΔV (in volts). From these data, determine which devices, if any, obey Ohm's law.

Device 1		Device 2		Device 3	
ΔV	i	ΔV	i	ΔV	i
2.00	4.50	2.00	1.50	2.00	6.50
3.00	6.75	3.00	2.50	3.00	8.75
4.00	9.00	4.00	3.00	4.00	11.00

FIGURE 26-19 ■ An assortment of carbon resistors. The circular bands are color-coding marks that identify the value of the resistance.

■ **FIGURE 26-20** ■ Circuit diagram symbol for an ohmic resistor.

FIGURE 26-21 ■ Depiction of the four color bands on a color-coded resistor with $R = 47 \text{ k}\Omega \pm 10\%$. See Table 26-1 for details

26-6 Resistance and Resistivity

Next we consider how the resistance of ohmic circuit elements such as metal wires or carbon resistors depends on their geometries. That is, how does the resistance of a short, broad object change if we stretch it so it is long and thin? To determine this, we fix our investigation on a single material. For example, we might experiment with copper wire. Relatively thick copper wire is commonly used in electric circuits because it has a very low resistance compared to other circuit elements. Thus, it can be used to connect circuit elements without adding much resistance to a circuit.

Observations

Consider a conducting wire with a potential difference across its ends as shown in Fig. 26-22. To start with, we will keep the thickness of the wire fixed and just decrease its length. If we apply a potential difference across the ends of the wire and use current and potential difference measurements, we can determine its resistance as a function of length. We find that its resistance is proportional to its length L . Thus, we can write

$$R = kL.$$

If instead we fix the length of the wire and decrease its thickness or cross-sectional area A , then the measured resistance of the wire increases as its cross-sectional area

TABLE 26-1
The Resistor Code^a

Black = 0	Blue = 6
Brown = 1	Violet = 7
Red = 2	Gray = 8
Orange = 3	White = 9
Yellow = 4	Silver = $\pm 10\%$
Green = 5	Gold = $\pm 5\%$

^aThe value in ohms = $AB \times 10^C \pm D$. (AB means the A band digit placed beside the B band digit, not A times B). The colors on bands A , B , and C represent the digits shown in Table 26-1. The D band represents the “tolerance” of the resistor. No band denotes $\pm 20\%$, a silver band denotes $\pm 10\%$, and a gold band denotes $\pm 5\%$. For example, a resistor with bands of Blue-Gray-Red-Silver has a value: $AB \times 10^C \pm D = 68 \times 10^2 \Omega \pm 10\%$ or $(6800 \pm 680)\Omega$, since $A = 6$, $B = 8$, $C = 2$, $D = \text{silver}$, ($\pm 10\%$).

FIGURE 26-22 ■ A potential difference ΔV is applied between the ends of a conducting wire of length L and cross section A , establishing a current i . Although the stationary ions that neutralize the conduction electrons that make up the current are not shown, the wire is, as always, essentially neutral electrically.

decreases. In fact we get an inverse relationship so that

$$R = k' \frac{1}{A}.$$

To combine these two results, we write that R is proportional to L and inversely proportional to A with a new proportionality constant, ρ , which we define as the **resistivity** of the wire. Thus,

$$R = \rho \frac{L}{A}. \quad (26-8)$$

The results of these resistivity observations are important for two reasons. First, the fact that resistance varies inversely with cross-sectional area implies that current passes through the volume of the conductor, and not just along the surface. This knowledge will be useful as we continue to think about how charge moves through wires and other circuit elements.

Second, we know that every conducting material has a resistivity ρ . Is it the same for all materials? The answer is no. Is it the same if the length (or area) of a wire is changed? The answer is yes. What we observe is that if we apply the same potential difference between the ends of geometrically similar (same L and same A) rods of copper and of glass, very different currents result. This investigation reveals that resistivity varies with material. That is, it is a property of the *material* from which the object is fashioned.

We have just made an important distinction:

Resistance is a property of an object. Resistivity is a property of a material.

It is important to note that resistivity is analogous in many ways to the concept of density. Density depends only on the kind of material being used (such as lead or Styrofoam). The density can be used to calculate the mass of a certain volume of a substance. Similarly, resistivity depends only on the material being used in the wire and not on the length or cross-sectional area of the wire. If you know the resistivity of a material then the resistance of a given wire can be calculated using Eq. 26-8 once its length and cross-sectional area are known.

Variation of Resistivity with Temperature

The values of most physical properties vary with temperature, and resistivity is no exception. Figure 26-23, for example, shows the variation of this property for copper over a wide temperature range. The relation between temperature and resistivity for copper—and for metals in general—is fairly linear over the temperature range commonly found in circuits. For such linear relations we can write an approximation based on the results of measurements as

$$\rho - \rho_0 \approx \rho_0 \alpha (T - T_0) \quad (\text{approx. temperature dependence of } \rho). \quad (26-9)$$

Here T_0 is a selected reference temperature and ρ_0 is the resistivity at that temperature. Usually $T_0 = 293 \text{ K}$ (room temperature), for which $\rho_0 = 1.69 \times 10^{-8} \Omega \cdot \text{m}$ for copper. This approximate relationship is good enough for most engineering purposes.

Because temperature enters into this expression only as a difference, it does not matter whether you use the Celsius or Kelvin scale in that equation because the sizes of degrees on these scales are identical. The quantity α , called the **temperature coefficient of resistivity**, is chosen so that the equation gives good agreement with

FIGURE 26-23 ■ The resistivity of copper as a function of temperature. The dot on the curve marks a convenient reference point ($T_0 = 293 \text{ K}$ and $\rho_0 = 1.69 \times 10^{-8} \Omega \cdot \text{m}$).

TABLE 26-2
Resistivities of Some Materials at Room Temperature (20°C)

Material	Resistivity, ρ ($\Omega \cdot \text{m}$)	Temperature Coefficient of Resistivity, α (K^{-1})
<i>Typical Metals</i>

experimental values for temperatures in the chosen range. Some values of α for metals are listed in Table 26-2.

The Hindenburg

When the zeppelin *Hindenburg* was preparing to land on May 6th, 1937, the handling ropes were let down to the ground crew. Exposed to the rain, the ropes became wet (and thus were able to conduct a current). In this condition, the ropes “grounded” the metal framework of the zeppelin to which they were attached; that is, the wet ropes formed a conducting path between the framework and the ground, making the electric potential of the framework the same as the ground’s. This should have also grounded the outer fabric of the zeppelin. The *Hindenburg*, however, was the first zeppelin to have its outer fabric painted with a sealant of large electrical resistivity. The fabric remained at the electric potential of the atmosphere at the zeppelin’s altitude of about 43 m. Due to the rainstorm, that potential was large relative to the potential at ground level.

The handling of the ropes apparently ruptured one of the hydrogen cells and released hydrogen between that cell and the zeppelin’s outer fabric, causing the reported rippling of the fabric. There was then a dangerous situation: the fabric was wet with conducting rainwater and was at a potential much different from the framework of the zeppelin. Apparently, charge flowed along the wet fabric and then sparked through the released hydrogen to reach the metal framework of the zeppelin, igniting the hydrogen in the process. The burning rapidly ignited the cells of hydrogen in the zeppelin and brought the ship down. If the sealant on the outer fabric of the *Hindenburg* had been of less resistivity (like that of other zeppelins), the *Hindenburg* disaster probably would not have occurred.

READING EXERCISE 26-8: Sketch a graph of i vs ΔV for a Nichrome wire like that in Fig. 26-22 but with the diameter of the wire cut in half. ■

READING EXERCISE 26-9: In the section above, we cited the fact the resistance of a wire to current was inversely proportional to the cross-sectional area of the wire as evidence that the current passes through the volume of the wire rather than along the surface of the wire. (a) Justify this assertion. (b) What expression would you expect to replace Eq. 26-8 if the current was along the surface of the wire instead? ■

READING EXERCISE 26-10: The figure shows three cylindrical copper conductors along with their face areas and lengths. Rank them according to the current through them, greatest first, when the same potential difference ΔV is placed across their lengths. ■

FIGURE 26-24 ■ A battery B sets up a current i in a circuit containing an unspecified conducting device.

The wire coils within a toaster have appreciable resistance. When there is a current through them, electrical energy is transferred to thermal energy of the coils, increasing their temperature. The coils then emit infrared radiation and visible light that can toast bread.

26-7 Power in Electric Circuits

Batteries store a certain amount of chemical energy. This chemical energy is transformed to electrical and other forms of energy as current flows through various circuit elements. At times we are interested in the rate at which a battery's energy is used up by a circuit. Just as we did in Section 9-10 where power is defined as the rate at which work is done by a force, we also use the term power to describe the rate at which electrical energy is delivered to a circuit.

We start our consideration of power by examining the energy delivered to an electrical device that is connected to a battery by ideal wires. Figure 26-24 shows a circuit consisting of a battery B that is connected by wires to an unspecified conducting device. The device might be a resistor, a storage battery (a rechargeable battery), a motor, or some other electrical device. If the wires in the circuit are thick enough they are ideal because they have essentially no resistance. When current is present in a wire with no resistance the entire wire is at the same potential. In other words, there is no potential difference between one end of an ideal wire and the other end. In this case, a battery maintains a potential difference of magnitude ΔV across its own terminals, and thus across the terminals of the unspecified device, with a greater potential at terminal a of the device than at terminal b .

Since there is an external conducting path between the two terminals of the battery, and since the battery maintains a fixed potential difference, the battery produces a steady current i in the circuit. This current is directed from terminal a to terminal b . The amount of charge dq moving between those terminals in time interval dt is equal to $i dt$. This charge dq moves through a decrease in potential difference across the terminals of the device of magnitude ΔV , and thus its electric potential energy U decreases in magnitude by the amount

$$dU = -dq\Delta V = -i dt(\Delta V).$$

The principle of conservation of energy tells us that the decrease in electric potential energy from a to b is accompanied by a transfer of energy to some other form. Since $P = dW/dt$ (Eq. 9-48), the power P associated with that transfer is the rate at which the battery does work. Since $dW = -dU = i dt(\Delta V)$, we get

$$P = i \Delta V \quad (\text{rate of electric energy transfer}). \quad (26-10)$$

Moreover, this power P is also the rate at which energy is transferred from the battery to the unspecified device. If that device is a motor connected to a mechanical load, the energy is transferred as work done on the load. If the device is a storage battery being charged, the energy is transferred to stored chemical energy in the storage battery. We know from observations that if the device is a resistor, the energy is transferred to internal thermal energy, tending to increase the resistor's temperature.

The unit of power following from the equation above is the volt-ampere ($V \cdot A$). We can write it as

$$1 \text{ V} \cdot \text{A} = \left(1 \frac{\text{J}}{\text{C}}\right) \left(1 \frac{\text{C}}{\text{s}}\right) = 1 \frac{\text{J}}{\text{s}} = 1 \text{ W}.$$

The course of an electron moving through a resistor at constant speed is much like that of a stone falling through syrup at constant terminal speed. The average kinetic energy of the electron remains constant, and its lost electric potential energy appears as thermal energy in the resistor and its surroundings. On a microscopic scale this energy transfer is due to collisions between the electron and the molecules of the resistor, which leads to an increase in the temperature of the resistor lattice. The mechanical energy thus transferred to thermal energy is *lost* because the transfer cannot be reversed. This energy transfer due to atomic collisions is discussed in more detail in Sections 26-10 and 26-11.

For a resistor or some other device with resistance R , we can combine Eqs. 26-5 ($R = \Delta V/i$) and 26-10 to obtain, for the rate of electric energy loss (or dissipation) due to a resistance, either

$$P = i^2 R \quad (\text{resistive dissipation}) \quad (26-11)$$

or

$$P = \frac{(\Delta V)^2}{R} \quad (\text{resistive dissipation}). \quad (26-12)$$

Caution: We must be careful to distinguish these two new equations from Eq. 26-10: $P = i \Delta V$ applies to electric energy transfers of all kinds; $P = i^2 R$ and $P = (\Delta V)^2/R$ apply only to the transfer of electric potential energy to thermal energy in a device with resistance.

READING EXERCISE 26-11: A potential difference ΔV is connected across a device with resistance R , causing current i through the device. Rank the following variations according to the change in the rate at which electrical energy is converted to thermal energy due to the resistance, greatest change first: (a) ΔV is doubled with R unchanged, (b) i is doubled with R unchanged, (c) R is doubled with ΔV unchanged, (d) R is doubled with i unchanged. ■

TOUCHSTONE EXAMPLE 26-2: Heating Wire

You are given a length of uniform heating wire made of a nickel-chromium-iron alloy called Nichrome; it has a resistance R of 72Ω . At what rate is energy dissipated in each of the following situations? (1) A potential difference of 120 V is applied across the full length of the wire. (2) The wire is cut in half, and a potential difference of 120 V is applied across the length of each half.

SOLUTION ■ The **Key Idea** is that a current in a resistive material produces a transfer of electrical energy to thermal energy; the rate of transfer (dissipation) is given by Eqs. 26-10 to 26-12. Because we know the potential ΔV and resistance R , we use

Eq. 26-12, which yields, for situation 1,

$$P = \frac{(\Delta V)^2}{R} = \frac{(120 \text{ V})^2}{72 \Omega} = 200 \text{ W}. \quad (\text{Answer})$$

In situation 2, the resistance of each half of the wire is $(72 \Omega)/2$, or 36Ω . Thus, the dissipation rate for each half is

$$P' = \frac{(120 \text{ V})^2}{36 \Omega} = 400 \text{ W},$$

and that for the two halves is

$$P = 2P' = 800 \text{ W.} \quad (\text{Answer})$$

This is four times the dissipation rate of the full length of wire.

Thus, you might conclude that you could buy a heating coil, cut it in half, and reconnect it to obtain four times the heat output. Why is this unwise? (What would happen to the amount of current in the coil?)

26-8 Current Density in a Conductor

We defined current so that it was a scalar—basically a “count” of the amount of charge crossing a surface per second with a sign to tell us in which direction the charge is crossing the surface—in the direction we choose as positive or opposite to it. Since in a current, charges are actually moving and have a velocity associated with them, there is a vector “hidden” in the concept of current. We can make it explicit by defining a new concept, the **current density**. If we have a volume that contains a set of moving charged particles, let the charge on each particle be e , let the density of the charges be n (number per unit volume), and let their average velocity be $\langle \vec{v} \rangle$. We then define the current density (or current percentage of cross-sectional area) as

$$\vec{J} \equiv ne\langle \vec{v} \rangle \quad (\text{definition of current density}). \quad (26-13)$$

As is the case for the volume flux of water described in Eq. 15-33, the total amount of charge flowing through a given element of area can be defined as the dot product of the current density and an area element. If the area element is infinitesimal we can write the amount of current through it as $\vec{J} \cdot d\vec{A}$, where $d\vec{A}$ is the area vector of the element, perpendicular to the plane of the area element. The total *conventional current* through the surface of a cross section of wire is then

$$i = \int \vec{J} \cdot d\vec{A}. \quad (26-14)$$

In most electrical conductors the charge carriers are negative. As we mentioned earlier, the term “conventional current” refers to the direction of flow of positive charge carriers. For a typical conductor such as copper, the electrons are moving in the opposite direction to the direction of the conventional current.

In Section 26-6 we concluded that in steady current through a conductor the charges must be flowing throughout the volume of the conductor. The key evidence for this is the inverse proportionality between resistance and the cross-sectional area of a conductor.* If we further assume that the direction of the current is parallel to $d\vec{A}$, then \vec{J} is also uniform and parallel to $d\vec{A}$. In this case Eq. 26-14 can be rewritten in terms of the magnitudes of the current density and area.

$$|i| = \int J dA = J \int dA = JA,$$

so
$$J = \frac{|i|}{A}, \quad (26-15)$$

*However, steady charge flow throughout a conductor is not true for the high-frequency alternating currents we treat in Chapter 33.

where A is the total area of the surface. From these equations, we see that the SI unit for current density is the ampere per square meter (A/m^2).

In Chapter 23 we represented an electric field with electric field lines. Figure 26-25 shows how current density can be represented with a similar set of lines, which we can call *streamlines*. The current, which is toward the right in Fig. 26-25, makes a transition from the wider conductor at the left to the narrower conductor at the right. Because charge is conserved during the transition, the current or rate at which the charges flow through the wire cannot change. However, the current density (or rate of charge flow per unit of cross-sectional area) does change—it is greater in the narrower conductor. The spacing of the streamlines suggests this increase in current density; streamlines that are closer together imply greater current density.

FIGURE 26-25 ■ Streamlines representing current density in the flow of charge through a constricted conductor.

READING EXERCISE 26-12: The sketches below show several copper wires with the same potential difference across them. Rank the current density magnitude from largest to smallest.

26-9 Resistivity and Current Density

Although i , ΔV , and R are the quantities that are directly measurable in electrical circuits, if we want to think more explicitly about what is happening in terms of the motion of charges it makes sense to reframe our Ohm's law relation in terms of the forces (or the electric field) and the current density. This gives us a generic relation that describes how forces affect the motion of charges without relying in any way on the properties of specific circuit elements in the way that Ohm's law does.

Recall that, for materials that obey Ohm's law, the resistance of a segment of a conductor R is related to the potential difference ΔV across it as well as the conventional current i passing through it. This relationship is given by

$$\Delta V = iR. \quad (\text{Eq. 26-7})$$

We can write this expression in an alternate form if we replace the potential difference ΔV with an expression involving the electric field \vec{E} . From Chapter 25, we know that the relationship between the electric field and the potential difference between two locations a and b is

$$V_a - V_b = \int_a^b \vec{E} \cdot d\vec{s}.$$

For a wire of length L with one end at location a and the other at location b , (Fig. 26-26), the electric field \vec{E} set up within the wire is constant. As a result, the expression above can be expressed in terms of the electric field magnitude E and the length of the wire L as

$$V_a - V_b = \pm EL,$$

FIGURE 26-26 ■ A length L between points a and b along a current-carrying conductor.

where we use the plus sign if \vec{E} and $d\vec{s}$ are in the same direction and the minus sign if \vec{E} and $d\vec{s}$ point in opposite directions. Combining the expression above with

$$R = \frac{V_a - V_b}{i}$$

and ignoring signs gives us

$$R = \frac{EL}{i} = \frac{EL}{JA}.$$

The substitution for i comes from the relationship between current i , current density \vec{J} , and the cross section of the wire A . We compare this relation with that presented earlier when we introduced ρ as the resistivity of the material in Eq. 26-8:

$$R = \rho \frac{L}{A}.$$

By combining the previous two equations, we see that resistivity can be defined in terms of the magnitudes of the microscopic quantities \vec{E} and \vec{J} as

$$\rho \equiv \frac{E}{J} \quad (\text{definition of } \rho). \quad (26-16)$$

If we combine the SI units of \vec{E} and \vec{J} we get, for the unit of ρ , the ohm-meter ($\Omega \cdot \text{m}$):

$$\text{units of } \rho = \frac{\text{units of } E}{\text{units of } J} = \frac{\text{V/m}}{\text{A/m}^2} = \frac{\text{V}}{\text{A}} \text{ m} = \Omega \cdot \text{m}.$$

(Do not confuse the *ohm-meter*, the unit of resistivity, with the *ohmmeter*, which is an instrument that measures resistance.)

Since \vec{E} and \vec{J} always point in the same direction, we can rewrite this expression in vector form as

$$\vec{E} = \rho \vec{J}. \quad (26-17)$$

However, be aware that these two relations hold only for *isotropic* materials—materials whose electrical properties are the same in all directions (like the metals used to make wires).

26-10 A Microscopic View of Current and Resistance

Our macroscopic studies tell us that there is a current in a conductor whenever there is a potential difference across it. Whenever Ohm's law holds, the current is directly proportional to the potential difference that causes it. Let's consider a length L of

thin conducting wire with a potential difference of ΔV between its ends. What happens microscopically to the charge carriers in this situation?

We already know that the conduction electrons in a metal serve as charge carriers, and that when there is a steady current, we can represent the density of electrons as n and the charge on each electron as e . What does Ohm's law tell us about the average velocity $\langle \vec{v} \rangle$ of these electrons? When Ohm's law holds so that $\Delta V = iR$ (Eq. 26-7), then according to Eq. 26-13, the current density is proportional to the average velocity of the charge carriers by definition,

$$\vec{J} \equiv ne\langle \vec{v} \rangle. \quad (\text{Eq. 26-13})$$

Since $\vec{E} = \rho\vec{J}$ (Eq. 26-17), we find that the electric field \vec{E} across the wire (associated with potential difference ΔV across the wire) is also proportional to the average velocity of the charge carriers,

$$\vec{E} = \rho ne\langle \vec{v} \rangle. \quad (26-18)$$

However, the electrostatic force on a charge carrier is given by $\vec{F}^{\text{elec}} = e\vec{E}$ (Eq. 23-4), so that

$$\vec{F}^{\text{elec}} = e\vec{E} = \rho ne^2\langle \vec{v} \rangle. \quad (26-19)$$

This is a dramatic and interesting result. It tells us that the average velocity, $\langle \vec{v} \rangle$, of a charge carrier is proportional to the electrostatic force on it! However, if the electrostatic force is the only force acting on the electron, then Newton's Second Law tells us that the electron should accelerate and not maintain a constant average velocity. To maintain a constant velocity, the *net force* on the charge carrier must be zero. Thus, there must be a second force. This situation is very similar to that associated with air drag where an object falling in the presence of a gravitational force reaches a terminal velocity as a result of an air drag acting in the opposite direction. Using Eq. 6-24 we see that

$$\vec{F}^{\text{net}} = \vec{F}^{\text{elec}} + \vec{D} = \rho ne^2\langle \vec{v} \rangle + \vec{D} = 0 \quad (26-20)$$

so that

$$\vec{D} = -e\vec{E} = -\rho ne^2\langle \vec{v} \rangle.$$

This leads us to conclude that there must be a drag force that is proportional to the average velocity of the charge carriers. The air drag force on a falling object is attributed to the action of many small air molecules hitting the falling object as it moves. Similarly, we can imagine that a charge carrier is being slowed down by hitting many stationary atoms and ions as it passes through the conductor. The interactions between charge carriers and the atoms in a conductor can only be described properly using quantum mechanics. Nonetheless, we attempt to picture the flow of charge past positive ions in Fig. 26-27.

What Is a Typical Average Charge Carrier Speed?

Solving $\vec{J} \equiv ne\langle \vec{v} \rangle$ (Eq. 26-13) for the average velocity and recalling Eq. 26-15 ($J = |i|/A$), we obtain the following expression for the average speed of the charge carrier,

$$|\langle \vec{v} \rangle| = \frac{|i|}{nAe} = \frac{J}{ne}. \quad (26-21)$$

The product ne , whose SI unit is the coulomb per cubic meter (C/m^3), is the *carrier charge density*.

At this point we can use Eq. 26-21 to find a typical value for the average speed for electrons flowing in a copper wire. Since copper has one conduction electron per atom

FIGURE 26-27 ■ Conduction electrons which are negative charge carriers drift at an average velocity $\langle \vec{v} \rangle$ in the opposite direction of the applied electric field \vec{E} . Their size is greatly exaggerated. By convention, the direction of the current density \vec{J} and the sense of the arrow representing the flow of conventional current are drawn in that same direction.

we can use measurements for the density of copper atoms of $n = 8.5 \times 10^{28}$ atoms/m³. Assume that our wire carries a current of 1.0 A and has a diameter of 2 mm so its cross-sectional area is 3×10^{-6} m². Then, according to Eq. 26-21, the average speed of the electrons is about

$$|\langle \vec{v} \rangle| = \frac{|i|}{nAe} = \frac{1 \text{ C/s}}{(8.5 \times 10^{28} \text{ atoms/m}^3)(3 \times 10^{-6} \text{ m}^2)(1.6 \times 10^{-19} \text{ C/atom})} \approx 2.5 \times 10^{-5} \text{ m/s}.$$

This typical average speed is extremely small compared to very high speed random thermal motion of the electrons. It would take an electron about 11 hours to move across a 10 cm stretch of wire. Although the conduction electrons move along a wire very slowly like tired snails, there are so many of them that the current can actually be relatively large.

A Microscopic View of Resistivity

We can carry our microscopic analysis further, by relating the resistivity of a conductor to the properties of its charge carriers and the average time between electron collisions. If an electron of mass m is placed in an electric field of magnitude E , the electron will experience an acceleration given by Newton's Second Law:

$$\vec{a} = \frac{\vec{F}}{m} = \frac{e\vec{E}}{m}. \quad (26-22)$$

The nature of the collisions experienced by conduction electrons is such that, after a typical collision, each electron will—so to speak—completely lose its memory of its previous average velocity. Between collisions a conduction electron will have a mean free path λ like that derived in Section 20-5 for molecules traveling in a gas. However, it moves with a typical random speed $v^{\text{eff}} = \lambda/\tau$ where τ is the average time between collisions. Each electron will then start off fresh after every encounter, moving off in a random direction. In the average time τ between collisions, a typical electron will undergo an acceleration \vec{a} in a direction opposite to that of the electric field as shown in Fig. 26-27. Thus, the average speed (often called the drift speed), the electron acquires in that direction is given by $|\langle \vec{v} \rangle| = a\tau$. Using Eq. 26-22 we get

$$|\langle \vec{v} \rangle| = a\tau = \frac{eE\tau}{m}. \quad (26-23)$$

Combining this result with $\vec{J} = ne\langle \vec{v} \rangle$ yields the average velocity of

$$\langle \vec{v} \rangle = \pm \frac{\vec{J}}{ne} = \pm \frac{e\vec{E}\tau}{m},$$

where we use the plus (+) sign for positive charge carriers and the minus (−) sign for negative charge carriers. We can combine the last two terms in the previous equation and solve for \vec{E} to get

$$\vec{E} = \left(\frac{m}{e^2 n \tau} \right) \vec{J}.$$

This equation shows a proportionality between the electric field in a wire and the amount of current. Note that the magnitude of the electric field in a wire is in turn proportional to the potential difference across the wire. Thus, our microscopic picture of resistivity for metallic conductors is consistent with our macroscopic

measurements, and it predicts a proportionality between potential difference and current.

Comparing the equation above with Eq. 26-17 ($\vec{E} = \rho\vec{J}$) leads to an expression for the resistivity in terms of the mass and charge of the carriers, the charge density n , and the average time between collisions

$$\rho = \frac{m}{e^2 n \tau}. \quad (26-24)$$

Conductivity

As well as referring to the resistivity of a material, we often speak of the conductivity σ of a material. This is simply the reciprocal of its resistivity, so

$$\sigma \equiv \frac{1}{\rho} \quad (\text{definition of } \sigma). \quad (26-25)$$

The SI unit of conductivity is the reciprocal ohm-meter $(\Omega \cdot \text{m})^{-1}$. The unit name mhos per meter is sometimes used (mho is ohm backward). The definition of conductivity, σ , allows us to write Eq. 26-17 ($\vec{E} = \rho\vec{J}$) in the alternative form

$$\vec{J} = \sigma\vec{E}. \quad (26-26)$$

READING EXERCISE 26-13: The figure shows positive charge carriers moving leftward through a wire. Are the following leftward or rightward: (a) the conventional current i , (b) the current density \vec{J} , (c) the electric field \vec{E} in the wire? *Hint:* You may want to review the discussion of conventional current in Section 26-8. ■

TOUCHSTONE EXAMPLE 26-3: Mean Free Time

What is the mean free time τ between collisions for the conduction electrons in copper?

SOLUTION ■ The **Key Idea** here is that the mean free time τ of copper is approximately constant, and in particular does not depend on any electric field that might be applied to a sample of the copper. Thus, we need not consider any particular value of applied electric field. However, because the resistivity ρ displayed by copper under an electric field depends on τ , we can find τ from Eq. 26-24 ($\rho = m/e^2 n \tau$). That equation gives us

$$\tau = \frac{m}{ne^2\rho}.$$

Taking the value of n , the number of conduction electrons per unit volume in copper, to be $8.5 \times 10^{28} \text{ m}^{-3}$, and taking the value of ρ from Table 26-2, the denominator then becomes

$$\begin{aligned} & (8.5 \times 10^{28} \text{ m}^{-3})(1.6 \times 10^{-19} \text{ C})^2(1.69 \times 10^{-8} \Omega \cdot \text{m}) \\ &= 3.67 \times 10^{-17} \text{ C}^2 \cdot \Omega / \text{m}^2 \\ &= 3.67 \times 10^{-17} \text{ kg/s}, \end{aligned}$$

where we converted units as

$$\frac{\text{C}^2 \cdot \Omega}{\text{m}^2} = \frac{\text{C}^2 \cdot \text{V}}{\text{m}^2 \cdot \text{A}} = \frac{\text{C}^2 \cdot \text{J/C}}{\text{m}^2 \cdot \text{C/s}} = \frac{\text{kg} \cdot \text{m}^2/\text{s}^2}{\text{m}^2/\text{s}} = \frac{\text{kg}}{\text{s}}.$$

Using these results and substituting for the electron mass m , we then have

$$\tau = \frac{9.1 \times 10^{-31} \text{ kg}}{3.67 \times 10^{-17} \text{ kg/s}} = 2.5 \times 10^{-14} \text{ s}. \quad (\text{Answer})$$

(b) The mean free path λ of the conduction electrons in a conductor is the average distance traveled by an electron between collisions. (This definition parallels that in Section 20-5 for the mean free path of molecules in a gas.) What is λ for the conduction electrons in copper?

SOLUTION ■ The **Key Idea** here is that the distance d any particle travels in a certain time t at a constant speed v is $d = vt$. To estimate v^{eff} , the speed at which the electrons typically move between collisions, we can think of the electrons as a “gas” of particles in thermal equilibrium with their surroundings inside the metal

wire. Equation 20-21 then tells us that a typical electron has a kinetic energy related to the Kelvin temperature of its environment by $(\frac{1}{2})m(v^2) = (\frac{3}{2})k_B T$ (where k_B is the Boltzmann constant). Taking the electron's effective speed in a room temperature (300 K) environment to be $v^{\text{rms}} = \sqrt{\langle v^2 \rangle}$ gives

$$\begin{aligned} v^{\text{eff}} &= \sqrt{3k_B T/m} = \sqrt{(3)(1.38 \times 10^{-23} \text{ J/K})(300 \text{ K})/(9.11 \times 10^{-31} \text{ kg})} \\ &= 1.168 \times 10^5 \text{ m/s} \end{aligned}$$

and

$$\begin{aligned} \lambda &= v^{\text{eff}} \tau = (1.168 \times 10^5 \text{ m/s})(2.5 \times 10^{-14} \text{ s}) \\ &= 2.9 \times 10^{-9} \text{ m} = 2.9 \text{ nm}. \end{aligned} \quad (\text{Answer})$$

This is about 10 times the distance between nearest-neighbor atoms in a copper lattice. While this is a reasonable sounding result, it turns out that the actual value of λ is about 10 times larger than this due to quantum effects.

26-11 Other Types of Conductors

In the last few chapters we have assumed that the conductors under consideration are metallic like copper or nichrome. As you can see from Table 26-2, one of the distinctive properties of metallic conductors is that they have positive temperature coefficients indicating that their resistivities *increase* with temperature. This property seems reasonable since the thermal energy in the metal lattice causes the atoms in the metal to vibrate more, which further impedes the flow of conduction electrons. In addition, Eq. 26-9 indicates that this increase of resistivity with temperature is approximately *linear*.

There are other types of conductors with resistivities that do not simply increase linearly with temperature. The most important of these are semiconductors, which lie at the heart of the microelectronic revolution. The resistivity of semiconductors decreases more or less linearly with temperature. Superconductors are another class of conductors that do not have the same temperature behavior as conductors. Although the resistivity of superconductors increases with temperature, it does so in a very nonlinear fashion.

Because of the importance of semiconductors and superconductors we describe some of their properties here. Both of these nonmetallic conductors have some amazing properties that we describe briefly in this section. However, in the next few chapters we return to the study—within the framework of classical physics—of *steady* currents of *conduction electrons* moving through *metallic conductors*.

Semiconductors

The basic element found in virtually all semiconductors is either silicon or germanium. Table 26-3 compares the properties of silicon—a typical semiconductor—and copper—a typical metallic conductor. We see that silicon has significantly fewer charge carriers, a much higher resistivity, and a temperature coefficient of resistivity that is both large and negative. Thus, although the resistivity of copper increases with temperature, that of pure silicon decreases.

Pure silicon has such a high resistivity that it is effectively an insulator and not of much direct use in microelectronic circuits. However, its resistivity can be greatly

TABLE 26-3
Some Electrical Properties of Copper and Silicon^a

Property	Copper	Silicon

^aRounded to one significant figure for easy comparison.

reduced in a controlled way by adding minute amounts of specific “impurity” atoms in a process called *doping*. Table 26-2 gives typical values of resistivity for silicon before and after doping with two different impurities, phosphorus and aluminum. Most semiconducting devices, such as transistors and junction diodes, are fabricated by the selective doping of different regions of the silicon with impurity atoms of different kinds.

A full explanation of the difference in resistivity between semiconductors and metallic conductors requires an understanding of quantum theory developed to explain atomic behavior. However, the difference has to do with the probability that electrons in a material can be made mobile. As we discuss in Section 22-6, in a metallic conductor some of the outermost electrons associated with an atom can move from one atom to the next without any additional energy. Thus, the electric field set up in the wire when a potential difference is applied drives current through a conductor.

In an insulator, considerable energy is required to free electrons so they can move through the material. Thermal energy cannot supply enough energy, and neither can any reasonable electric field applied to the insulator. Thus, no electrons are available to move through the insulator, and hence no current occurs even with an applied electric field. A semiconductor is like an insulator *except* that the energy required to free some electrons can be adjusted through doping. Doping can supply either electrons or positive charge carriers held very loosely within the material that are easy to get moving.*

In a semiconductor, the density of charge carriers is small but increases very rapidly with temperature as the increased thermal agitation makes more charge carriers available. This causes a *decrease* of resistivity with increasing temperature, as indicated by the negative temperature coefficient of resistivity for silicon in Table 26-3. The same increase in collision rate we noted for metals also occurs for semiconductors, but its effect is swamped by the rapid increase in the number of charge carriers.

Superconductors

In 1911, Dutch physicist Kamerlingh Onnes discovered that the resistivity of mercury absolutely disappears at temperatures below about 4 K (Fig. 26-28). This phenomenon of **superconductivity** is of vast potential importance in technology because it means charge can flow through a superconducting conductor without producing thermal energy losses. Currents created in a superconducting ring, for example, have persisted for several years without any measurable decrease; the electrons making up the current require a force and a source of energy at start-up time, but not thereafter.

Prior to 1986, the technological development of superconductivity was throttled by the cost of producing the extremely low temperatures that were required to achieve the effect. In 1986, however, new ceramic materials were discovered that become superconducting at considerably higher (and thus cheaper to produce) temperatures. Practical application of superconducting devices at room temperature may eventually become feasible.

Superconductivity is a much different phenomenon from conductivity. In fact, the best of the normal conductors, such as silver and copper, cannot become superconducting at any temperature, and the new ceramic superconductors are actually insulators when they are not at low enough temperatures to be in a superconducting state.

One explanation for superconductivity is that the electrons making up the current move in coordinated pairs. One of the electrons in a pair may electrically distort the molecular structure of the superconducting material as it moves through, creating a short-lived concentration of positive charge nearby. The other electron in the pair may then be attracted toward this positive charge. According to the theory, such coor-

FIGURE 26-28 ■ The resistance of mercury drops to zero at a temperature of about 4 K.

A disk-shaped magnet is levitated above a superconducting material that has been cooled by liquid nitrogen. The goldfish is along for the ride.

*Explaining what positive charge carriers are and how they move is complex. For now just consider the charge carriers as negative (that is, electrons).

dination between electrons would prevent them from colliding with the molecules of the material and thus would eliminate electrical resistance. The theory worked well to explain the pre-1986, lower temperature superconductors, but new theories appear to be needed for the newer, higher temperature superconductors.

Problems

SEC. 26-3 ■ BATTERIES AND ELECTRIC CURRENT

- 1. Coulombs and Electrons** A current of 5.0 A exists in a $10\ \Omega$ resistor for 4.0 min. How many (a) coulombs and (b) electrons pass through any cross section of the resistor in this time?
- 2. Charged Belt** A charged belt, 50 cm wide, travels at 30 m/s between a source of charge and a sphere. The belt carries charge into the sphere at a rate corresponding to $100\ \mu\text{A}$. Compute the surface charge density on the belt.
- 3. Isolated Sphere** An isolated conducting sphere has a 10 cm radius. One wire carries a current of 1.000 002 0 A into it. Another wire carries a current of 1.000 000 0 A out of it. How long would it take for the sphere to increase in potential by 1000 V?

SEC. 26-5 ■ RESISTANCE AND OHM'S LAW

- 4. Electrical Cable** An electrical cable consists of 125 strands of fine wire, each having $2.65\ \mu\Omega$ resistance. The same potential difference is applied between the ends of all the strands and results in a total current of 0.750 A. (a) What is the current in each strand? (b) What is the applied potential difference? (c) What is the resistance of the cable?
- 5. Electrocutation** A human being can be electrocuted if a current as small as 50 mA passes near the heart. An electrician working with sweaty hands makes good contact with the two conductors he is holding, one in each hand. If his resistance is $2000\ \Omega$, what might the fatal voltage be?

SEC. 26-6 ■ RESISTANCE AND RESISTIVITY

- 6. Trolley Car** A steel trolley-car rail has a cross-sectional area of $56.0\ \text{cm}^2$. What is the resistance of 10.0 km of rail? The resistivity of the steel is $3.00 \times 10^{-7}\ \Omega \cdot \text{m}$.
- 7. Conducting Wire** A conducting wire has a 1.0 mm diameter, a 2.0 m length, and a $50\ \text{m}\Omega$ resistance. What is the resistivity of the material?
- 8. A Wire** A wire 4.00 m long and 6.00 mm in diameter has a resistance of $15.0\ \text{m}\Omega$. A potential difference of 23.0 V is applied between the ends. (a) What is the current in the wire? (b) Calculate the resistivity of the wire material. Identify the material. (Use Table 26-2.)
- 9. A Coil** A coil is formed by winding 250 turns of insulated 16-gauge copper wire (diameter = 1.3 mm) in a single layer on a cylindrical form of radius 12 cm. What is the resistance of the coil? Neglect the thickness of the insulation (Use Table 26-2.)
- 10. What Temperature** (a) At what temperature would the resistance of a copper conductor be double its resistance at 20.0°C ? (Use 20.0°C as the reference point in Eq. 26-9; compare your an-

swer with Fig. 26-23.) (b) Does this same “doubling temperature” hold for all copper conductors regardless of shape or size?

- 11. Longer Wire** A wire with a resistance of $6.0\ \Omega$ is drawn out through a die so that its new length is three times its original length. Find the resistance of the longer wire, assuming that the resistivity and density of the material are unchanged.
- 12. A Certain Wire** A certain wire has a resistance R . What is the resistance of a second wire, made of the same material, that is half as long and has half the diameter?
- 13. Two Conductors** Two conductors are made of the same material and have the same length. Conductor A is a solid wire of diameter 1.0 mm. Conductor B is a hollow tube of outside diameter 2.0 mm and inside diameter 1.0 mm. What is the resistance ratio R_A/R_B , measured between their ends?
- 14. Flashlight Bulb** A common flashlight bulb is rated at 0.30 A and 2.9 V (the values of the current and voltage under operating conditions). If the resistance of the bulb filament at room temperature (20°C) is $1.1\ \Omega$, what is the temperature of the filament when the bulb is on? The filament is made of tungsten.
- 15. Metal Rod** When a metal rod is heated, not only its resistance but also its length and its cross-sectional area change. The relation $R = \rho L/A$ suggests that all three factors should be taken into account in measuring ρ at various temperatures. (a) If the temperature changes by $1.0\ \text{C}^\circ$, what percentage changes in R , L , and A occur for a copper conductor? (b) The coefficient of linear expansion for copper is $1.7 \times 10^{-5}/\text{K}$. What conclusion do you draw?
- 16. Gauge Number** If the gauge number of a wire is increased by 6, the diameter is halved; if a gauge number is increased by 1, the diameter decreases by the factor $2^{1/6}$ (see the table in Problem 32). Knowing this, and knowing that 1000 ft of 10-gauge copper wire has a resistance of approximately $1.00\ \Omega$, estimate the resistance of 25 ft of 22-gauge copper wire.

SEC. 26-7 ■ POWER IN ELECTRIC CIRCUITS

- 17. X-Ray Tube** A certain x-ray tube operates at a current of 7.0 mA and a potential difference of 80 kV. What is its power in watts?
- 18. A Student** A student kept his 9.0 V, 7.0 W radio turned on at full volume from 9:00 P.M. until 2:00 A.M. How much charge went through it?
- 19. Space Heater** A 120 V potential difference is applied to a space heater whose resistance is $14\ \Omega$ when hot. (a) At what rate is electric energy transferred to heat? (b) At $5.0\ \text{¢}/\text{kW}\cdot\text{h}$, what does it cost to operate the device for 5.0 h?
- 20. Thermal Energy** Thermal energy is produced in a resistor at a rate of 100 W when the current is 3.00 A. What is the resistance?

21. Energy Is Dissipated An unknown resistor is connected between the terminals of a 3.00 V battery. Energy is dissipated in the resistor at the rate of 0.540 W. The same resistor is then connected between the terminals of a 1.50 V battery. At what rate is energy now dissipated?

22. Space Heater Two A 120 V potential difference is applied to a space heater that dissipates 500 W during operation. (a) What is its resistance during operation? (b) At what rate do electrons flow through any cross section of the heater element?

23. Radiant Heater A 1250 W radiant heater is constructed to operate at 115 V. (a) What will be the current in the heater? (b) What is the resistance of the heating coil? (c) How much thermal energy is produced in 1.0 h by the heater?

24. Heating Element A heating element is made by maintaining a potential difference of 75.0 V across the length of a Nichrome wire that has a $2.60 \times 10^{-6} \text{ m}^2$ cross section. Nichrome has a resistivity of $5.00 \times 10^{-7} \Omega \cdot \text{m}$. (a) If the element dissipates 5000 W, what is its length? (b) If a potential difference of 100 V is used to obtain the same dissipation rate, what should the length be?

25. Nichrome Heater A Nichrome heater dissipates 500 W when the applied potential difference is 110 V and the wire temperature is 800°C. What would be the dissipation rate if the wire temperature were held at 200°C by immersing the wire in a bath of cooling oil? The applied potential difference remains the same, and α for Nichrome at 800°C is $4.0 \times 10^{-4}/\text{K}$.

26. 100 W Lightbulb A 100 W lightbulb is plugged into a standard 120 V outlet. (a) How much does it cost per month to leave the light turned on continuously? Assume electric energy costs 12¢/kW·h. (b) What is the resistance of the bulb? (c) What is the current in the bulb? (d) Is the resistance different when the bulb is turned off?

27. Linear Accelerator A linear accelerator produces a pulsed beam of electrons. The pulse current is 0.50 A, and each pulse has a duration of 0.10 μs . (a) How many electrons are accelerated per pulse? (b) What is the average current for an accelerator operating at 500 pulses/s? (c) If the electrons are accelerated to an energy of 50 MeV, what are the average and peak powers of the accelerator?

28. Cylindrical Resistor A cylindrical resistor of radius 5.0 mm and length 2.0 cm is made of material that has a resistivity of $3.5 \times 10^{-5} \Omega \cdot \text{m}$. What is the potential difference when the energy dissipation rate in the resistor is 1.0 W?

29. Copper Wire A copper wire of cross-sectional area $2.0 \times 10^{-6} \text{ m}^2$ and length 4.0 m has a current of 2.0 A uniformly distributed across that area. How much electric energy is transferred to thermal energy in 30 min?

SEC. 26-8 ■ CURRENT DENSITY IN A CONDUCTOR

30. Small But Measurable A small but measurable current of $1.2 \times 10^{-10} \text{ A}$ exists in a copper wire whose diameter is 2.5 mm. Assuming the current is uniform, calculate (a) the current density and (b) the average electron speed.

31. A Beam A beam contains 2.0×10^8 doubly charged positive ions per cubic centimeter, all of which are moving north with a speed of $1.0 \times 10^5 \text{ m/s}$. (a) What are the magnitude and direction of the current density \vec{J} ? (b) Can you calculate the total current i in this ion beam? If not what additional information is needed?

32. The U.S. Electric Code The (United States) National Electric Code, which sets maximum safe currents for insulated copper wires of various diameters, is given (in part) in the table. Plot the safe current density as a function of diameter. Which wire gauge has the maximum safe current density? (“Gauge” is a way of identifying wire diameters, and 1 mil = 10^{-3} in.)

Gauge	4	6	8	10	12	14	16	18
Diameter, mils	204	162	129	102	81	64	51	40
Safe current, A	70	50	35	25	20	15	6	3

33. A Fuse A fuse in an electric circuit is a wire that is designed to melt, and thereby open the circuit, if the current exceeds a predetermined value. Suppose that the material to be used in a fuse melts when the current density rises to 440 A/cm^2 . What diameter of cylindrical wire should be used to make a fuse that will limit the current to 0.50 A?

34. Near Earth Near the Earth, the density of protons in the solar wind (a stream of particles from the Sun) is 8.70 cm^{-3} , and their speed is 470 km/s. (a) Find the current density of these protons. (b) If the Earth’s magnetic field did not deflect them, the protons would strike the planet. What total current would the Earth then receive?

35. Steady Beam A steady beam of alpha particles ($q = +2e$) traveling with constant kinetic energy 20 MeV carries a current of 0.25 μA . (a) If the beam is directed perpendicular to a plane surface, how many alpha particles strike the surface in 3.0 s? (b) At any instant, how many alpha particles are there in a given 20 cm length of the beam? (c) Through what potential difference is it necessary to accelerate each alpha particle from rest to bring it to an energy of 20 MeV?

36. Current Density (a) The current density across a cylindrical conductor of radius R varies in magnitude according to the equation

$$J = J_0 \left(1 - \frac{r}{R} \right),$$

where r is the distance from the central axis. Thus, the current density has a maximum magnitude of $J_0 = |\vec{J}_0|$ at that axis ($r = 0$) and decreases linearly to zero at the surface ($r = R$). Calculate the current in terms of J_0 and the conductor’s cross-sectional area $A = \pi R^2$. (b) Suppose that, instead, the current density is a maximum J_0 at the cylinder’s surface and decreases linearly to zero at the axis: $J = J_0 r/R$. Calculate the magnitude of the current. Why is the result different from that in (a)?

37. How Long How long does it take electrons to get from a car battery to the starting motor? Assume the current is 300 A and the electrons travel through a copper wire with cross-sectional area 0.21 cm^2 and length 0.85 m. (*Hint:* Assume one conduction electron per atom and take the number density of copper atoms to be $8.5 \times 10^{28} \text{ atoms/m}^3$.)

38. Nichrome A wire of Nichrome (a nickel-chromium-iron alloy commonly used in heating elements) is 1.0 m long and 1.0 mm^2 in cross-sectional area. It carries a current of 4.0 A when a 2.0 V potential difference is applied between its ends. Calculate the conductivity σ of Nichrome.

39. When Applied When 115 V is applied across a wire that is 10 m long and has a 0.30 mm radius, the current density is $1.4 \times 10^4 \text{ A/m}^2$. Find the resistivity of the wire.

40. Truncated Right-

Circular Cone A resistor has the shape of a truncated right-circular cone (Fig. 26-29). The end radii are a and b , and the altitude is L . If the taper is small, we may assume that the current density is uniform across any cross section. (a) Calculate the resistance of this object. (b) Show that your answer reduces to $\rho(L/A)$ for the special case of zero taper (that is, for $a = b$).

FIGURE 26-29 ■ Problem 40.

SEC. 26-10 ■ A MICROSCOPIC VIEW OF CURRENT AND RESISTANCE

41. Gas Discharge Tube A current is established in a gas discharge tube when a sufficiently high potential difference is applied across the two electrodes in the tube. The gas ionizes; electrons move toward the positive terminal and singly charged positive ions toward the negative terminal. (a) What is the magnitude of the current in a hydrogen discharge tube in which 3.1×10^{18} electrons and 1.1×10^{18} protons move past a cross-sectional area of the tube each second? (b) What is the direction of the current density \vec{J} ?

42. A Block A block in the shape of a rectangular solid has a cross-sectional area of 3.50 cm^2 across its width, a front-to-rear length of 15.8 cm , and a resistance of 935Ω . The material of which the block is made has 5.33×10^{22} conduction electrons/ m^3 . A potential difference

of 35.8 V is maintained between its front and rear faces. (a) What is the current in the block? (b) If the current density is uniform, what is its value? (c) What is the average or drift speed of the conduction electrons? (d) What is the magnitude of the electric field in the block?

43. Earth's Lower Atmosphere Earth's lower atmosphere contains negative and positive ions that are produced by radioactive elements in the soil and cosmic rays from space. In a certain region, the atmospheric electric field strength is 120 V/m , directed vertically down. This field causes singly charged positive ions, at a density of $620/\text{cm}^3$, to drift downward and singly charged negative ions, at a density of $550/\text{cm}^3$, to drift upward (Fig. 26-30). The measured conductivity of the air in that region is $2.70 \times 10^{-14} (1/\Omega \cdot \text{m})$. Calculate (a) the average ion speed, assumed to be the same for positive and negative ions, and (b) the current density.

FIGURE 26-30 ■ Problem 43.

Additional Problems

44. Saving on Your Electric Bill Fluorescent bulbs deliver the same amount of light using much less power. If one kW-hr costs 12¢ , estimate the amount of money you would save each month by replacing all the 75 W incandescent bulbs in your house by 10 W fluorescent ones than incandescent ones. *Be sure to clearly state your assumptions.*

45. Building a Water Heater The nickel-chromium alloy Nichrome has a resistivity of about $10^{-6} \Omega\cdot\text{m}$. Suppose you want to build a small heater out of a coil of Nichrome wire and a 6 V battery in order to heat 30 ml of water from a temperature of 20 C to 40 C in 1 min . Assume the battery has negligible internal resistance.

- How much heat energy (in joules) do you need to do this?
- How much power (in watts) do you need to do it in the time indicated?
- What resistance should your Nichrome coil have in order to produce this much power in heat?
- Can you create a coil having these properties? (*Hint:* Can you find a plausible length and cross-sectional area for your wire that will give you the resistance you need?)
- If the internal resistance of the battery were $1/3 \Omega$, how would it affect your calculation? (Only explain what you would have to do; don't recalculate the size of your coil.)

46. A Confusing Thing One of the most confusing things about wiring circuits and figuring out what you've done is that many arrangements are electrically equivalent. Unless you have unusual

powers of visualization it is often hard to recognize this. For example, three of the circuits shown in Fig. 26-31 are electrically equivalent and one is not. Answer questions (a) through (d) that follow.

- Which circuit is not like the others? Explain why it's different.
- Draw circuit diagrams for each of the arrangements and label each diagram as A, B, C, or D. (c) Examine your diagrams. Is it possible for neat circuit diagrams that look superficially different to represent the same set of electrical connections?

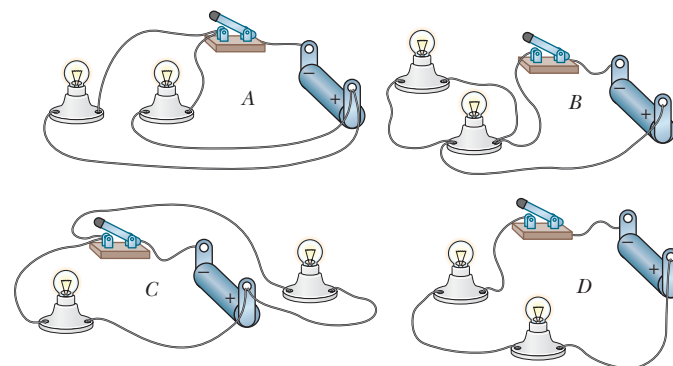

FIGURE 26-31 ■ Problem 46.

47. Draw the Circuit Diagram Draw a neat circuit diagram for each of the two circuits shown in Fig. 26-32 using the standard symbols for bulbs, batteries, and switches.

FIGURE 26-32 ■ Problem 47.

48. Charge Through Conductor The charge passing through a conductor increases over time as $q(t) = (1.6 \text{ C/s}^2)t^2 + (2.2 \text{ C/s})t$, where t is in seconds. (a) What equation describes the current in the circuit as a function of time? (b) What is the current in the conductor at $t = 0.0 \text{ s}$ and at $t = 2.0 \text{ s}$?

49. Increases Over Time The charge passing through a conductor increases over time as $q(t) = (1.5 \text{ C/s}^3)t^3 - (4.5 \text{ C/s}^2)t^2 + (2 \text{ C/s})t$,

where t is in seconds. (a) What equation describes the current in the circuit as a function of time? (b) What is the current in the conductor at $t = 0.0 \text{ s}$ and at $t = 1.0 \text{ s}$?

50. 1994 Honda Accord Consider a 1994 Honda Accord with a battery that is rated at 52 ampere-hours. This battery is supposed to be able to deliver 1 ampere of current to electrical devices in a car for at least 52 hours or 2 amperes for 26 hours, and so on. Suppose you leave the car lights turned on when you park the car and the car lights draw 20 amperes of current. How long will it be before your battery is dead?

51. The Resistance of a Pocket Calculator A typical AAA battery delivers a nearly constant voltage of 1.5 V and stores about 3 kJ of energy. From the time it takes you to use up the batteries in your calculator, estimate the resistance of your calculator. (If you don't have a calculator of this type, make a plausible estimate of how long it might take to use up the batteries. Give some reason for your estimate.)

27

Circuits

The electric eel (*Electrophorus*) lurks in rivers of South America, killing the fish on which it preys with pulses of current. It does so by producing a potential difference of several hundred volts along its length; the resulting current in the surrounding water, from near the eel's head to the tail region, can be as much as one ampere. If you were to brush up against this eel while swimming, you might wonder (after recovering from the very painful stun):

How can the electric eel manage to produce a current that large without shocking itself?

The answer is in this chapter.

27-1 Electric Currents and Circuits

Knowing how to analyze circuits by predicting the currents through their elements and the potential differences across them is a valuable skill. Such knowledge enables engineers and scientists to design electrical devices and helps them make productive use of existing devices. Our goal in this chapter is to understand the behavior of relatively simple electric circuits by applying concepts such as current, potential difference, and resistors developed in the previous chapter. We will start by considering very simple ideal circuits and then go on to consider circuits with multiple loops and batteries such as those shown in Fig. 27-1. Toward the end of the chapter we will introduce the concept of emf or electromotive force associated with batteries and other power sources. In particular, we will consider how to extend our analysis to the behavior of circuits powered by nonideal batteries that have internal resistance.

Ideal Circuits

As we so often do in developing physical ideas, we start by analyzing how a system behaves under ideal conditions. Only then do we introduce real-world complexities that require us to modify our methods of analysis. The ideal circuits we consider first have three characteristics:

1. **They are powered by ideal batteries.** As stated in Section 26-3, an ideal battery “maintains a constant potential difference across its terminals.” This means there is a negligible amount of “electric friction” and the potential difference, ΔV_B , across the terminals of an ideal battery stays the same, regardless of the amount of charge flowing through it. But as the chemical potential energy of a real battery decreases, it develops some *internal resistance*, and the potential difference across its terminals decreases if its current increases.
2. **All circuit elements, other than the battery and connecting wires, are ohmic devices having a significant resistance.** As discussed in Section 26-5, an *ohmic device* has a constant value of resistance, R , that is not a function of the amount of current passing through it. Although lightbulbs and some other circuit elements are not ohmic, standard carbon resistors obey Ohm’s law and have a constant resistance over a large current range. We make use of the fact that the potential difference across the terminals of an ohmic device is directly proportional to the current, i , flowing through it and is given by $\Delta V = iR$ (Eq. 26-7).
3. **Ideal conducting wires connect the battery to circuit elements.** Copper wiring is used in most circuits found in consumer devices, households, and industries. We can use Eq. 26-7 and data from Table 26-2 to determine that the resistance of a 30 cm length of common 22 gauge copper wire is about 0.1Ω . If this wire was connected to a 10Ω resistor, the additional resistance of the wire would add 1% to the overall resistance. In connecting larger resistors, the influence of the resistance of the wire is even smaller. Because the resistance in the wire is so small, the potential difference between the ends of even a relatively long continuous connecting wire is for all practical purposes negligible. In ideal circuits, we assume there is no potential drop across connecting wires.

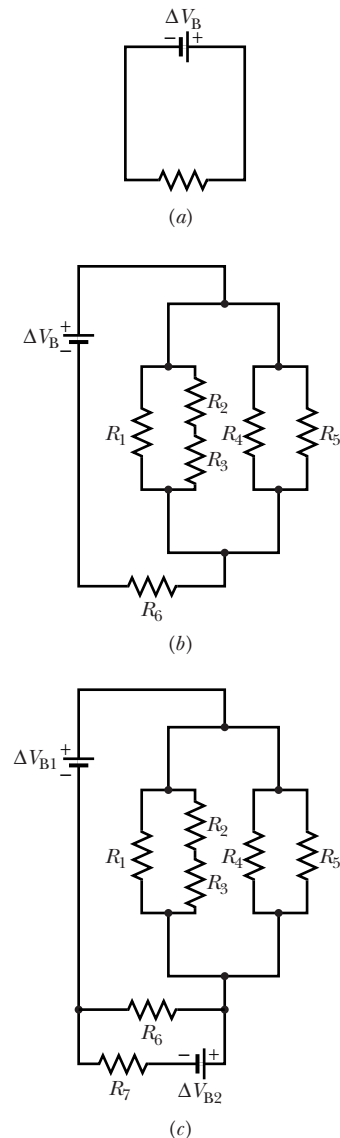

FIGURE 27-1 ■ Several types of ideal circuits we will learn to analyze in this chapter consist of ideal batteries, conducting wires with negligible resistance and ohmic resistors. (a) A single-loop circuit. (b) A single-battery, multiple-loop circuit. (c) A multiple-loop circuit with multiple batteries.

READING EXERCISE 27-1: Show that the resistance of a 30 cm (≈ 12 inch) length of 22 gauge copper wire of diameter 0.024 cm has a resistance of about 0.1Ω . *Hint:* You will need to use information from Table 26-2 along with Eq. 26-7. ■

FIGURE 27-2 ■ A single-loop circuit in which a resistor R is connected across an ideal battery B with potential difference ΔV_B . The resulting current i is the same throughout the circuit.

27-2 Current and Potential Difference in Single-Loop Circuits

Suppose we want to design or operate an electrical device such as a CD player or refrigerator. The operation of the given device will require a certain minimum current or potential difference. How would we calculate the amount of current in a circuit or the potential difference between two points within the device? That is the topic of this section.

We start out our discussion of current in circuits by focusing on the part of the circuit outside of the battery. That is, we will focus on current that passes from one battery terminal, through the circuit, and back to the other terminal. At the end of the chapter we will review and extend our previous discussions about what goes on inside devices like batteries and generators.

Consider the simple *single-loop* circuit of Fig. 27-2 consisting of an ideal battery, a resistor, R , and two ideal connecting wires. Unless otherwise indicated, we assume that wires in circuits have negligible resistance. Their function, then, is merely to provide pathways along which charge carriers can move. Through use of stored chemical energy (a form of internal potential energy), the battery keeps one of its terminals (called the positive terminal and often labeled $+$) at a higher electric potential than the other terminal (called the negative terminal and labeled $-$).

The mobile negative charge carriers in the circuit wires move preferentially toward the positive terminal and away from the negative terminal. As a result, for the circuit shown in Fig. 27-2, we have a net flow of negative charge in a counterclockwise direction. In Chapter 26, we discussed the fact that a flow of negative electrons in one direction is macroscopically indistinguishable from a flow of positive charges in the other direction. For historical reasons we continue the practice established in that chapter of working with current as if the charge carriers are positive.

The direction of the conventional current in the circuit shown in Fig. 27-2 is noted with arrows that are labeled i . Unless otherwise noted, we will continue the practice of using conventional (positive) current in our analysis of electric circuits. We will reach the same conclusions about the fundamental behavior of circuits as we would if we had used electron currents.

To begin learning how to calculate currents in circuits, let's start with the ideal circuit depicted in Fig. 27-2. We have marked the points just before and after each element with the letters a , b , c , and d . Let's start at point a and proceed around the circuit in either direction, adding any changes in potential we encounter. Once we return to our starting point, we must also have returned to our starting potential. In words, the potential energy change per unit of charge traveling through the battery plus the potential energy change of the charge traveling through the wires and the resistors must be zero. This can be denoted as

$$\Delta V_{a \rightarrow b} + \Delta V_{b \rightarrow c} + \Delta V_{c \rightarrow d} + \Delta V_{d \rightarrow a} = \Delta V_{a \rightarrow a} = 0 \text{ V}.$$

For our simple circuit in Fig. 27-2 the charges gain potential while traveling from a to b due to the energy boost from the battery so that $\Delta V_{a \rightarrow b} = V_b - V_a = \Delta V_B$. The charges then flow freely from b to c through the first segment of the ideal conductor with no potential loss since the wire has a negligible resistance. Then the charges flow through the resistor, R . Finally, they flow back to point a , through another length of ideal wire.

$$\Delta V_B + \Delta V_{c \rightarrow d} = 0 \text{ V},$$

where ΔV_B represents a positive change in potential per unit charge as charges proceed from point a to point b by moving through the battery. Recall that if our ohmic resistor has a fixed value R , then we noted in Eq. 26-7 that $\Delta V = iR$ where i is the cur-

rent passing through the circuit. However, Eq. 26-7 didn't specify whether the ΔV refers to $\Delta V_{c \rightarrow d}$ or $\Delta V_{d \rightarrow c} = -\Delta V_{c \rightarrow d}$. It is clear from the context that if we proceed through the loop from c to d , $\Delta V_{c \rightarrow d}$ must be negative so it will cancel the ΔV_B , which we know is positive. This tells us the following about the mathematics of finding the potential difference across a resistor:

$$\Delta V_{d \rightarrow c} = iR \quad \text{and} \quad \Delta V_{c \rightarrow d} = -iR.$$

In other words, charges lose potential as they travel through a resistor. This makes sense physically because resistors give off energy in the form of heat and light. So our battery acts as a pump to increase the potential energy of a charge and the charge loses potential energy in passing through a resistive device.

This can be summarized as the loop rule.

LOOP RULE: The algebraic sum of the changes in potential encountered in a complete traversal of any loop of a circuit must be zero.

This is often referred to as *Kirchhoff's loop rule* (or *Kirchhoff's voltage law*), after German physicist Gustav Robert Kirchhoff. This rule is analogous to what happens when you hike around a mountain. If you start from any point on a mountain and return to the same point after walking around it, the algebraic sum of the changes in elevation you encounter must be zero. Thus, you end up at the same gravitational potential as you had before you started. Although we developed this rule through consideration of a single-loop circuit, it also holds for any complete loop in a *multi-loop* circuit, no matter how complicated.

In Fig. 27-2, we will start at point a , whose potential is V_a , and mentally walk clockwise around the circuit until we are back at a , keeping track of potential changes as we move. (Our starting point is at the low-potential terminal of the battery—the negative terminal.) The potential difference between the battery terminals is equal to ΔV_B . When we pass through the battery from the low to high-potential terminal, the change in potential is positive.

As we walk along the top wire to the top end of the resistor, there is no potential change because the wire has negligible resistance; it is at the same potential as the high-potential terminal of the battery. So too is the top end of the resistor. When we pass through the resistor in the direction of the current flow, the potential decreases by an amount equal to $-iR$. We know the potential decreases because we are moving from the higher potential terminal of the resistor to the lower potential terminal.

For a walk around a single-loop circuit of total resistance R in *the direction of the current* our loop rule gives us

$$\Delta V_B - iR = 0 \text{ V}.$$

Solving this equation for i gives us

$$i = \frac{\Delta V_B}{R} \quad (\text{single-loop circuit}). \quad (27-1)$$

If we apply the loop rule to a complete walk around a single-loop circuit of total resistance R *against the direction of current*, the rule gives us

$$-\Delta V_B + iR = 0 \text{ V},$$

and we again find that

$$i = \frac{\Delta V_B}{R} \quad (\text{single-loop circuit}).$$

Thus, you may mentally circle a loop in either direction to apply the loop rule.

To prepare for circuits more complex than Fig. 27-2, let us summarize two rules for finding potential differences as we move around a chosen loop:

RESISTANCE RULE: For a move through a resistor in the direction of the conventional current, the change in potential is $-iR$; in the opposite direction of current flow it is $+iR$.

POTENTIAL RULE: For a move through a source of potential difference from low potential (for example, the negative terminal on a battery denoted a) to high potential (for example, the positive terminal on a battery denoted b) the change in potential is positive and given by $V_b - V_a = \Delta V_B$; in the opposite direction it is negative and given by $V_a - V_b = -\Delta V_B$.

What happens to the amount of current as it passes through a resistor? Is the current going into the resistor the same as the current coming out of the resistor? Or does a resistor (for example, a lightbulb) “use up” current? Recall that in Fig. 26-5 we depicted observations involving batteries and bulbs that clearly showed current is constant throughout a single loop circuit when resistors are connected in series. You can easily replicate these observations using fresh flashlight batteries, copper wires, and 1.5 V bulbs.

READING EXERCISE 27-2: It is asserted above that we can infer that the current flow into and out of a resistor is the same because three lightbulbs connected in series glow equally brightly. Suppose the resistors shown in Fig. 27-3a are lightbulbs. Describe the brightness of the third bulb relative to the first and second bulbs under the following assumptions: (a) All the current is used up by the first bulb; (b) most of the current is used up by the first bulb; (c) a small amount of the current was used up by the first bulb. ■

READING EXERCISE 27-3: The figure to the right shows the conventional current i in a single-loop circuit with a battery B and a resistor R (and wires of negligible resistance). At points a , b , and c , rank (a) the amount of the current and (b) the electric potential, greatest first. ■

(a)

(b)

FIGURE 27-3 ■ (a) Three resistors are connected in series between points a and b . (b) An equivalent circuit, with the three resistors replaced with their equivalent resistance R_{eq} .

27-3 Series Resistance

We now turn our attention to more complicated single-loop circuits. Figure 27-3a shows three resistors connected in series to an ideal battery with potential difference ΔV_B between its terminals. Note that the three resistors are connected one after another between b and c , c and d , and d and a . Also an ideal battery maintains a potential difference across the series of resistors (between points a and b). If we apply the loop rule for charges moving in the direction of conventional current from point a at the negative terminal of the battery and proceeding through the loop until we encounter point a , again we get

$$\Delta V_{a \rightarrow b} + \Delta V_{b \rightarrow c} + \Delta V_{c \rightarrow d} + \Delta V_{d \rightarrow a} = 0 \text{ V.} \quad (27-2)$$

Because we know that current is not used up by a resistor, we know the current flowing through the loop is the same everywhere, and so the current through each resistor must be the same. We also assume there is no potential difference along any segment of wire. If we consider the three resistors separately, applying the loop rule in the

same manner (starting at the positive terminal of the battery and proceeding through the loop in the direction of conventional current) gives

$$\Delta V_B + (-iR_1) + (-iR_2) + (-iR_3) = 0 \text{ V.}$$

By rearranging terms in the equation above we get

$$\Delta V_B - i(R_1 + R_2 + R_3) = 0 \text{ V,} \quad (27-3)$$

and defining an equivalent resistance as $R_{\text{eq}} = R_1 + R_2 + R_3$ we find that Eq. 27-3 reduces to the same form as Eq. 27-1 with the equivalent resistance playing the role of the resistance in a circuit that has only one resistance. This is illustrated in Fig. 27-3.

Equating these two expressions tells us two things. First, the potential difference across the whole series of resistors is equal to the sum of the potential differences across the three resistors. Second, the potential difference across the whole series of resistors is equal to the potential difference across our ideal battery. Figure 27-3*b* shows the equivalent resistance, with a new resistor R_{eq} , that can replace the three resistors of Fig. 27-3*a*.

The result $R_{\text{eq}} = R_1 + R_2 + R_3$ is not surprising because it is compatible with the experimental findings we presented in Section 26-6: the resistance of a length of wire is directly proportional to its length (Eq. 26-8). Imagine three different carbon resistors like those depicted in the previous chapter (Fig. 26-21). Suppose these resistors are connected by ideal conductors (with almost no resistivity) having the same graphite material in their centers each with the same cross-sectional area. Giving the resistors different values of resistance would involve having the centers of the resistors be three different lengths. We would then expect the total resistance to be proportional to the sum of the three lengths of the resistors' graphite centers.

Obviously, we can extend our method of finding the equivalent resistance from 3 to N resistors by expanding Eq. 27-3 into the equation

$$R_{\text{eq}} = R_1 + R_2 + R_3 + \cdots + R_N = \sum_{j=1}^N R_j \quad (N \text{ resistors in series}). \quad (27-4)$$

Note that when resistors are in series, their equivalent resistance is always *greater* than that of any of the individual resistors. Also, the current moving through resistors wired in series can move along only a single route. If there are additional routes so the currents in different resistors are different, the resistors are not connected in series.

In general:

If N resistors in series were covered by a box, the resistors could be replaced by a single equivalent resistor with a value $R_{\text{eq}} = R_1 + R_2 + R_3 + \cdots + R_N$. Someone making measurements outside the box could not tell whether there is a single equivalent resistor or a series of individual resistors.

In short, we conclude that if we replace a series of resistors with a single equivalent resistor, the new circuit will have the same overall potential differences and currents as the original one (so long as we don't measure potential drops between the resistors wired in series).

More on Ammeters

Analog ammeters work by measuring the torque exerted by magnetic forces on a current-carrying wire. We discuss more about their operation in Chapter 29 on magnetic

FIGURE 27-4 ■ This depicts how an ammeter can be inserted into a series circuit to measure the current. The third resistor represents the small resistance R_A of the ammeter itself.

fields. However, we continue our discussion of these devices from Chapter 26 and consider some important attributes the ammeter must have.

Recall from Chapter 26 that to measure the current in a wire, you are to break or cut the wire and insert the ammeter in series with an arm of the circuit so the current to be measured passes through the meter. (In Fig. 27-4, ammeter A is set up to measure current i).

When measuring the current in a circuit (or anything else for that matter) it is imperative that the measurement tool does not significantly change the quantity you are trying to measure. Hence, it is essential that the resistance R_A of the ammeter be very small compared to other resistances in the circuit. Otherwise, the presence of the meter will significantly change the current flow in the circuit, and measured current will be an inaccurate representation of the true current.

READING EXERCISE 27-4: In Fig. 27-3a, if $R_1 > R_2 > R_3$, rank the three resistances according to (a) the current through them and (b) the potential difference across them, greatest first. ■

READING EXERCISE 27-5: Consider an ammeter inserted into the circuit shown in Fig. 27-4. Compare the amount of current flowing through R_1 under the following three conditions: (a) without the ammeter inserted, (b) when the ammeter has a resistance much less than the equivalent resistance of $R_1 + R_2$, and (c) when the ammeter has a resistance equal to the equivalent resistance of $R_1 + R_2$. Explain your reasoning. Discuss the implications of your result on designing an ammeter. ■

27-4 Multiloop Circuits

FIGURE 27-5 ■ A multiloop circuit consisting of three branches: left-hand branch bad , right-hand branch bcd , and central branch bd . The circuit has three loops we could choose to follow: left-hand loop $badb$, right-hand loop $bcd b$, and big loop $badcb$.

Figure 27-5 shows a circuit containing more than one loop. There are two points (b and d) at which the current branches split off or come together. We call such branching points **junctions**. For the circuit shown in Fig. 27-5, we would say there are two junctions, at b and d , and there are three *branches* connecting these junctions. The branches are the left branch (bad), the right branch (bcd), and the central branch (bd).

What are the currents in the three branches? We arbitrarily label the currents, using a different subscript for each branch. Because current is not used up and there are no additional branching points, current i_1 has the same value everywhere in branch bad , i_2 has the same value everywhere in branch bcd , and i_3 is the current through branch bd . The directions of the currents are assigned arbitrarily.

Consider junction d for a moment: charge comes into that junction via incoming currents i_1 and i_3 , and it leaves via outgoing current i_2 . Because charged particles neither accumulate nor disperse at the junction, the total incoming charge must be equal to the total outgoing charge. Hence, through conservation of charge arguments, we conclude that the total current coming into junction d must equal the total current leaving junction d ,

$$i_{\text{in}} = i_{\text{out}},$$

or

$$i_1 + i_3 = i_2. \quad (27-5)$$

You can easily check that application of this condition to junction b leads to exactly the same equation. This expression for the current in branch 2 thus suggests a general principle:

JUNCTION RULE: The sum of the currents entering any junction must be equal to the sum of the currents leaving that junction.

This rule is often called *Kirchhoff's junction rule* (or *Kirchhoff's current law*). It is simply a statement of the conservation of charge for a steady flow of charge—there is neither a buildup nor a depletion of charge at a junction. Thus, our basic tools for solving complex circuits are the *loop rule* (based on the conservation of energy) and the *junction rule* (based on the conservation of charge).

The relationship between i_1 , i_2 , and i_3 above is a single equation involving three unknowns. To solve the circuit completely (that is, to find all three currents), we need two more equations involving those same unknowns. We obtain them by applying the loop rule twice. In the circuit of Fig. 27-5, we have three loops from which to choose: the left-hand loop ($badb$), the right-hand loop ($bcd b$), and the big loop ($badcb$). Which two loops we choose turns out not to matter so long as we manage to pass through all the circuit elements at least once. For now, let's choose the left-hand loop and the right-hand loop.

If we traverse the left-hand loop in a counterclockwise direction from point b , the loop rule gives us

$$\Delta V_{B1} - i_1 R_1 + i_3 R_3 = 0 \text{ V}, \quad (27-6)$$

where ΔV_{B1} is the difference in potential between the terminals of battery 1. If we traverse the right-hand loop in a counterclockwise direction from point b , the loop rule gives us an equation involving battery 2,

$$-i_3 R_3 - i_2 R_2 - \Delta V_{B2} = 0 \text{ V}. \quad (27-7)$$

We now have three equations (Eqs. 27-5, 27-6, and 27-7) containing the three unknown currents, and they can be solved by a variety of mathematical techniques.

If we had applied the loop rule to the big loop, we would have obtained (moving counterclockwise from b) the equation

$$\Delta V_{B1} - i_1 R_1 - i_2 R_2 - \Delta V_{B2} = 0 \text{ V}.$$

This equation may look like fresh information, but in fact it is only the sum of Eqs. 27-6 and 27-7. (It would, however, yield the proper results when used with Eq. 27-5 and either 27-6 or 27-7.)

It is important to note that the assumed direction of the currents in a branch of the circuit do not have to be correct to get a correct solution. We must only keep track of the assumptions we have made. If in solving the resulting algebraic expressions we find that one of our currents turns out to have a negative value, then (because of the negative value) we know we made a wrong assumption about the direction of the current in that branch of the circuit.

In general, the total number of equations needed will be equal to the total number of independent loops in the circuit. The number of independent loops is simply the minimum number of loops needed to cover every branch in the circuit. Although some branches could be covered twice, every circuit element would be “covered” at least once. For example, we need at least two equations to cover all the loops in the circuit in Fig. 27-5 and at least three equations to cover all the loops in the more complex circuit in Fig. 27-6.

27-5 Parallel Resistance

Figure 27-6a shows three resistances connected by branching junctions. Resistances that are parts of separate loops like those in Fig. 27-6a are said to be connected *in parallel* to the battery. Resistors connected “in parallel” are directly wired together on one side and directly wired together on the other side, and a potential difference ΔV

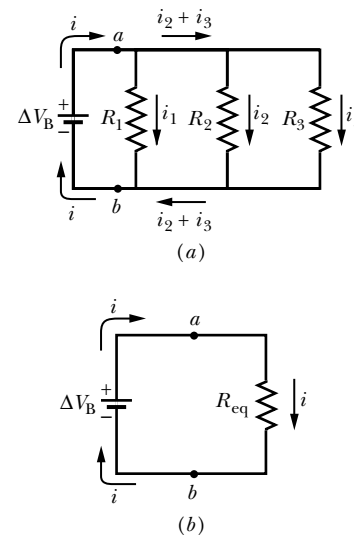

FIGURE 27-6 (a) Three resistors connected in parallel across points a and b . (b) An equivalent circuit, with the three resistors replaced with their equivalent resistance R_{eq} .

is applied across the pair of connected sides. Thus, the resistances have the same potential difference ΔV across them, producing a current through each. Because we are assuming ideal wires, there is no potential difference across the wires. Therefore, the potential across the top branch of the circuit is constant everywhere equal to the potential at the positive pole of the battery, and the potential across the bottom branch of the circuit is constant everywhere equal to the potential at the negative pole of the battery. In general,

When a potential difference ΔV is applied across resistances connected in parallel, each resistor has the same potential difference ΔV across it.

Notice that we have again labeled the currents in each of the branches i_1 , i_2 , and i_3 . We have discussed the way in which the current into a junction is equal to the current out of the junction. We have not yet discussed in what proportions currents divide when there is a branch (a choice of path) in a circuit. Are all three currents i_1 , i_2 , and i_3 equal? If not, which of these currents is largest? The answer to this question becomes clear when we write out the expressions for current through each of the resistors in Fig. 27-6 using the potential rule for loops. For the case pictured here, we have

$$i_1 = \frac{\Delta V}{R_1}, \quad i_2 = \frac{\Delta V}{R_2}, \quad \text{and} \quad i_3 = \frac{\Delta V}{R_3}. \quad (27-8)$$

Since each resistor is connected so it has the same potential difference across it, it is straightforward to see how the sizes of the currents compare to each other. If the resistances are all equal, the current through each is the same. However, if the three resistances are not equal, more current flows through the smaller resistances. This outcome is consistent with what we might predict based solely on an understanding that a resistor is just a device that resists the flow of current.

If we want to simplify how we think about a circuit that has resistors wired in parallel (like that shown in Fig. 27-6a), we can treat the three resistors in parallel as if they have been replaced by a single equivalent resistor R_{eq} . Figure 27-6b shows the three parallel resistances replaced with an equivalent resistance R_{eq} . The applied potential difference ΔV_B is maintained by a battery. We can see from this figure that the potential difference across the equivalent resistance would have to be the same as the potential difference applied across each of the original resistors. Furthermore, the equivalent resistor would have to have the same total current ($i_1 + i_2 + i_3$) through it as the original three resistors.

Resistances connected in parallel can be replaced with an equivalent resistance R_{eq} . If the equivalent resistance has the same potential difference applied across it, then the current through it will equal the sum of currents flowing through the original resistors.

To derive an expression for R_{eq} in Fig. 27-6b, we first write the current in each of the resistors in Fig. 27-6a as

$$i_1 = \frac{\Delta V}{R_1}, \quad i_2 = \frac{\Delta V}{R_2}, \quad \text{and} \quad i_3 = \frac{\Delta V}{R_3}, \quad (\text{Eq. 27-8})$$

where ΔV is the potential difference between a and b . If we apply the junction rule at point a in Fig. 27-6a and then substitute these values, we find

$$i = i_1 + i_2 + i_3 = \Delta V \left(\frac{1}{R_1} + \frac{1}{R_2} + \frac{1}{R_3} \right). \quad (27-9)$$

If we instead consider the parallel combination with the equivalent resistance R_{eq} (Fig. 27-6b), we have

$$i = \frac{\Delta V}{R_{\text{eq}}} = \Delta V \left(\frac{1}{R_{\text{eq}}} \right). \quad (27-10)$$

Comparing the two equations above leads to

$$\frac{1}{R_{\text{eq}}} = \frac{1}{R_1} + \frac{1}{R_2} + \frac{1}{R_3}. \quad (27-11)$$

The result $1/R_{\text{eq}} = 1/R_1 + 1/R_2 + 1/R_3$ is not surprising because it is compatible with the experimental findings we presented in Section 26-6: the resistance of a length of wire is inversely proportional to its cross-sectional area (Eq. 26-8). To see this connection, imagine three different carbon resistors like those depicted in the last chapter (Fig. 26-21) connected in parallel. Then giving them different values of resistance would involve having the centers of the resistors have three different cross-sectional areas. Because the resistors are connected in parallel, we would then expect the total cross-sectional area to be the sum of the three cross-sectional areas of the resistors' graphite centers so $A_{\text{eq}} = A_1 + A_2 + A_3$. Since the cross-sectional area and resistance are inversely proportional, we get $1/R_{\text{eq}} = 1/R_1 + 1/R_2 + 1/R_3$.

Extending Eq. 27-11 to the case of n resistors, we have

$$\frac{1}{R_{\text{eq}}} = \sum_{j=1}^n \frac{1}{R_j} \quad (n \text{ resistors in parallel}). \quad (27-12)$$

Since we often deal with the case of two resistors in parallel, it is worth it for us to consider this case a bit more. For the case of two resistors, the equivalent resistance is

$$\frac{1}{R_{\text{eq}}} = \frac{1}{R_1} + \frac{1}{R_2}.$$

With a bit of algebra, this becomes

$$R_{\text{eq}} = \frac{R_1 R_2}{R_1 + R_2} \quad (2 \text{ resistors in parallel}). \quad (27-13)$$

If you accidentally took the equivalent resistance to be the sum divided by the product, you would notice at once that this result would be dimensionally incorrect.

Note that when two or more resistors are connected in parallel, the equivalent resistance is smaller than any of the combining resistances.

More on the Voltmeter

Recall from our discussion in Chapter 26 that a meter used to measure potential differences is called a *voltmeter*. To measure the potential difference between any two points in the circuit, the voltmeter terminals are connected across those points, without breaking or cutting the wire. In Fig. 27-7, voltmeter V is set up to measure the potential difference across a resistor R_1 . The voltmeter is inserted in parallel to R_1 by connecting its terminals to points d and e in the circuit.

To prevent the voltmeter from affecting a measurement, it is essential that the resistance R_V of a voltmeter be *very large* compared to the resistance of the circuit element across which the voltmeter is connected. Otherwise, the meter becomes an important circuit element by drawing a significant current through itself. This change

FIGURE 27-7 ■ A single-loop circuit, showing how to connect a voltmeter (V). The third resistor R_V represents the resistance of the voltmeter itself. We assume that R_V is very large compared to R_1 and R_2 .

in current flow can alter the potential difference to be measured. On the other hand, even if the potential difference across the voltmeter is large, if a very small current flows through the voltmeter, the flow of current through R_1 will not change very much.

READING EXERCISE 27-6: A battery, with potential ΔV_B across it, is connected to a combination of two identical resistors and a current i flows through the battery. What is the potential difference across and the current through either resistor if the resistors are (a) in series, and (b) in parallel? ■

READING EXERCISE 27-7: Consider the voltmeter inserted into the circuit shown in Fig. 27-7. Describe what would happen if the voltmeter has a resistance $R_V \ll R_1$. How would this affect the potential difference measured across the resistor R_1 ? Describe what would happen if the voltmeter has a resistance $R_V \gg R_1$. How would this affect the potential difference measured across the resistor R_1 ? Which case would give the most “accurate” measure of the potential difference across the resistor when the voltmeter is not a part of the circuit? ■

READING EXERCISE 27-8: Suppose the resistors in Fig. 27-6a are all identical lightbulbs. Rank the brightness of the three bulbs. Compare the brightness of each of the bulbs to the brightness of one of the bulbs alone connected to the same battery. ■

TOUCHSTONE EXAMPLE 27-1: One Battery and Four Resistances

Figure 27-8a shows a multiloop circuit containing one ideal battery and four resistances with the following values:

$$R_1 = 20 \, \Omega, \quad R_2 = 20 \, \Omega, \quad \Delta V_B = 12 \, \text{V}, \\ R_3 = 30 \, \Omega, \quad \text{and} \quad R_4 = 8.0 \, \Omega.$$

(a) What is the current through the battery?

SOLUTION ■ First note that the current through the battery must also be the current through R_1 . Thus, one **Key Idea** here is that we might find that current by applying the loop rule to a loop that includes R_1 because the current would be included in the potential difference across R_1 . Either the left-hand loop or the big loop will do. Noting that the potential difference arrow of the battery points upward so the current the battery supplies is clockwise, we might apply the loop rule to the left-hand loop, clockwise from point a . With i being the current through the battery, we would get

$$+\Delta V_B - iR_1 - iR_2 - iR_4 = 0 \, \text{V}. \quad (\text{incorrect})$$

However, this equation is incorrect because it assumes that R_1 , R_2 , and R_4 all have the same current i . Resistances R_1 and R_4 do have the same current, because the current passing through R_4 must pass through the battery and then through R_1 with no change in value. However, that current splits at junction point b —only part passes through R_2 , and the rest through R_3 .

To distinguish the several currents in the circuit, we must label them individually as in Fig. 27-8b. Then, circling clockwise from a , we can write the loop rule for the left-hand loop as

$$+\Delta V_B - i_1 R_1 - i_2 R_2 - i_1 R_4 = 0 \, \text{V}.$$

Unfortunately, this equation contains two unknowns, i_1 and i_2 ; we need at least one more equation to find them.

A second **Key Idea** is that an easier option is to simplify the circuit of Fig. 27-8b by finding equivalent resistances. Note carefully that R_1 and R_2 are *not* in series and thus cannot be replaced with an equivalent resistance. However, R_2 and R_3 are in parallel, so we can use either Eq. 27-12 or Eq. 27-13 to find their equivalent resistance R_{23} . From the latter,

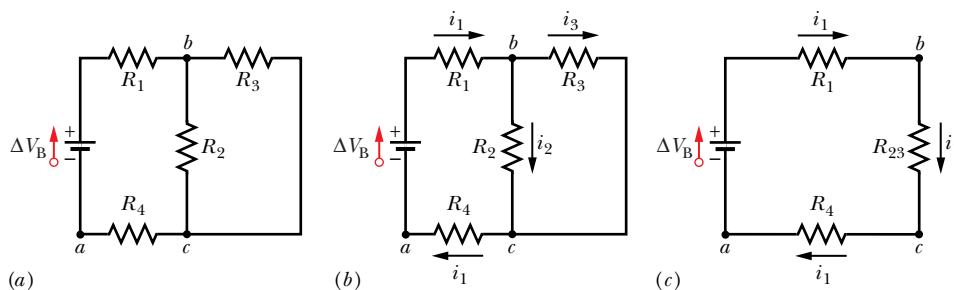

FIGURE 27-8 ■ (a) A multiloop circuit with an ideal battery of potential difference ΔV_B and four resistances. (b) Assumed currents through the resistances. (c) A simplification of the circuit, with resistances R_2 and R_3 replaced with their equivalent resistance R_{23} . The current through R_{23} is equal to that through R_1 and R_4 .

$$R_{23} = \frac{R_2 R_3}{R_2 + R_3} = \frac{(20 \Omega)(30 \Omega)}{50 \Omega} = 12 \Omega.$$

We can now redraw the circuit as in Fig. 27-8c; note that the current through R_{23} must be i_1 because charge that moves through R_1 and R_4 must also move through R_{23} . For this simple one-loop circuit, the loop rule (applied clockwise from point a) yields

$$+\Delta V_B - i_1 R_1 - i_1 R_{23} - i_1 R_4 = 0 \text{ V}.$$

Substituting the given data, we find

$$12 \text{ V} - i_1(20 \Omega) - i_1(12 \Omega) - i_1(8.0 \Omega) = 0 \text{ V},$$

which gives us

$$i_1 = \frac{12 \text{ V}}{40 \Omega} = 0.30 \text{ A}. \quad (\text{Answer})$$

(b) What is the current i_2 through R_2 ?

SOLUTION ■ One **Key Idea** here is that we must work backward from the equivalent circuit of Fig. 27-8c, where R_{23} has replaced the parallel resistances R_2 and R_3 . A second **Key Idea** is

that, because R_2 and R_3 are in parallel, they both have the same potential difference across them as their equivalent R_{23} . We know the current through R_{23} is $i_1 = 0.30 \text{ A}$. Thus, we can use Eq. 26-5 $R = \Delta V/i$ to find the potential difference ΔV_{23} across R_{23} :

$$\Delta V_{23} = i_1 R_{23} = (0.30 \text{ A})(12 \Omega) = 3.6 \text{ V}.$$

The potential difference across R_2 is thus 3.6 V, so the current i_2 in R_2 must be, by Eq. 26-5,

$$i_2 = \frac{\Delta V_2}{R_2} = \frac{3.6 \text{ V}}{20 \Omega} = 0.18 \text{ A}. \quad (\text{Answer})$$

(c) What is the current i_3 through R_3 ?

SOLUTION ■ We can answer by using the same technique as in (b), or we can use this **Key Idea**: The junction rule tells us that at point b in Fig. 27-8b, the incoming current i_1 and the outgoing currents i_2 and i_3 are related by

$$i_1 = i_2 + i_3.$$

This gives us

$$i_3 = i_1 - i_2 = 0.30 \text{ A} - 0.18 \text{ A} = 0.12 \text{ A}. \quad (\text{Answer})$$

TOUCHSTONE EXAMPLE 27-2: Three Batteries and Five Resistances

Figure 27-9 shows a circuit with three ideal batteries in it. Two of these batteries labeled ΔV_{B2} are identical. The circuit elements have the following values:

$$\Delta V_{B1} = 3.0 \text{ V}, \quad \Delta V_{B2} = 6.0 \text{ V}, \quad R_1 = 2.0 \Omega, \quad R_2 = 4.0 \Omega.$$

FIGURE 27-9 ■ A multiloop circuit with three ideal batteries and five resistances.

Find the amount and direction of the current in each of the three branches.

SOLUTION ■ It is not worthwhile to try to simplify this circuit, because no two resistors are in parallel, and the resistors that are in series (those in the right branch or those in the left branch) present no problem. So our **Key Idea** is to apply the junction and loop rules to this circuit.

Using arbitrarily chosen directions for the currents as shown in Fig. 27-9, we apply the junction rule at point a by writing

$$i_3 = i_1 + i_2. \quad (27-14)$$

An application of the junction rule at junction b gives only the same equation, so we next apply the loop rule to any two of the three loops of the circuit. We first arbitrarily choose the left-hand loop, arbitrarily start at point a , and arbitrarily traverse the loop in the counterclockwise direction, obtaining

$$-i_1 R_1 - \Delta V_{B1} - i_1 R_1 + \Delta V_{B2} + i_2 R_2 = 0 \text{ V}.$$

Substituting the given data and simplifying yield

$$i_1(4.0 \Omega) - i_2(4.0 \Omega) = 3.0 \text{ V}. \quad (27-15)$$

For our second application of the loop rule, we arbitrarily choose to traverse the right-hand loop clockwise from point a , finding

$$+i_3 R_1 - \Delta V_{B2} + i_3 R_1 + \Delta V_{B2} + i_2 R_2 = 0 \text{ V}.$$

Substituting the given data and simplifying yield

$$i_2(4.0 \Omega) + i_3(4.0 \Omega) = 0 \text{ V}. \quad (27-16)$$

Using Eq. 27-14 to eliminate i_3 from Eq. 27-16 and simplifying give us

$$i_1(4.0 \Omega) + i_2(8.0 \Omega) = 0 \text{ V}. \quad (27-17)$$

We now have a system of two equations (Eqs. 27-15 and 27-17) in two unknowns (i_1 and i_2) to solve either by hand (which is easy enough here) or with a math computer software package. (One solution technique is Cramer's rule, given in Appendix E.) We find

$$i_2 = -0.25 \text{ A.}$$

(The minus sign signals that our arbitrary choice of direction for i_2 in Fig. 27-9 is wrong; i_2 should point up through ΔV_{B2} and R_2 .) Substituting $i_2 = -0.25 \text{ A}$ into Eq. 27-17 and solving for i_1 then give us

$$i_1 = 0.50 \text{ A.} \quad (\text{Answer})$$

With Eq. 27-14 we then find that

$$i_3 = i_1 + i_2 = 0.25 \text{ A.} \quad (\text{Answer})$$

The positive answers we obtained for i_1 and i_3 signal that our choices of directions for these currents are correct. We can now correct the direction for i_2 and write its amount as

$$i_2 = 0.25 \text{ A.} \quad (\text{Answer})$$

27-6 Batteries and Energy

So far we have discussed ideal batteries that can be characterized as maintaining a constant potential difference between their terminals no matter what current is flowing through them. Also, we have concentrated on analyzing what happens in the part of the circuit that lies outside the battery. In this section we consider more about what goes on inside batteries and how real, not so ideal, batteries behave.

The amazing thing about a battery is that positive charge carriers enter with a low potential energy and other carriers emerge from the battery at a higher potential. Energy transformations inside a battery enable charges to overcome the forces exerted on them by the electric field inside the battery. Positive carriers seem to move opposite to the battery's electric field, whereas negative charge carriers move with it. There must be some other force present inside an energy-providing device enabling charges to swim upstream against electrical forces. The outdated term given to this "force" is electromotive force. Its abbreviation, which we still use today, is *emf*. How is this "force" defined? Where does it come from in a typical battery?

We define the *emf*, \mathcal{E} , of a battery in terms of the work done per unit charge on charges flowing into it:

$$\mathcal{E} \equiv \frac{dW}{dq} \quad (\text{definition of electromotive force}). \quad (27-18)$$

In words, the battery *emf* is the work per unit charge it does to move charge from one terminal to the other. The SI unit for *emf* is the joule/coulomb. In Chapter 25 we defined one joule/coulomb as the *volt*. There must be some source of energy within a battery, enabling it to do work on the charges. The energy source may be chemical, as in a battery (or a fuel cell). Temperature differences may supply the energy, as in a thermopile; or the Sun may supply it, as in a solar cell. As you can see, the term electromotive force is very misleading since it is not a force at all, but has the same units as electrostatic potential (energy per unit charge). Furthermore *emf* is a scalar quantity and is not a vector quantity like a force is.

When a battery is connected to a circuit, it transfers energy to the charge carriers passing through it. Let's look at one example of how chemical action can do this. For this purpose we will consider the chemical reactions that take place inside one cell of a lead acid battery used in most automobiles. A lead acid battery consists of several cells wired together in series. Each cell has two metal plates surrounded by a liquid bath of chemicals. In a lead-acid cell, the negative plate is made of pure lead, and the positive plate is made of lead-oxide. These plates are immersed in sulfuric acid mixed with water. The acid dissociates in the water into hydronium ions (H_3O^+) and bisulfate ions (HSO_4^-). This is shown in Fig. 27-10. Both the lead and lead oxide can react

FIGURE 27-10 ■ The chemical constituents of the lead acid battery.

with the bisulfate ions as follows:

The two electrons produced on the pure lead plate pile up on it. The second reaction removes the two electrons it needs from the lead oxide plate. Thus, each time the pair of reactions occur, electrons are added to the negative plate and removed from the positive plate. If the cell were not connected to a circuit, the reactions would stop when the charge difference gets so large that the energy needed to put more charges on the plates is greater than the energy released by the reactions. If the battery is connected to an external circuit, then as the charges flow through the circuit, they are removed from one plate and put back on the other; the process can keep going until all the sulfuric acid (HSO_4) is consumed.

Note that when we talk about a battery as a charge pump, this is somewhat misleading because the electrons removed by the chemical reaction at one battery terminal (plate) are not the same electrons released at the other terminal.

There are hundreds of different types of chemical batteries. The lead-acid battery action described here simply serves as an example of how chemical reactions can cause charge separation in a battery.

27-7 Internal Resistance and Power

In our evaluation of circuits up to this point, we have assumed the current passes through the battery (or other emf source) without encountering any resistance within it. We call such a battery or other emf device “ideal.”

An **ideal emf device** is one that lacks any resistance to the movement of charge through it. The potential difference between the terminals of an *ideal* emf device is equal to the emf of the device. For example, an ideal battery with an emf of 12.0 V has a potential difference of 12.0 V between its terminals. Very fresh alkaline batteries are nearly ideal.

A **real emf device** has internal resistance to the movement of charge through it. For a real emf device (for example, a real battery), the only situation for which the potential difference between its terminals is equal to its emf is when the device is not connected to a circuit, and thus does not have current through it. However, when the device has current through it, the potential difference between its terminals differs from its emf.

Figure 27-11a shows circuit elements that describe the behavior of a real battery, with internal resistance r , wired to an external resistor of resistance R . The internal

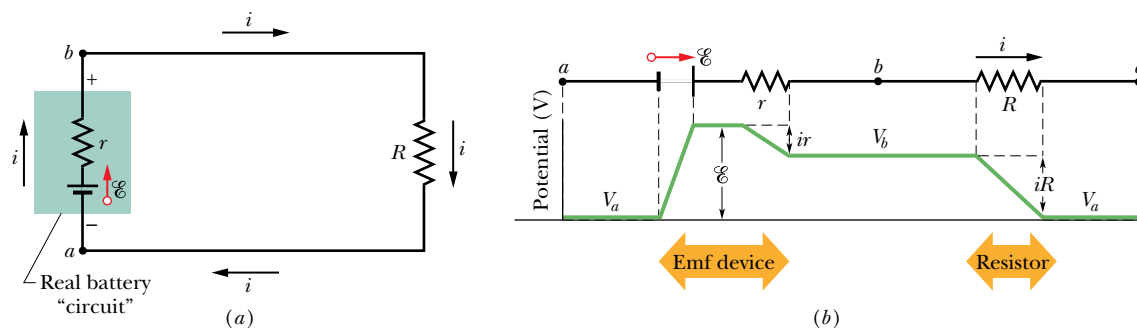

FIGURE 27-11 (a) A single-loop circuit containing a real battery having internal resistance r and emf \mathcal{E} . (b) The same circuit, now spread out in a line. The potentials encountered in traversing the circuit clockwise from a are also shown. The potential V_a is arbitrarily assigned a value of zero, and other potentials in the circuit are graphed relative to V_a .

resistance of the battery is the electrical resistance of the conducting materials of the battery and thus is an unavoidable feature of any real battery. However, as an illustration, a real battery is depicted in Fig. 27-11*b* as if it could be separated into an ideal battery with potential difference \mathcal{E} between its terminals and a resistor of resistance r . The order in which the symbols for these separated parts are drawn does not matter.

If we apply the potential (loop) rule, proceeding clockwise and beginning at point a , the *changes* in potential give us

$$\Delta V_{a \rightarrow b} + \Delta V_R = 0 \text{ V},$$

$$\text{or} \quad \mathcal{E} + \Delta V_{\text{internal resistance}} + \Delta V_R = 0 \text{ V}. \quad (27-19)$$

It is customary to keep track of potential differences as if the charge carriers are positive. Thus, we go through both resistances in the direction of the *conventional* current (defined in the previous chapter as the direction of flow we would find if the charge carriers were positive instead of negative):

$$\mathcal{E} - ir - iR = 0 \text{ V}. \quad (27-20)$$

Solving for the current, we find

$$i = \frac{\mathcal{E}}{R + r}. \quad (27-21)$$

Note that this equation reduces to Eq. 27-1 if the battery is ideal so that $r = 0 \Omega$.

Figure 27-11*b* shows graphically the changes in electric potential around the circuit. (To better link Fig. 27-11*b* with the *closed circuit* in Fig. 27-11*a*, imagine curling the graph into a cylinder with point a at the left overlapping point a at the right.) Note how traversing the circuit is like walking up and down a (potential) mountain and returning to your starting point—you also return to the starting elevation.

In this book, if a battery is not described as real or if no internal resistance is indicated, you can assume for simplicity that it is ideal.

Implications of Internal Resistance in Real EMF Devices

To understand the implications of internal resistance in emf devices for real circuits, let's try to make our understanding a bit more quantitative. To start with, let's see how $\Delta V_B = \Delta V_{a \rightarrow b} = V_b - V_a$, the potential difference across the battery terminals in Fig. 27-11, is affected by the existence of an internal resistance in the battery. To calculate $V_b - V_a$, we start at point a and follow the shorter path around to b , which takes us clockwise through the battery. We then have

$$V_a + \mathcal{E} - ir = V_b,$$

$$\text{or} \quad V_b - V_a = \Delta V_B = \mathcal{E} - ir, \quad (27-22)$$

where r is the internal resistance of the battery and \mathcal{E} is the emf of the battery. This expression tells us the potential difference of the battery is equal to the emf minus the drop in potential associated with internal resistance.

Furthermore, if we refer back to Eq. 27-21,

$$i = \frac{\mathcal{E}}{R + r},$$

and substitute this expression for current (in the circuit shown in Fig. 27-11) into our expression for the potential difference across the battery terminals, we get

$$\Delta V_B = \mathcal{E} - \left(\frac{\mathcal{E}r}{R + r} \right).$$

With some algebra, we get the following generally applicable expression:

$$\Delta V_B = \mathcal{E} \frac{R}{R + r}. \quad (27-23)$$

For example, suppose that in Fig. 27-11, $\mathcal{E} = 12 \text{ V}$, $R = 10 \text{ } \Omega$, and $r = 2.0 \text{ } \Omega$. Then the equation above tells us the potential across the battery's terminals is

$$\Delta V_B = (12 \text{ V}) \frac{10 \text{ } \Omega}{10 \text{ } \Omega + 2.0 \text{ } \Omega} = 10 \text{ V}.$$

In “pumping” charge through itself, the battery (via electrochemical reactions) does work per unit charge of $\mathcal{E} = 12 \text{ J/C}$, or 12 V . However, because of the internal resistance of the battery, it produces a potential difference of only 10 J/C , or 10 V , across its terminals.

If the internal resistance becomes large compared to the overall resistance in the circuit, the available potential difference of the battery, electrical generator, or other emf device will drop significantly. This drop in available potential difference results in a reduction in the amount of current in the circuit. This is especially important to consider when circuits are designed with a low resistance so they will carry a large current.

For example, consider the circuit shown in Fig. 27-6 (three resistors in parallel with a battery) and let $R = 3 \text{ } \Omega$ for each resistor. The equivalent resistance in the circuit is $R_{\text{eq}} = 1 \text{ } \Omega$. If the potential difference source is taken to be an ideal battery (internal resistance $r = 0$), the current in the circuit is

$$i = \frac{\Delta V_B}{R_{\text{eq}}} = \frac{12 \text{ V}}{1 \text{ } \Omega} = 12 \text{ A}.$$

The 12 amps are split evenly between each branch (because the resistances are all equal), so each resistor has 4 amps of current flowing through it.

However, if the potential difference source is a real battery with $\mathcal{E} = 12 \text{ V}$ and internal resistance $r = 2.0 \text{ } \Omega$, then the available potential difference from the battery is

$$\Delta V_B = (12 \text{ V}) \frac{1 \text{ } \Omega}{1 \text{ } \Omega + 2.0 \text{ } \Omega} = 4 \text{ V}.$$

The total current in the circuit is then

$$i = \frac{\Delta V_B}{R_{\text{eq}}} = \frac{4 \text{ V}}{1 \text{ } \Omega} = 4 \text{ A}.$$

This current is still split between each of the branches of the circuit, so for the case of the real battery, the current flowing through each resistor is now only $4/3$ amp. In comparison to the 4 amps produced by the ideal battery, one can see how the internal resistance of an emf device can play a significant role in the functioning of real circuits.

Power

When a battery or some other type of emf device does work on the charge carriers to establish a current i , it transfers energy from its source of energy (such as the chemical source in a battery) to the charge carriers. Because a real emf device has an internal resistance r , it also transfers energy to internal thermal energy via resistive dissipation, discussed in Chapter 26. Let us relate these transfers.

The net rate P of energy transfer from the emf device to the charge carriers is given by

$$P = i \Delta V, \quad (27-24)$$

where ΔV is the potential across the terminals of the emf device. (Note that this is the power associated with the transfer). If we apply this expression to the circuit shown in Fig. 27-11 (from Eq. 27-24 above), we can substitute $\Delta V_B = \mathcal{E} - ir$ into Eq. 27-24 to find

$$P = i(\mathcal{E} - ir) = i\mathcal{E} - i^2r. \quad (27-25)$$

We see that the term i^2r in Eq. 27-25 is the rate P_r of energy transfer to thermal energy within the emf device:

$$P_r = i^2r \quad (\text{internal dissipation rate}). \quad (27-26)$$

Then the term $i\mathcal{E}$ in Eq. 27-25 must be the rate P_{emf} at which the emf device transfers energy to *both* the charge carriers and to internal thermal energy. Thus,

$$P_{\text{emf}} = i\mathcal{E} \quad (\text{power of emf device}). \quad (27-27)$$

If a battery is being *recharged*, with a “wrong way” current through it, the energy transfer is then from the charge carriers to the battery—both to the battery’s chemical energy and to the energy dissipated in the internal resistance r . The rate of change of the chemical energy is given by Eq. 27-27, the rate of dissipation is given by Eq. 27-26, and the rate at which the carriers supply energy is given by Eq. 27-24.

As is the case for mechanics, the accepted SI unit for electrical power is the watt. One watt is equal to one joule-sec.

TOUCHSTONE EXAMPLE 27-3: Two Real Batteries

Let’s consider a circuit with two *nonideal* batteries that have internal resistances. Since the potential differences across the terminals of these batteries are not constant, we characterize each battery in terms of its emf (\mathcal{E}_1 or \mathcal{E}_2) and internal resistances (r_1 or r_2). The emfs and resistances in the circuit of Fig. 27-12a have the following values:

$$\mathcal{E}_1 = 4.4 \text{ V}, \quad \mathcal{E}_2 = 2.1 \text{ V}, \quad r_1 = 2.3 \ \Omega, \quad r_2 = 1.8 \ \Omega, \quad R = 5.5 \ \Omega.$$

(a) What is the current i in the circuit?

SOLUTION ■ The **Key Idea** here is that we can get an expression involving the current i in this single-loop circuit by applying the loop rule. Although knowing the direction of i is not necessary, we can easily determine it from the emfs of the two batteries. Because \mathcal{E}_1 is greater than \mathcal{E}_2 , battery 1 controls the direction of i , so that direction

is clockwise. Let us then apply the loop rule by going counterclockwise—against the current—and starting at point a . We find

$$-\mathcal{E}_1 + ir_1 + iR + ir_2 + \mathcal{E}_2 = 0 \text{ V}.$$

Check that this equation also results if we apply the loop rule clockwise or start at some point other than a . Also, take the time to compare this equation term by term with Fig. 27-12b, which shows the potential changes graphically (with the potential at point a arbitrarily taken to be zero).

Solving the above loop equation for the current i , we obtain

$$\begin{aligned} i &= \frac{\mathcal{E}_1 - \mathcal{E}_2}{R + r_1 + r_2} = \frac{4.4 \text{ V} - 2.1 \text{ V}}{5.5 \ \Omega + 2.3 \ \Omega + 1.8 \ \Omega} \\ &= 0.2396 \text{ A} \approx 240 \text{ mA}. \end{aligned} \quad (\text{Answer})$$

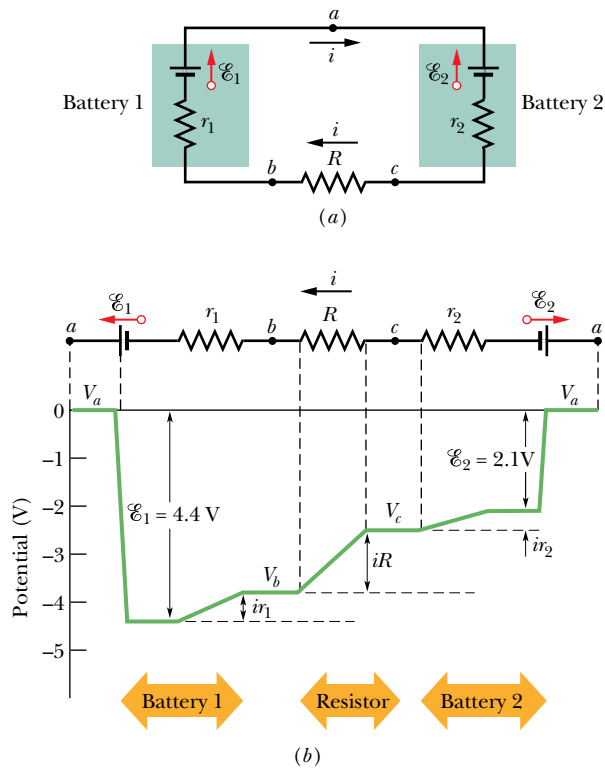

FIGURE 27-12 (a) A single-loop circuit containing two real batteries and a resistor. The batteries oppose each other; that is, they tend to send current in opposite directions through the resistor. (b) A graph of the potentials encountered in traversing this circuit counterclockwise from point a , with the potential at a arbitrarily taken to be zero. (To better link the circuit with the graph, mentally cut the circuit at a and then unfold the left side of the circuit toward the left and the right side of the circuit toward the right.)

(b) What is the potential difference between the terminals of battery 1 in Fig. 27-12a?

SOLUTION ■ The **Key Idea** is to sum the potential differences between points a and b . Let us start at point b (effectively the negative terminal of battery 1) and travel clockwise through battery 1 to point a (effectively the positive terminal), keeping track of potential changes. We find that

$$V_b - ir_1 + \mathcal{E}_1 = V_a,$$

which gives us

$$\begin{aligned} V_a - V_b &= -ir_1 + \mathcal{E}_1 \\ &= -(0.2396 \text{ A})(2.3 \Omega) + 4.4 \text{ V} \\ &= +3.84 \text{ V} \approx 3.8 \text{ V}, \end{aligned}$$

which is less than the emf of the battery. You can verify this result by starting at point b in Fig. 27-12a and traversing the circuit counterclockwise to point a .

TOUCHSTONE EXAMPLE 27-4: Electric Eel

Electric fish generate current with biological cells called *electroplaques*, which are physiological emf devices. The electroplaques in the South American eel shown in the photograph that opens this chapter are arranged in 140 rows, each row stretching horizontally along the body and each containing 5000 electroplaques. The arrangement is suggested in Fig. 27-13a; each electroplaque has an emf \mathcal{E} of 0.15 V and an internal resistance r of 0.25 Ω . The water surrounding the eel completes a circuit between the two ends of the electroplaque array, one end at the animal's head and the other near its tail.

(a) If the water surrounding the eel has resistance $R_{\text{water}} = 800 \Omega$, how much current can the eel produce in the water?

SOLUTION ■ The **Key Idea** here is that we can simplify the circuit of Fig. 27-13a by replacing combinations of emfs and internal

resistances with equivalent emfs and resistances. We first consider a single row. The total emf \mathcal{E}_{row} along a row of 5000 electroplaques is the sum of the emfs:

$$\mathcal{E}_{\text{row}} = 5000\mathcal{E} = (5000)(0.15 \text{ V}) = 750 \text{ V}.$$

The total resistance R_{row} along a row is the sum of the internal resistances of the 5000 electroplaques:

$$R_{\text{row}} = 5000r = (5000)(0.25 \Omega) = 1250 \Omega.$$

We can now represent each of the 140 identical rows as having a single emf \mathcal{E}_{row} and a single resistance R_{row} , as shown in Fig. 27-13b.

In Fig. 27-13b, the emf between point a and point b on any row is $\mathcal{E}_{\text{row}} = 750 \text{ V}$. Because the rows are identical and because they are all connected together at the left in Fig. 27-13b, all points b in

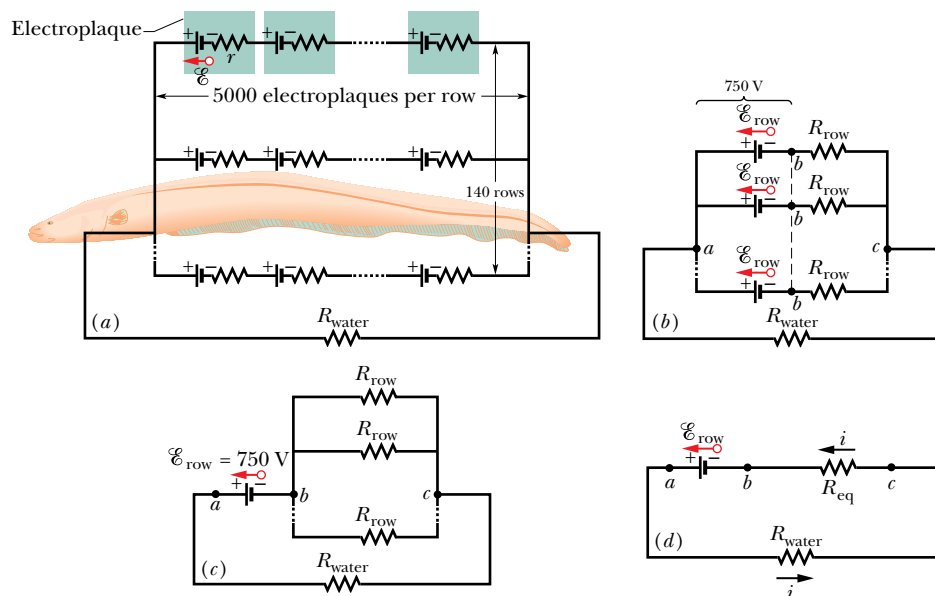

FIGURE 27-13 (a) A model of the electric circuit of an eel in water. Each electroplaque of the eel has an emf \mathcal{E} and internal resistance r . Along each of 140 rows extending from the head to the tail of the eel, there are 5000 electroplaques. The surrounding water has resistance R_{water} . (b) The emf \mathcal{E}_{row} and resistance R_{row} of each row. (c) The emf between points a and b is \mathcal{E}_{row} . Between points b and c are 140 parallel resistances R_{row} . (d) The simplified circuit, with R_{eq} replacing the parallel combination.

that figure are at the same electric potential. Thus, we can consider them to be connected so that there is only a single point b . The emf between point a and this single point b is $\mathcal{E}_{\text{row}} = 750 \text{ V}$, so we can draw the circuit as shown in Fig. 27-13c.

Between points b and c in Fig. 27-13c are 140 resistances $R_{\text{row}} = 1250 \Omega$, all in parallel. The equivalent resistance R_{eq} of this combination is given by Eq. 27-12 as

$$\frac{1}{R_{\text{eq}}} = \sum_{j=1}^{140} \frac{1}{R_j} = 140 \frac{1}{R_{\text{row}}},$$

or

$$R_{\text{eq}} = \frac{R_{\text{row}}}{140} = \frac{1250 \Omega}{140} = 8.93 \Omega.$$

Replacing the parallel combination with R_{eq} , we obtain the simplified circuit of Fig. 27-13d. Applying the loop rule to this circuit counterclockwise from point b , we have

$$\mathcal{E}_{\text{row}} - iR_{\text{water}} - iR_{\text{eq}} = 0 \text{ V}.$$

Solving for i and substituting the known data, we find

$$i = \frac{\mathcal{E}_{\text{row}}}{R_{\text{water}} + R_{\text{eq}}} = \frac{750 \text{ V}}{800 \Omega + 8.93 \Omega} = 0.927 \text{ A} \approx 0.93 \text{ A}. \quad (\text{Answer})$$

If the head or tail of the eel is near a fish, much of this current could pass along a narrow path through the fish, stunning or killing it.

(b) How much current i_{row} travels through each row of Fig. 27-13a?

SOLUTION ■ The **Key Idea** here is that since the rows are identical, the current into and out of the eel is evenly divided among them:

$$i_{\text{row}} = \frac{i}{140} = \frac{0.927 \text{ A}}{140} = 6.6 \times 10^{-3} \text{ A}. \quad (\text{Answer})$$

Thus, the current through each row is small, about two orders of magnitude smaller than the current through the water. This tends to spread the current through the eel's body, so that it need not stun or kill itself when it stuns or kills a fish.

Problems

SECS. 27-2 AND 27-3 ■ CURRENT AND POTENTIAL DIFFERENCE IN SINGLE LOOP CIRCUITS, SERIES RESISTANCE

1. Three Resistors In Fig. 27-14, take $R_1 = R_2 = R_3 = 10 \Omega$. If the potential difference across the ideal battery is $\Delta V_B = 12 \text{ V}$, find: (a) the equivalent resistance of the circuit and (b) the direction the current flows in the circuit. (c) Which point, A or B , is at higher potential?

FIGURE 27-14 ■ Problems 1, 3, and 5.

2. Two Ideal Batteries Figure 27-15 shows two ideal batteries with $\Delta V_{B1} = 12\text{ V}$ and $\Delta V_{B2} = 8\text{ V}$. (a) What is the direction of the current in the resistor? (b) Which battery is doing positive work? (c) Which point, A or B , is at the higher potential?

FIGURE 27-15 ■ Problem 2.

3. Total Current In Fig. 27-14, take $R_1 = 10\ \Omega$, $R_2 = 15\ \Omega$, and $R_3 = 20\ \Omega$. If the potential difference across the ideal battery is $\Delta V_B = 15\text{ V}$, find: (a) the equivalent resistance of the circuit, (b) the current through each of the resistors, and (c) the total current in the circuit.

4. If Potential at P Is In Fig. 27-16, if the potential at point P is 100 V , what is the potential at point Q ?

FIGURE 27-16 ■ Problem 4.

5. Voltages In Fig. 27-14, take $R_1 = 12\ \Omega$, $R_2 = 15\ \Omega$, and $R_3 = 25\ \Omega$. If the potential difference across the ideal battery is $\Delta V_B = 15\text{ V}$, find the potential differences across each of the resistors.

6. Neglecting Wires Figure 27-17 shows a $6.00\ \Omega$ resistor connected to a 12.0 V battery by means of two copper wires. The wires each have length 20.0 cm and radius 1.00 mm . In such circuits we generally neglect the potential differences along wires and the transfer of energy to thermal energy in them. Check the validity of this neglect for the circuit of Fig. 27-17: What are the potential differences across (a) the resistor and (b) each of the two sections of wire? At what rate is energy lost to thermal energy in (c) the resistor and (d) each of the two sections of wire?

FIGURE 27-17 ■ Problem 6.

7. Single Loop The current in a single-loop circuit with one resistance R is 5.0 A . When an additional resistance of $2.0\ \Omega$ is inserted in series with R , the current drops to 4.0 A . What is R ?

8. Ohmmeter A simple ohmmeter is made by connecting an ideal 1.50 V flashlight battery in series with a resistance R and an ammeter that reads from 0 to 1.00 mA , as shown in Fig. 27-18. Resistance R is adjusted so that when the clip leads are shorted together, the meter deflects to its full-scale value of 1.00 mA . What external resistance across the leads results in a deflection of (a) 10% , (b) 50% , and (c) 90% of full scale? (d) If the ammeter has a resistance of $20.0\ \Omega$ and the internal resistance of the battery is negligible, what is the value of R ?

FIGURE 27-18 ■ Problem 8.

SECS. 27-4 AND 27-5 ■ MULTILoop CIRCUITS AND PARALLEL RESISTANCE

9. Sizes and Directions What are the sizes and directions of the currents through resistors (a) R_2 and (b) R_3 in Fig. 27-19, where

each of the three resistances is $4.0\ \Omega$?

10. Changes The resistances in Figs. 27-20a and b are all $6.0\ \Omega$, and the batteries are ideal 12 V batteries. (a) When switch S in Fig. 27-20a is closed, what is the change in the electric potential difference ΔV_{R_1} across resistor 1, or does ΔV_{R_1} remain the same? (b) When switch S in Fig. 27-20b is closed, what is the change in the electric potential difference ΔV_{R_1} across resistor 1, or does ΔV_{R_1} remain the same?

FIGURE 27-19 ■ Problem 9.

23. Four Resistors Four 18.0 Ω resistors are connected in parallel across a 25.0 V battery. What is the current through the battery?

24. Network Shown (a) In Fig. 27-29, what is the equivalent resistance of the network shown? (b) What is the current in each resistor? Put $R_1 = 100$ Ω , $R_2 = R_3 = 50$ Ω , $R_4 = 75$ Ω , and $\Delta V_B = 6.0$ V; assume the battery is ideal.

25. Nine Copper Wires Nine copper wires of length l and diameter d are connected in parallel to form a single composite conductor of resistance R . What must be the diameter D of a single copper wire of length l if it is to have the same resistance?

26. Voltmeter A voltmeter (of resistance $R_{\Delta V}$) and an ammeter (of resistance R_A) are connected to measure a resistance R , as in Fig. 27-30a. The resistance is given by $R = \Delta V/i$, where ΔV is the voltmeter reading and i is the current in the resistance R . Some of the

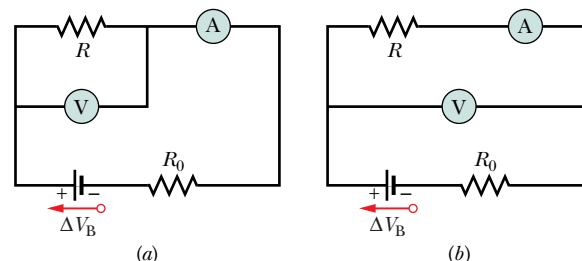

FIGURE 27-30 ■ Problems 26 to 28.

current i' registered by the ammeter goes through the voltmeter, so that the ratio of the meter readings ($= \Delta V/i'$) gives only an *apparent* resistance reading R' . Show that R and R' are related by

$$\frac{1}{R} = \frac{1}{R'} - \frac{1}{R_{\Delta V}}.$$

Note that as $R_{\Delta V} \rightarrow \infty$, $R' \rightarrow R$. Ignore R_0 for now.

27. Ammeter and Voltmeter (See Problem 26.) If an ammeter and a voltmeter are used to measure resistance, they may also be connected as in Fig. 27-30b. Again the ratio of the meter readings gives only an apparent resistance R' . Show that now R' is related to R by

$$R = R' - R_A,$$

in which R_A is the ammeter resistance. Note that as $R_A \rightarrow 0$ Ω , $R' \rightarrow R$. Ignore R_0 for now.

28. What Will the Meters Read (See Problems 26 and 27.) In Fig. 27-30, the ammeter and voltmeter resistances are 3.00 Ω and 3.00 Ω , respectively. Take $\Delta V_B = 12.0$ V for the ideal battery and $R_0 = 100$ Ω . If $R = 85.0$ Ω , (a) what will the meters read for the two different connections (Figs. 27-30a and b)? (b) What apparent resistance R' will be computed in each case?

29. Given a Number You are given a number of $10\ \Omega$ resistors, each capable of dissipating only $1.0\ \text{W}$ without being destroyed. What is the minimum number of such resistors that you need to combine in series or in parallel to make a $10\ \Omega$ resistance that is capable of dissipating at least $5.0\ \text{W}$?

30. Asymptote In Fig. 27-31a, resistor 3 is a variable resistor and the battery is an ideal $12\ \text{V}$ battery. Figure 27-31b gives the current i through the battery as a function of R_3 . The curve has an asymptote of $2.0\ \text{mA}$ as $R_3 \rightarrow \infty$. What are (a) resistance R_1 and (b) resistance R_2 ?

FIGURE 27-31 Problem 30.

31. Box Figure 27-32 shows a section of a circuit. The electric potential difference between points A and B that connect the section to the rest of the circuit is $V_A - V_B = 78\ \text{V}$, and the current through the $6.0\ \Omega$ resistor is $6.0\ \text{A}$. Is the device represented by “Box” absorbing or providing energy to the circuit and at what rate?

FIGURE 27-32 Problem 31.

32. Arrangement of N Resistors In Fig. 27-33, a resistor and an arrangement of n resistors in parallel are connected in series with an ideal battery. All the resistors have the same resistance. If one more identical resistor were added in parallel to the n resistors already in parallel, the current through the battery would change by 1.25% . What is the value of n ?

FIGURE 27-33 Problem 32.

33. Rate of Energy Transfer In Fig. 27-34, where each resistance is $4.00\ \Omega$, what are the sizes and directions of currents (a) i_1 and (b) i_2 ? At what rates is energy being transferred at (c) the $4.00\ \text{V}$ battery and (d) the $12.0\ \text{V}$ battery, and for each, is the battery supplying or absorbing energy?

FIGURE 27-34 Problem 33.

34. Both Batteries Are Ideal Both batteries in Fig. 27-35a are ideal. ΔV_{B1} of battery 1 has a fixed value but ΔV_{B2} of battery 2 can be varied between $1.0\ \text{V}$ and $10\ \text{V}$. The plots in Fig. 27-35b give the currents through the two batteries as a function of ΔV_{B2} . You must decide which plot corresponds to which battery, but for both plots, a

FIGURE 27-35 Problem 34.

negative current occurs when the direction of the current through the battery is opposite the direction of that battery’s potential difference. What are (a) ΔV_{B1} (b) resistance R_1 , and (c) resistance R_2 ?

35. Work Done by Ideal Battery (a) How much work does an ideal battery with $\Delta V_B = 12.0\ \text{V}$ do on an electron that passes through the battery from the positive to the negative terminal? (b) If 3.4×10^{18} electrons pass through each second, what is the power of the battery?

36. Portion of a Circuit Figure 27-36 shows a portion of a circuit. The rest of the circuit draws current i at the connections A and B , as indicated. Take $\Delta V_{B1} = 10\ \text{V}$, $\Delta V_{B2} = 15\ \text{V}$, $R_1 = R_2 = 5.0\ \Omega$, $R_3 = R_4 = 8.0\ \Omega$, and $R_5 = 12\ \Omega$. For each of four values of i — 0 , 4.0 , 8.0 , and $12\ \text{A}$ —find the current through each ideal battery and state whether the battery is charging or discharging. Also find the potential difference ΔV_{AB} between points A and B .

FIGURE 27-36 Problem 36.

37. Adjusted Value In Fig. 27-37, R_s is to be adjusted in value by moving the sliding contact across it until points a and b are brought to the same potential. (One tests for this condition by momentarily connecting a sensitive ammeter between a and b ; if these points are at the same potential, the ammeter will not deflect.) Show that when this adjustment is made, the following relation holds:

$$R_x = R_s \left(\frac{R_2}{R_1} \right).$$

FIGURE 27-37 Problem 37.

An unknown resistance (R_x) can be measured in terms of a standard (R_s) using this device, which is called a Wheatstone bridge.

38. What Are the Currents In Fig. 27-38, what are currents (a) i_2 , (b) i_4 , (c) i_1 , (d) i_3 , and (e) i_5 ?

FIGURE 27-38 ■ Problem 38.

39. Sizes and Directions Two

What are the sizes and directions of (a) current i_1 and (b) current i_2 in Fig. 27-39, where each resistance is 2.00Ω ? (Can you answer this making only mental calculations?) (c) At what rate is energy being transferred in the 5.00 V battery at the left, and is the energy being supplied or absorbed by the battery?

FIGURE 27-39 ■ Problem 39.

40. Size and Direction Three (a) What are the size and direction of current i_1 in Fig. 27-40, where each resistance is 2.0Ω ? What are the powers of (b) the 20 V battery, (c) the 10 V battery, and (d) the 5.0 V battery, and for each, is energy being supplied or absorbed?

FIGURE 27-40 ■ Problem 40.

41. Size and Direction Four (a) What are the size and direction of current i_1 in Fig. 27-41? (b) How much energy is dissipated by all four resistors in 1.0 min ?

FIGURE 27-41 ■ Problem 41.

SEC. 27-7 ■ INTERNAL RESISTANCE AND POWER

42. Chemical Energy A 5.0 A current is set up in a circuit for 6.0 min by a rechargeable battery with a 6.0 V emf. By how much is the chemical energy of the battery reduced?

43. Flashlight Battery A standard flashlight battery can deliver about $2.0 \text{ W}\cdot\text{h}$ of energy before it runs down. (a) If a battery costs 80¢ , what is the cost of operating a 100 W lamp for 8.0 h using batteries? (b) What is the cost if energy is provided at 12¢ per kilowatt-hour?

44. Power Supplied Power is supplied by a device of emf \mathcal{E} to a transmission line with resistance R . Find the ratio of the power dissipated in the line for $\mathcal{E} = 110\,000 \text{ V}$ to that dissipated for $\mathcal{E} = 110 \text{ V}$, assuming the power supplied is the same for the two cases.

45. Car Battery A certain car battery with a 12 V emf has an initial charge of $120 \text{ A}\cdot\text{h}$. Assuming that the potential across the terminals stays constant until the battery is completely discharged, for how long can it deliver energy at the rate of 100 W ?

46. Energy Transferred A wire of resistance 5.0Ω is connected to a battery whose emf \mathcal{E} is 2.0 V and whose internal resistance is 1.0Ω . In 2.0 min , (a) how much energy is transferred from chemical to electrical form? (b) How much energy appears in the wire as thermal energy? (c) Account for the difference between (a) and (b).

47. Assume the Batteries Assume that the batteries in Fig. 27-42 have negligible internal resistance. Find (a) the current in the circuit, (b) the power dissipated in each resistor, and (c) the power of each battery, stating whether energy is supplied by or absorbed by it.

FIGURE 27-42 ■ Problem 47.

48. Both Batteries In Fig. 27-43a, both batteries have emf $\mathcal{E} = 1.20 \text{ V}$ and the external resistance R is a variable resistor. Figure 27-43b gives the electric potentials ΔV_T between the terminals of each battery as functions of R : Curve 1 corresponds to battery 1 and curve 2 corresponds to battery 2. What are the internal resistances of (a) battery 1 and (b) battery 2?

(a)

(b)

FIGURE 27-43 ■ Problem 48.

49. Find Internal Resistance The following table gives the electric potential difference ΔV_T across the terminals of a battery as a function of current i being drawn from the battery. (a) Write an equation that represents the relationship between the terminal potential difference ΔV_T and the current i . Enter the data into your graphing calculator and perform a linear regression fit of ΔV_T versus i . From the parameters of the fit, find (b) the battery's emf and (c) its internal resistance.

i (A):	50	75	100	125	150	175	200
ΔV_T (V):	10.7	9.0	7.7	6.0	4.8	3.0	1.7

50. Make Plots In Fig. 27-11a, put $\mathcal{E} = 2.0 \text{ V}$ and $r = 100 \Omega$. Plot (a) the current and (b) the potential difference across R , as functions of R over the range 0 to 500Ω . Make both plots on the same graph. (c) Make a third plot by multiplying together, for various values of R , the corresponding values on the two plotted curves. What is the physical significance of this third plot?

51. Energy Converted A car battery with a 12 V emf and an internal resistance of 0.040Ω is being charged with a current of 50 A . (a) What is the potential difference across its terminals? (b) At what rate is energy being dissipated as thermal energy in the battery? (c) At what rate is electric energy being converted to chemical energy? (d) What are the answers to (a) and (b) when the battery is used to supply 50 A to the starter motor?

52. What Value of R (a) In Fig. 27-44, what value must R have if the current in the circuit is to be 1.0 mA ? Take $\mathcal{E}_1 = 2.0 \text{ V}$, $\mathcal{E}_2 = 3.0 \text{ V}$, and $r_1 = r_2 = 3.0 \Omega$. (b) What is the rate at which thermal energy appears in R ?

FIGURE 27-44 ■ Problem 52.

53. Circuit Section In Fig. 27-45, circuit section AB absorbs energy at a rate of 50 W when a current $i = 1.0$

FIGURE 27-45 ■ Problem 53.

A passes through it in the indicated direction. (a) What is the potential difference between A and B ? (b) emf device X does not have internal resistance. What is its emf? (c) What is its *polarity* (the orientation of its positive and negative terminals)?

54. Lights of an Auto When the lights of an automobile are switched on, an ammeter in series with them reads 10 A and a voltmeter connected across them reads 12 V . See Fig. 27-46. When the electric starting motor is turned on, the ammeter reading drops to 8.0 A and the lights dim somewhat. If the internal resistance of the battery is 0.050Ω and that of the ammeter is negligible, what are (a) the emf of the battery and (b) the current through the starting motor when the lights are on?

FIGURE 27-46 ■ Problem 54.

55. Same EMF Two batteries having the same emf \mathcal{E} but different internal resistances r_1 and r_2 ($r_1 > r_2$) are connected in series to an external resistance R . (a) Find the value of R that makes the potential difference zero between the terminals of one battery. (b) Which battery is it?

56. Starting Motor The starting motor of an automobile is turning too slowly, and the mechanic has to decide whether to replace the motor, the cable, or the battery. The manufacturer's manual says that the 12 V battery should have no more than 0.020Ω internal resistance, the motor no more than 0.200Ω resistance, and the cable no more than 0.040Ω resistance. The mechanic turns on the motor

and measures 11.4 V across the battery, 3.0 V across the cable, and a current of 50 A . Which part is defective?

57. Maximum Power (a) In Fig. 27-11a, show that the rate at which energy is dissipated in R as thermal energy is a maximum when $R = r$. (b) Show that this maximum power is $P = \mathcal{E}^2/4r$.

58. Solar Cell A solar cell generates a potential difference of 0.10 V when a 500Ω resistor is connected across it, and a potential difference of 0.15 V when a 1000Ω resistor is substituted. What are (a) the internal resistance and (b) the emf of the solar cell? (c) The area of the cell is 5.0 cm^2 , and the rate per unit area at which it receives energy from light is 2.0 mW/cm^2 . What is the efficiency of the cell for converting light energy to thermal energy in the 1000Ω external resistor?

59. Maximum Energy Two batteries of emf \mathcal{E} and internal resistance r are connected in parallel across a resistor R , as in Fig. 27-47a. (a) For what value of R is the rate of electrical energy dissipation by the resistor a maximum? (b) What is the maximum energy dissipation rate?

FIGURE 27-47 ■ Problems 59 and 60.

60. Either Parallel or Series You are given two batteries of emf \mathcal{E} and internal resistance r . They may be connected either in parallel (Fig. 27-47a) or in series (Fig. 27-47b) and are to be used to establish a current in a resistor R . (a) Derive expressions for the current in R for both arrangements. Which will yield the larger current (b) when $R > r$ and (c) when $R < r$?

FIGURE 27-48 ■ Problem 61.

61. Batteries Are Ideal In Fig. 27-48, $\mathcal{E}_1 = 3.00 \text{ V}$, $\mathcal{E}_2 = 1.00 \text{ V}$, $R_1 = 5.00 \Omega$, $R_2 = 2.00 \Omega$, $R_3 = 4.00 \Omega$, and both batteries are ideal. What is the rate at which energy is dissipated in (a) R_1 , (b) R_2 , and (c) R_3 ? What is the power of (d) battery 1 and (e) battery 2?

62. For What Value of R In the circuit of Fig. 27-49, for what value of R will the ideal battery transfer energy to the resistors (a) at a rate of 60.0 W , (b) at the maximum possible rate, and (c) at the minimum possible rate? (d) What are those rates?

FIGURE 27-49 ■ Problem 62.

63. Calculate Current (a) Calculate the current through each ideal battery in Fig. 27-50. Since the batteries are ideal $\mathcal{E} = \Delta V_B$ in each case. Assume that $R_1 = 1.0 \Omega$, $R_2 = 2.0 \Omega$, $\mathcal{E}_1 = 2.0 \text{ V}$ and $\mathcal{E}_2 = \mathcal{E}_3 = 4.0 \text{ V}$. (b) Calculate $V_a - V_b$.

FIGURE 27-50 Problem 63.

64. Constant Value In the circuit of Fig. 27-51, \mathcal{E} has a constant value but R can be varied. Find the value of R that results in the maximum heating in that resistor. The battery is ideal.

FIGURE 27-51 Problem 64.

Additional Problems

65. True or False For the circuit in Fig. 27-52, indicate whether the statements are true or false. If a statement is false, give a correct statement.

(a) Some of the current is used up when the bulb is lit; the current in wire B is smaller than the current in wire A .

(b) A current probe will have the same readings if connected to read the current in wire A or wire B . The current flows from the battery, through wire A , through the bulb, and then back to the battery through wire B .

(c) The current flows toward the bulb in both wires A and B .

(d) The (positive) current flows from the battery, through wire A , and then back to the battery through wire B .

(e) If wire A is left connected but wire B is disconnected, the bulb will still light.

FIGURE 27-52 Problem 65.

66. Use the Model (a) Use our model for electric current to rank the networks shown in Fig. 27-53 in order by resistance. Explain your reasoning.

FIGURE 27-53 Problem 66.

(b) If a battery were connected to each of the circuits, in which case would the current through the battery be the largest? The smallest? Explain your reasoning.

67. Examine the Circuits Examine the circuits shown in Fig. 27-54 and indicate whether you think each of the following two statements are true or false. Please explain your reasoning.

FIGURE 27-54 Problem 67.

(a) Circuits 1 and 2 are different. The brightness of the two bulbs in circuit 1 are the same, but in circuit 2 the bulb closest to the battery is brighter than the bulb that is further away.

(b) Circuit diagrams only show electrical connections, so the drawings in circuits 1 and 2 are electrically equivalent and the brightness of the two bulbs is the same in both circuits 1 and 2.

68. Which Diagram (a) Identify which of the nice, neat circuit diagrams (A , B , C , or D) in Fig. 27-55c corresponds to the messy circuit drawing in Fig. 27-55a. Explain the reasons for your answer.

FIGURE 27-55 Problem 68.

(b) Which neat circuit diagram corresponds to the messy circuit drawing in Fig. 27-55b. Explain the reasons for your answer.

FIGURE 27-56 Problem 69.

69. At Which Point (a) For the circuit in Fig. 27-56, at which point A , B , C , D or E is the voltage the lowest? Explain. (b) At which point is the potential energy of a positive charge the highest? Explain. (c) At which point is the current the largest? Explain.

70. Bulbs 1 Through 6 (a) For the circuit shown in Fig. 27-57, rank bulbs 1 through 6 in order of descending brightness. Explain the reasoning for your ranking. (b) Now assume that the filament of lightbulb 6 breaks. Again rank the bulbs in order of descending brightness. Explain the reasoning for your ranking.

FIGURE 27-57 Problem 70.

71. The Circuit Diagram The circuit diagram in Fig. 27-58 shows two unlabeled resistors attached to identical bulbs. Explain how you would interpret the brightness of bulbs *A* and *B* to decide which resistor is larger.

FIGURE 27-58 ■ Problem 71.

72. Three Circuits Which of the three circuits shown in Fig. 27-59, if any, are electrically identical? Which are different? Explain your answers.

FIGURE 27-59 ■ Problem 72.

73. An Unscrewed Bulb Examine the circuit shown in Fig. 27-60. (a) Rank the bulbs according to brightness and explain your reasoning. (b) How will the brightness of bulbs 1 and 3 change if bulb 4 is unscrewed? Explain. (c) How will the brightness of bulbs 1, 3, 5, and 6 change if a conducting wire is connected between points *A* and *F*? Explain.

FIGURE 27-60 ■ Problem 73.

74. Examine the Circuit Examine the circuit shown in Fig. 27-61. (a) Assume that the switch is *open*. State which bulbs or combination of bulbs are in series, and in parallel. (b) Assume that the switch is *closed*. State whether the bulbs in the circuit are arranged in series or parallel.

FIGURE 27-61 ■ Problem 74.

75. Examine the Circuit Two Examine the circuit shown in Fig. 27-62. (a) Assume that the switch is *open*. Rank the bulbs according to brightness and explain your reasoning. (b) Assume that the switch is *closed*. Rank the bulbs according to brightness and explain your reasoning.

FIGURE 27-62 ■ Problem 75.

76. More Current If the batteries in Fig. 27-63 are identical, which circuit draws more current? Circuit *A*? Circuit *B*? Neither? Show your calculations and reasoning.

FIGURE 27-63 ■ Problem 76.

77. Which Are Connected In the circuits shown in Fig. 27-64, state which resistors are connected in series with which other resistors, which are connected in parallel with which other resistors, and which are neither in series nor parallel.

FIGURE 27-64 ■ Problem 77.

78. Lots of Batteries and a Bulb Figure 27-65 shows identical batteries connected in different arrangements to the same lightbulb. Assume the batteries have negligible internal resistances. The positive terminal of each battery is marked with a plus. Rank these arrangements on the basis of bulb brightness from the highest to the lowest. Please explain your reasoning.

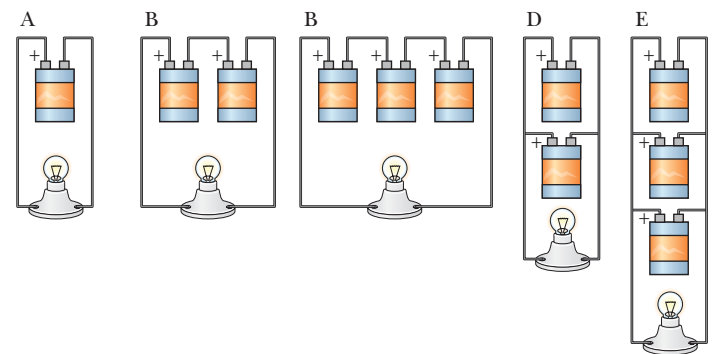

FIGURE 27-65 ■ Problem 78.

79. Constant Current Source We have studied batteries that provide a fixed voltage across their terminals. In that case, we had to examine our circuit and use our physical principles in order to calculate the current through the battery. In neuroscience, it is sometimes useful to use a constant current source (CCS), which instead provides a fixed amount of current through itself. In this case, we have to use our physical principles in order to calculate the voltage drop across the source.

Suppose we have a constant current source (denoted CSS) that always provides a current of $i_c = 10^{-6}$ amps. For the three circuits shown in Fig. 27-66, find the voltage drop across the current source. Each resistor has a resistance $R = 2000 \Omega$. (If you prefer, you may leave your answer in terms of the symbols i_c and R .)

FIGURE 27-66 ■ Problem 79.

80. Tracking Around a Circuit The circuit shown in Fig. 27-67 contains an ideal battery and three resistors. The battery has an emf of 1.5 V , $R_1 = 2 \Omega$, $R_2 = 3 \Omega$, and $R_3 = 5 \Omega$. Also shown in Fig. 27-67 is a graph tracking some quantity around the circuit. Make three

FIGURE 27-67 ■ Problem 80.

copies of this graph. On the first, plot the voltage a test charge would experience as it moved through the circuit. On the second, plot the electric field a test charge would experience as it moved through the circuit. On the third, plot the current one would measure crossing a plane perpendicular to the wire of the circuit as one goes through the circuit.

81. Modeling a Nerve Membrane (From a homework set in a graduate course in synaptic physiology) As a result of a complex set of biochemical reactions, the cell membrane of a nerve cell pumps ions (Na^+ and K^+) back and forth across itself, thereby maintaining an electrostatic potential difference from the inside to the outside of the membrane. Modifications on the conditions can result in changes in those potentials.

Part of the process can be modeled by treating the membrane as if it were a simple electric circuit consisting of batteries, resistors, and a switch. A simple model of the membrane of a nerve cell is shown in Fig. 27-68. It consists of two batteries (ion pumps) with voltages $\Delta V_1 = 100 \text{ mV}$ and $V_2 = 50 \text{ mV}$. The resistance to flow across the membrane is represented by two resistors with resistances $R_1 = 10 \text{ K } \Omega$ and $R_2 = 90 \text{ K } \Omega$. The variability is represented by a switch, S_1 .

FIGURE 27-68 ■ Problem 81.

Four points on the circuit are labeled by the letters a – d . The point b represents the outside of the membrane and the point d the inside of the membrane.

- What is the voltage difference across the membrane (i.e., between d and b) when the switch is open?
- What is the current flowing around the loop when the switch is closed?
- What is the voltage drop across the resistor R_1 when the switch is open? Closed?
- What is the voltage drop across the resistor R_2 when the switch is open? Closed?
- What is the potential difference across the membrane (i.e., between d and b) when the switch is closed?
- If the locations of resistances R_1 and R_2 were reversed, would the voltages across the cell membrane be different?

82. Find the Five Currents

Consider the circuit in Fig. 27-69. (a) Apply the junction rule to junctions d and a and the loop rule to the three loops to produce five simultaneous, linearly independent equations. (b) Represent the five linear equations by the matrix equation $[A][B] = [C]$, where

$$[B] = \begin{bmatrix} i_1 \\ i_2 \\ i_3 \\ i_4 \\ i_5 \end{bmatrix}.$$

FIGURE 27-69 ■ Problem 82 and 83.

What are the matrices $[A]$ and $[C]$? (c) Have the calculator perform $[A]^{-1}[C]$ to find the values of i_1, i_2, i_3, i_4 , and i_5 .

83. Knowing the Currents For the same situation as in Problem 82 and having already solved for the five unknown currents, do the following. (a) Find the electric potential difference across the 9Ω resistor. (b) Find the rate at which work is being done on the 7Ω resistor. (c) Find the rate at which the 12 V battery is doing work on the circuit. (d) Find the rate at which the 4 V battery is doing work on the circuit. (e) Of the points in the circuit labeled a and c , which is at the higher electric potential?

28

Capacitance

In 1964 Harold “Doc” Edgerton of MIT, who was renowned for his ability to take high-quality stop-action photos, captured this image of a bullet penetrating an apple. This stop-action photo was made by leaving the camera shutter open and tripping a high-speed electronic flash device at just the right time to illuminate the apple and bullet. Since the bullet was moving at 900 m/s, Edgerton used a flash with a duration of only $0.3 \mu\text{s}$. This meant that the bullet only moved 0.3 mm during the flash. If we were doing ordinary photography we would probably illuminate the apple with a 100 W lightbulb using an exposure time of $1/20 \text{ s}$ to provide about 5 J of energy for illumination. But providing the necessary 5 J of electrical energy for the illumination in a time period of $0.3 \mu\text{s}$ requires 15 MW of power.

How is it possible to provide the energy needed to stop a bullet’s action when it is only illuminated for a tiny fraction of a second?

The answer is in this chapter.

28-1 The Uses of Capacitors

In Chapter 26 we discussed transferring excess charge to a pair of metal plates as shown in Fig. 26-1. The pair of metal plates is an example of the basic component of a **capacitor**. A capacitor can be constructed using any two conductors separated by an insulator. If we connect each conductor making up a capacitor to one of the terminals of a source of potential difference such as a battery, one conductor acquires a net positive charge while the other conductor acquires the same amount of net negative charge. The conductors can be any shape. Figure 28-1 shows some possible capacitor

FIGURE 28-1 ■ Three capacitors of different sizes and shapes have been connected to a battery. They each consist of a pair of conductors separated by an insulator. In each case the battery removes electrons from one of the two conductors, leaving it with excess positive charge and forces the same number of electrons to the opposite conductor.

FIGURE 28-2 ■ An assortment of capacitors commonly found in electrical circuits. The structures of these devices are hidden.

FIGURE 28-3 ■ When a battery is connected across the terminals of a capacitor, the capacitor stores electrical energy.

geometries. No matter what shape or size a capacitor's conductors are, we often casually refer to the conductors as “plates.”

There are many reasons for constructing and studying capacitors: they are useful circuit elements and they can store energy.

Capacitors in Electrical Circuits

Since a capacitor consists of conductors separated by an insulator, no current can flow *through* it. So at first glance, it doesn't seem to make sense to use a capacitor as a circuit element. Surprisingly, capacitors have very interesting and useful properties in circuits with changing currents through their other components. For example, variable capacitors are vital elements that enable us to tune radio and television receivers. They are found in most household electrical devices. Capacitors are used to control the frequency of the flashing lights used for warning signals at construction sites. The coaxial cables used to carry high-frequency microwave and radio signals are cylindrical capacitors. Microscopic capacitors are used in communications and computers to shape the timing and strength of time-varying signal transmissions. Figure 28-2 shows some of the many sizes and shapes of capacitors commonly found in electric circuits.

Capacitors as Energy Storage Devices

Just as you can store potential energy by pulling a bowstring, stretching a spring, compressing a gas, or lifting a book, you can also store electrical energy in the electric field found inside a “charged” capacitor as shown in Figs. 28-3 and 28-4. For example, energy storage in microscopic capacitors enables them to function as memory devices in modern digital computers and in the charge-coupled devices (CCDs) used in video cameras. Energy stored in capacitors can also be used to keep computer circuits running smoothly during brief power outages. A much larger capacitor lies at the heart of a battery-powered photoflash unit. This capacitor accumulates electrical energy relatively slowly during the time between flashes, building up an electric field as it does so.

The electric field across the capacitor plates stores energy that can be released rapidly to create an intensive flash of light. (It is important to note that because capacitors are storehouses for electrical energy, some electrical devices can give you a nasty shock if you open them and accidentally touch both terminals of a capacitor—even when the device is turned off.)

28-2 Capacitance

Figure 28-5 shows a capacitor made from a conventional arrangement of a pair of metal plates. A device consisting of two parallel conducting plates of area A separated by a distance d is called a *parallel-plate capacitor*. The circuit symbol we use to represent a capacitor ($-||-$) is based on the structure of a parallel-plate capacitor but is used for capacitors of all shapes. For the purpose of defining capacitance in a simple manner, we will consider an ideal capacitor as two flat parallel conductors (or **plates**) with a perfect insulator between its plates. This perfect insulator allows absolutely no current to pass between them. For simplicity, at first we choose to consider the situation where there is no matter (such as air, glass, or plastic) between the capacitor plates. We just have a vacuum between the plates. We further assume we will charge our capacitor with an ideal battery. Recall that an ideal battery has no internal resistance, so its emf and the potential difference across its terminals are always the same. In Section 28-6 and those following we will relax some of these idealized restrictions.

Equal and Opposite Excess Charge on Plates

When capacitor plates of any shape are connected to a battery or some other voltage source, electrons flow from the negative terminal of the battery through the connecting wire and onto one plate of the capacitor. Meanwhile, the positive terminal of the battery attracts electrons from the other plate. These electrons are pulled through the wires of the circuit, away from the capacitor plate, and leave behind an excess of positive metal atoms with missing electrons. During this process, we cannot find an electric field outside of the capacitor so the overall capacitor seems to be electrically neutral. Hence, we must conclude that at any given time one plate has net or excess charge of $+q$ while the other has a net charge of $-q$. The chemical reactions taking place in the battery are complex, so the electrons pulled off one plate are not necessarily the same ones being pushed through the wires of the circuit onto the other plate. However, the battery does deposit one electron on the negative plate for every one it pulls off the positive plate. We will call this process *charge separation*. Sometimes the process is called *charging*.

To understand how a capacitor works, it is important to note that charge separation occurs as a result of charge flow in the wires of the circuit. Charges are not transferred from one plate to the other inside an ideal capacitor.

Why Do Capacitor Plates Stop Accumulating Charge?

Observations show that the battery eventually stops pulling electrons off the positively charged plate and depositing electrons on the negatively charged plate. This is because as electrons build up on the negative plate, they oppose the battery's action and start repelling the flow of additional electrons. Similarly, it becomes harder and harder for the battery to pull electrons off the positive plate as the atoms carrying positive net charge pull back on them. When enough charge has accumulated on the

FIGURE 28-4 ■ When a “charged” capacitor is disconnected from its battery and wired in series with a bulb, the energy stored in it can light the bulb for a short period of time.

FIGURE 28-5 ■ A parallel-plate capacitor with identical plates of area A and spacing d is connected to a battery with potential difference ΔV . The plates have equal and opposite excess charges of amount $|q|$ on their facing surfaces.

FIGURE 28-6 ■ As the field lines show, the electric field due to the charged plates is uniform in the central region between the plates. The field is not uniform at the edges of the plates, as indicated by the “fringing” of the field lines there.

plates, the force exerted on an electron by the battery and the oppositely directed forces exerted on it by the other charges on a plate cancel each other. No more electrons can flow from one plate to the other. We can use a high-quality voltmeter to measure the potential difference across a capacitor just disconnected from a battery. This measurement shows that *charge separation stops when the potential difference across a capacitor is the same as the potential difference across the battery.*

Factors Affecting Charge Separation Capacity

By convention we refer to the *charge on a capacitor* as $|q|$, the absolute value of the net charge on each plate. Although we refer to a capacitor with charges q and $-q$ on its plates as “charged,” a capacitor is electrically neutral so we are actually describing its charge separation created by a voltage source. What factors might affect the capacity for charge separation in a parallel-plate capacitor? We can use our knowledge of electrostatics to explore the effects of several factors. In particular, we will explore how we expect charge to depend on the potential difference across the battery terminals and on geometric factors such as the area of the plates and their spacing (Fig. 28-6):

- 1. Potential Difference, ΔV :** For a given capacitor of any shape, we would expect the charge separation to be larger when the potential difference the battery places across the capacitor plates is larger. How much larger? Consider a group of n charges distributed on the plates of a capacitor. Since the plates are conductors, each one is an equipotential surface. According to Eq. 25-25 we can find the electric potential at a given point on a plate relative to infinity. We just need to know the locations of the group of n charges distributed on the capacitor plates. The potential is given by

$$V = k \sum_{i=1}^n \frac{q_i}{r_i} \quad (\text{Eq. 25-25})$$

where r_i represents the radial distance between the point where the potential is being calculated and the location of the i th charge. By examining this equation we can see that if the potential is to be doubled, there needs to be twice as much charge at each location on the capacitor plates. We expect the amount of the charge separation on a capacitor to be proportional to the potential difference across its plates. We predict

$$|q| \propto |\Delta V|.$$

As you will see in the next subsection, the constant of proportionality between the amount of excess charge on each plate and the potential difference across the plates for a given capacitor is known as its *capacitance*. We will deal more formally with the definition of capacitance and its units in the next section.

- 2. Influence of Plate Area, A :** Consider a parallel-plate capacitor. For a given potential difference and plate spacing, d , how do we expect the charge separation capacity to depend on the area of the plates? When the plates have a large area, the electrons the battery is trying to push on the negative plate have more room to spread out. Likewise, the unneutralized atoms left behind when electrons are pulled off the positive plate can be distributed further apart. We expect that as the area of the plates increases, it will be easier to remove or deposit electrons on them.

A simple experiment can be done to show that the charge separation capacity is in fact directly proportional to area. In this experiment, two sheets of aluminum

FIGURE 28-7 ■ Two rectangular pieces of aluminum foil are wedged between the insulating pages of a book. A multimeter is used to measure the capacitance of the system. The result shows capacitance increasing in direct proportion to the area of the conducting aluminum plates.

foil are placed opposite each other and separated by the insulating pages of a book. A multimeter like that described in Section 26-4 can be used to measure capacitance. Measurements are taken for different areas of foil. The results are shown in Fig. 28-7. We derive this relationship theoretically in the next section.

- 3. Influence of Plate Spacing, d :** Once again we consider a parallel-plate capacitor. For a given potential difference and plate area, A , how do we expect the charge separation capacity to depend on the spacing between the plates? When the plates have a small spacing, the excess positive charges on one plate are quite close to the excess negative charges on the other plate. Since opposite charges attract each other, these charges pull on each other across the insulating gap even though they cannot cross the gap. This attraction helps to counterbalance the repulsion between the like charges on each plate. As the spacing between plates becomes smaller, we expect the overall capacity for the charge separation caused by the battery action to become larger.

A simple experiment can be done to show that the charge separation capacity does in fact increase as the spacing between plates decreases. In this experiment, two sheets of aluminum foil are placed opposite each other and separated by the insulating pages of a book. A multimeter is used to measure capacitance as different numbers of pages are inserted between the foil plates. The results are shown in Fig. 28-8. This graph shows that the capacitance of the foil plate system is inversely proportional to the spacing, d , between the plates. We derive this relationship theoretically in the next section.

Defining Capacitance

As we just discussed in the last subsection, the amount of the excess charge on each plate of a capacitor, $|q|$, and the size of the potential difference, $|\Delta V|$, across it should be proportional to each other, so

$$|q| = C|\Delta V|. \quad (28-1)$$

FIGURE 28-8 ■ Two rectangular pieces of aluminum foil are wedged between the insulating pages of a book. The capacitance of the system is measured as a function of the spacing between the plates. The result shows that capacitance is inversely proportional to the spacing.

The proportionality constant C is defined as the **capacitance**. The capacitance is a measure of how much excess charge must be put on each of the plates to produce a certain potential difference between them: the greater the capacitance, the larger the charge separation created by a given potential difference.

For a parallel-plate capacitor, experimental results have shown us its capacitance depends directly on the plate areas and inversely on the spacing between plates. We will see in Sections 28-6 and 28-7 that capacitance will also depend on the nature of the insulating material inserted between the plates. Capacitors having different shapes will not have the same simple relationships between plate area and spacing. In the next section, we will use the definition of electric potential and Gauss' law to identify the theoretical geometric factors for several different types of capacitors including parallel-plate, cylindrical, and spherical capacitors.

Capacitance Units

The SI unit of capacitance following from this expression is the coulomb per volt. This unit occurs so often that it is given a special name, the *farad* (F):

$$1 \text{ farad} = 1 \text{ F} = 1 \text{ coulomb per volt} = 1 \text{ C/V}. \quad (28-2)$$

As you will see, the farad is a very large unit. Fractions of the farad, such as the microfarad ($1 \mu\text{F} = 10^{-6} \text{ F}$) and the picofarad ($1 \text{ pF} = 10^{-12} \text{ F}$), are more convenient units in practice. A summary of units and their common notations is shown in Table 28-1.

TABLE 28-1
Units of Capacitance

microfarad: $10^{-6} \text{ F} = 1 \mu\text{F}$

nanofarad: $10^{-9} \text{ F} = 1 \text{ nF} = 1000 \mu\mu\text{F}$

picofarad: $10^{-12} \text{ F} = 1 \text{ pF} = 1 \mu\mu\mu\text{F}$

READING EXERCISE 28-1: Does the capacitance C of a capacitor increase, decrease, or remain the same (a) when the excess charge of amount $|q|$ on its plates is doubled and (b) when the potential difference ΔV_c across it is tripled? ■

28-3 Calculating the Capacitance

Our task here is to calculate the capacitance of a capacitor once we know its geometry. Because we will consider a number of different geometries, it seems wise to develop a general plan to simplify the work. In brief, our plan is as follows:

1. Assume a charge of amount $|q|$ on each of the “plates.”
2. Calculate the electric field \vec{E} between the plates in terms of this amount of charge, using Gauss' law.
3. Knowing \vec{E} , calculate the potential difference ΔV between the plates from

$$V_2 - V_1 = - \int_1^2 \vec{E} \cdot d\vec{s}. \quad (\text{Eq. 25-16})$$

4. Calculate C from $|q| = C|\Delta V|$ (Eq. 28-1).

Before we start, we can simplify the calculation of both the electric field and the potential difference by making certain assumptions. We discuss each in turn.

Calculating the Electric Field

To relate the electric field \vec{E} between the plates of a capacitor to the amount of excess charge $|q|$ on either plate, we shall use Gauss' law:

$$\epsilon_0 \oint \vec{E} \cdot d\vec{A} = q^{\text{net}} = q. \quad (28-3)$$

Here q is the net charge enclosed by a Gaussian surface, and $\oint \vec{E} \cdot d\vec{A}$ is the net electric flux through that surface. In all cases we shall consider, the Gaussian surface will be such whenever electric flux passes through it, \vec{E} will have a uniform magnitude $E = |\vec{E}|$, and the vectors \vec{E} and $d\vec{A}$ will be parallel. This equation will then reduce to

$$|q| = \epsilon_0 EA \quad (\text{special case of Eq. 28-3}), \quad (28-4)$$

in which A is the area of the part of the Gaussian surface through which flux passes. For convenience, we shall always draw the Gaussian surface in such a way it completely encloses the charge on the positive plate; see Fig. 28-9 for an example.

Calculating the Potential Difference

In the notation of Chapter 25 (Eq. 25-16), the potential difference between the plates of a capacitor is related to the field \vec{E} by

$$V_2 - V_1 = - \int_1^2 \vec{E} \cdot d\vec{s}, \quad (28-5)$$

in which the integral is to be evaluated along any path starting on one plate and ending on the other. We shall always choose a path following an electric field line, from the negative plate to the positive plate. For this path, the vectors \vec{E} and $d\vec{s}$ will have opposite directions, so the dot product $\vec{E} \cdot d\vec{s}$ will be equal to $-|\vec{E}||d\vec{s}|$. The right side of this equation will then be positive. Letting ΔV represent the difference, $V_2 - V_1$, we can then recast the relationship as

$$\Delta V = - \int_-^+ |\vec{E}||d\vec{s}| \quad (\text{special case of Eq. 28-5}), \quad (28-6)$$

in which the “-” and “+” remind us that our path of integration starts on the negative plate and ends on the positive plate.

We are now ready to apply $|q| = \epsilon_0 EA$ (Eq. 28-4) and $\Delta V = - \int_-^+ |\vec{E}||d\vec{s}|$ (Eq. 28-6) to some particular cases.

A Parallel-Plate Capacitor

We assume, as Fig. 28-9 suggests, that the plates of our parallel-plate capacitor are so large and so close together we can neglect the fringing of the electric field at the edges of the plates, taking \vec{E} to be constant throughout the region between the plates. This configuration was used in old-time radios. As we will see in Chapter 33, the frequency of an oscillating circuit depends on the capacitance. In old radios (those built before the time that tiny transistors became ubiquitous), the dial was connected to a set of nested metal plates. When the dial was turned, some of the plates rotated while others stayed fixed. By turning the dial, the overlap of the plates changed, changing the capacitance and thereby the frequency of the signal selected.

We draw a Gaussian surface enclosing just the excess charge q on the positive plate, as in Fig. 28-9. Recall from above that

$$|q| = \epsilon_0 EA, \quad (28-7)$$

where A is the area of each of the plates.

Equation 28-6 yields

$$\Delta V = \int_-^+ |\vec{E}||d\vec{s}| = |\vec{E}| \int_0^d ds = Ed. \quad (28-8)$$

FIGURE 28-9 ■ A charged parallel-plate capacitor. A Gaussian surface encloses the charge on the positive plate. The integration of Eq. 28-6 is taken along a path extending directly from the negative plate to the positive plate.

Here, $|\vec{E}| = E$ can be placed outside the integral because it is a constant; the second integral then is simply the plate separation d .

Combining these two expressions with the relation $|q| = C|\Delta V|$ (Eq. 28-1), we find

$$C = \frac{\epsilon_0 A}{d} \quad (\text{parallel-plate capacitor}). \quad (28-9)$$

This theoretical relationship matches the results of the experiments we presented in the last section. The capacitance does indeed depend only on geometrical factors—namely, the plate area A and the plate separation d . Note that C increases as we increase the plate area A or decrease the separation d .

As an aside, we point out that this expression suggests one of our reasons for writing the electrostatic constant in Coulomb's law in the form $1/4\pi\epsilon_0$. If we had not done so, the expression for the capacitance of a parallel-plate capacitor above—which is used more often in engineering practice than Coulomb's law—would have been less simple in form. We note further that it permits us to express the permittivity constant ϵ_0 in a unit more appropriate for use in problems involving capacitors; namely,

$$\epsilon_0 = 8.85 \times 10^{-12} \text{ F/m} = 8.85 \text{ pF/m}. \quad (28-10)$$

We have previously expressed this constant as

$$\epsilon_0 = 8.85 \times 10^{-12} \text{ C}^2/\text{N}\cdot\text{m}^2. \quad (28-11)$$

FIGURE 28-10 ■ A cross section of a long cylindrical capacitor, showing a cylindrical Gaussian surface of radius r (that encloses the positive “plate”) and the radial path of integration along which Eq. 28-6 is to be applied. If we visualize the central conductor as the cross section of a sphere rather than that of a long cylindrical wire then this figure also illustrates a spherical capacitor.

A Cylindrical Capacitor

Fig. 28-10 shows, in cross section, a cylindrical capacitor of length L formed by two coaxial cylinders of radii a and b . We assume $L \gg b$ so we can neglect the fringing of the electric field occurring at the ends of the cylinders. Each plate contains an amount of excess charge $|q|$. This configuration is important because coaxial cables are used in the communications industry for the long distance transmission of electrical signals (Fig 28-11).

The electric field inside the cylinder is highly symmetrical, so we can use Gauss's law to determine its values. As a Gaussian surface, we choose a cylinder

FIGURE 28-11 ■ Coaxial cables and connectors are used for long-distance transmission of television and radio signals. The cable consists of a central conducting wire surrounded by a layer of insulation and then a cylindrical conductor. All three elements are centered on the same axis. Coaxial cables are good examples of cylindrical capacitors.

of length L and radius r , closed by end caps and placed as is shown in Fig. 28-10. Then

$$|q| = \epsilon_0 |\vec{E}| A = \epsilon_0 |\vec{E}| (2\pi r L),$$

in which $2\pi r L$ is the area of the curved part of the Gaussian surface. There is no flux through the end caps. Solving for $|\vec{E}|$ yields

$$|\vec{E}| = \frac{|q|}{2\pi\epsilon_0 L r}. \quad (28-12)$$

Substitution of this result into our general expression for potential difference yields

$$\Delta V = \int_{-}^{+} \vec{E} \cdot d\vec{s} = -\frac{q}{2\pi\epsilon_0 L} \int_b^a \frac{dr}{r} = \frac{q}{2\pi\epsilon_0 L} \ln\left(\frac{b}{a}\right), \quad (28-13)$$

where here $ds = -dr$ (we integrated radially inward). From the relation $C = |q/\Delta V|$, we then have

$$C = 2\pi\epsilon_0 \frac{L}{\ln(b/a)} \quad (\text{cylindrical capacitor}). \quad (28-14)$$

We see that the capacitance of a cylindrical capacitor, like that of a parallel-plate capacitor, depends only on geometrical factors, in this case L , b , and a .

A Spherical Capacitor

Fig. 28-10 can also serve as a central cross section of a capacitor consisting of two concentric spherical shells, of radii a and b . As a Gaussian surface we draw a sphere of radius r concentric with the two shells; then

$$|q| = \epsilon_0 EA = \epsilon_0 E(4\pi r^2),$$

in which $4\pi r^2$ is the area of the spherical Gaussian surface. We solve this equation for $|\vec{E}|$, obtaining

$$E = |\vec{E}| = k \frac{|q|}{r^2} = \frac{1}{4\pi\epsilon_0} \frac{|q|}{r^2}, \quad (28-15)$$

which we recognize as the expression for the electric field due to a uniform spherical charge distribution from Chapter 24.

If we substitute this expression into Eq. 28-6, we find

$$\Delta V = \int_{-}^{+} \vec{E} \cdot d\vec{s} = -\frac{|q|}{4\pi\epsilon_0} \int_b^a \frac{dr}{r^2} = \frac{|q|}{4\pi\epsilon_0} \left(\frac{1}{a} - \frac{1}{b} \right) = \frac{|q|}{4\pi\epsilon_0} \frac{b-a}{ab}, \quad (28-16)$$

where again we have substituted $-dr$ for ds . If we now substitute this into $|q| = C|\Delta V|$ (Eq. 28-1) and solve for C , we find

$$C = 4\pi\epsilon_0 \frac{ab}{b-a} \quad (\text{spherical capacitor}). \quad (28-17)$$

An Isolated Sphere

We can assign a capacitance to a *single* isolated spherical conductor of radius R by assuming that the “missing plate” is a conducting sphere of infinite radius. After all, the field lines leaving the surface of a positively charged isolated conductor must end somewhere; the walls of the room in which the conductor is housed can serve effectively as our sphere of infinite radius.

To find the capacitance of the isolated conductor, we first rewrite the expression for a spherical capacitor above as

$$C = 4\pi\epsilon_0 \frac{a}{1 - a/b}.$$

If we then let $b \rightarrow \infty$ and substitute R for a , we find

$$C = 4\pi\epsilon_0 R \quad (\text{isolated sphere}). \quad (28-18)$$

Note that this formula and the others we have derived for capacitance (Eqs. 28-9, 28-14, and 28-17) involve the constant ϵ_0 multiplied by a quantity having the dimensions of a length.

READING EXERCISE 28-2: Consider capacitors charged by and then removed from the same battery. Does the charge on the capacitor plates increase, decrease, or remain the same in each of the following situations? (a) The plate separation of a parallel-plate capacitor is increased. (b) The radius of the inner cylinder of a cylindrical capacitor is increased. (c) The radius of the outer spherical shell of a spherical capacitor is increased. ■

READING EXERCISE 28-3: Consider capacitors charged by identical batteries. If the capacitors stay connected to the batteries, does the amount of excess charge on the capacitor plates increase, decrease, or remain the same in each of the following situations? (a) The plate separation of a parallel-plate capacitor is increased. (b) The radius of the inner cylinder of a cylindrical capacitor is increased. (c) The radius of the outer spherical shell of a spherical capacitor is increased. ■

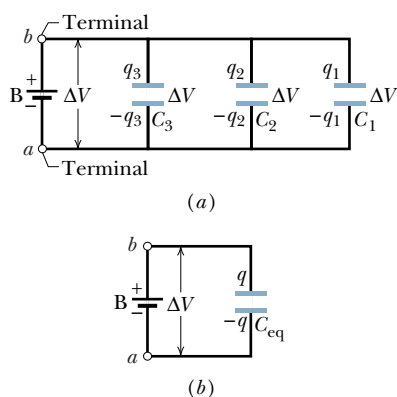

FIGURE 28-12 ■ (a) Three capacitors connected in parallel to battery B. The battery maintains a positive potential difference $\Delta V = V_b - V_a$ across its terminals and thus across each fully charged capacitor. (b) The equivalent capacitor, with capacitance C_{eq} , replaces the parallel combination.

28-4 Capacitors in Parallel and in Series

When there is a combination of capacitors in a circuit, we can often replace that combination with an **equivalent capacitor**—that is, a single capacitor having the same behavior as the actual combination of capacitors. With such a replacement, we can simplify circuits. This is similar to the approach we took with resistors in Chapter 27. In addition, circuits often have what is termed *stray capacitance* due to the presence of conductors and insulators in other types of circuit elements. Knowing how the effective capacitance of such elements might combine with each other and other capacitors in the vicinity is vital to the design of high-performance circuits. In this section we discuss the behavior of two basic types of capacitor combinations—parallel and series.

Capacitors in Parallel

Figure 28-12a shows an electric circuit in which three capacitors are connected *in parallel* with battery B. This description has little to do with where the capacitor plates appear in the diagram. Rather, “in parallel” means that one plate of each capacitor is wired directly to one plate of the other capacitors. The opposite plates of the capacitors are also wired to each other. When the parallel combination is connected to a

battery, the battery's potential difference ΔV_B is applied across all three capacitors as shown in Fig. 28-12a.

We can anticipate how the parallel combination will behave by considering the special case in which all three capacitors are parallel-plate capacitors with the same spacing. What happens in this case is that the effective area of the plates of the combined network of capacitors is equal to the sum of the three areas. Using Eq. 28-9 we see

$$C_{\text{eq}} = \frac{\epsilon_0 A}{d} = \frac{\epsilon_0(A_1 + A_2 + A_3)}{d} = \frac{\epsilon_0 A_1}{d} + \frac{\epsilon_0 A_2}{d} + \frac{\epsilon_0 A_3}{d} = C_1 + C_2 + C_3.$$

Even if the three capacitors are of different types with each having a different geometry, we expect the effective area of the combination will be increased. The proof of the pudding is in the experiment. It turns out that a multimeter set to measure capacitance can be used to verify

$$C_{\text{eq}} = C_1 + C_2 + C_3,$$

for parallel combinations of three capacitors of all sorts of different types. Since the potential difference across a parallel combination of capacitors connected to a voltage source is the same, we can use the expression $|q| = C|\Delta V|$ (Eq. 28-1) to show that if $C_{\text{eq}} = C_1 + C_2 + C_3$, then

$$\frac{|q_{\text{eq}}|}{|\Delta V|} = \frac{|q_1|}{|\Delta V|} + \frac{|q_2|}{|\Delta V|} + \frac{|q_3|}{|\Delta V|},$$

so that

$$|q_{\text{eq}}| = |q_1| + |q_2| + |q_3|.$$

In general,

When a potential difference ΔV is applied across several capacitors connected in parallel, that potential difference ΔV is applied across each capacitor. The total amount of the excess charge $|q|$ found on each plate of the equivalent capacitor is equal to the sum of the excess charge amounts found on each of the capacitors.

When we analyze a circuit of capacitors in parallel, we can simplify it with this mental replacement:

Capacitors connected in parallel can be replaced with an equivalent capacitor that has the same total charge $|q|$ and the same potential difference ΔV as the actual capacitors.

We can easily extend our method for finding the equivalent capacitance for three capacitors to any number of capacitors. For n capacitors wired in parallel,

$$C_{\text{eq}} = \sum_{j=1}^n C_j \quad (n \text{ capacitors in parallel}). \quad (28-19)$$

To find the equivalent capacitance of a parallel combination, we simply add the individual capacitances.

FIGURE 28-13 (a) Three capacitors connected in series to battery B. The battery maintains a positive potential difference ΔV between the top and bottom plates of the series combination. (b) The equivalent capacitor, with capacitance C_{eq} , replaces the series combination.

Capacitors in Series

Figure 28-13a shows three capacitors connected *in series* to battery B. This description has little to do with where the capacitors are located on the drawing. Rather, “in series” means the capacitors are wired serially, one after the other, so a battery can set up a potential difference ΔV across the two ends of the series as shown in Fig. 28-13a.

Let’s consider what goes on with the charges on the capacitor plates by following a *chain reaction* of events, in which the charging of each capacitor causes the charging of the next capacitor. We start with capacitor 3 and work upward to capacitor 1. When the battery is first connected to the series of capacitors, it produces a net charge $-q$ on the bottom plate of capacitor 3. That charge then repels negative charge from the top plate of capacitor 3 (leaving it with a net or excess charge $+q$). The repelled negative charge moves to the bottom plate of capacitor 2 (giving it charge $-q$). That excess negative charge on the bottom plate of capacitor 2 then repels negative charge from the top plate of capacitor 2 (leaving it with charge $+q$) to the bottom plate of capacitor 1 (giving it a net charge $-q$). Finally the excess charge on the bottom plate of capacitor 1 helps move negative charge from the top plate of capacitor 1 to the battery, leaving that top plate with net charge $+q$. We see then that the potential differences existing across the capacitors in the series produce identical amounts of excess charge $|q|$ on their plates.

Since the amounts of excess charge on each pair of plates in a series connection are the same, we can use Eq. 28-1, $|q| = C|\Delta V|$, to summarize our reasoning in equation form:

$$|q_1| = |q_2| = |q_3| = |q|,$$

and so

$$|\Delta V_1| = \frac{|q|}{C_1}, \quad |\Delta V_2| = \frac{|q|}{C_2}, \quad \text{and} \quad |\Delta V_3| = \frac{|q|}{C_3}.$$

The total potential difference ΔV due to the battery is the sum of these three potential differences. Thus,

$$|\Delta V| = |\Delta V_1| + |\Delta V_2| + |\Delta V_3|,$$

so that

$$\frac{|q|}{C_{\text{eq}}} = \frac{|q|}{C_1} + \frac{|q|}{C_2} + \frac{|q|}{C_3}.$$

The equivalent capacitance is then

$$C_{\text{eq}} = \frac{|q|}{|\Delta V|} \quad \text{and also} \quad \frac{1}{C_{\text{eq}}} = \frac{1}{C_1} + \frac{1}{C_2} + \frac{1}{C_3}.$$

When a potential difference of size $|\Delta V|$ is applied across several capacitors connected in series, each of the capacitors has the same amount of excess charge $|q|$ on its plates. The sum of the potential differences across the entire network of capacitors is equal to the size of the applied potential difference $|\Delta V|$.

Here is an important point about capacitors in series: When charge is shifted from one capacitor to another in a series of capacitors, it can move along only one route, such as from capacitor 3 to capacitor 2 in Fig. 28-13a. If there are additional routes, the capacitors are not in series. Hence, when we analyze a circuit of capacitors in series, we can simplify it with this mental replacement:

TABLE 28-2
Series and Parallel Resistors and Capacitors

Resistors		Capacitors	
Series	Parallel	Series	Parallel
$R_{\text{eq}} = \sum_{j=1}^n R_j$	$\frac{1}{R_{\text{eq}}} = \sum_{j=1}^n \frac{1}{R_j}$	$\frac{1}{C_{\text{eq}}} = \sum_{j=1}^n \frac{1}{C_j}$	$C_{\text{eq}} = \sum_{j=1}^n C_j$
Eq. 27-4	Eq. 27-12	Eq. 28-20	Eq. 28-19
1. Same current through all resistors	1. Same potential difference across all resistors	1. Same excess charge on all capacitors	1. Same potential difference across all capacitors
2. Potential differences across each resistor add	2. Currents through each resistor add	2. Potential differences across each capacitor add	2. Excess charges on attached plates add

Capacitors connected in series can be replaced with an equivalent capacitor having the same amount of excess charge $|q|$ on each plate and the same size of potential difference $|\Delta V|$ as the size of the total potential differences across the individual capacitors.

We can easily extend our method of determining the equivalent capacitance of a set of capacitors wired in series from three capacitors to n capacitors by using the expression

$$\frac{1}{C_{\text{eq}}} = \sum_{j=1}^n \frac{1}{C_j} \quad (n \text{ capacitors in series}). \quad (28-20)$$

Using this expression, you can show that the equivalent of a series of capacitances is always less than the least capacitance in the series. This can also be predicted qualitatively since the effective insulated separation between the top and bottom plate increases since $d = d_1 + d_2 + d_3$. According to Eq. 28-9, capacitance is inversely proportional to plate separation.

Table 28-2 summarizes the equivalence relations for resistors and capacitors in series and in parallel. It also presents the information about potential differences and charges on the combinations we determined by thinking about the physics of how the charges move and distribute themselves in these different geometrical configurations.

READING EXERCISE 28-4: A battery with a potential difference ΔV is used to store an amount of excess charge $|q|$ on each of two identical capacitors and is then disconnected. The two capacitors are then connected to each other. What is the potential difference across each capacitor and the amount of excess charge on each capacitor plate when the capacitors are wired (a) in parallel and (b) in series? ■

TOUCHSTONE EXAMPLE 28-1: Equivalent Capacitance

(a) Find the equivalent capacitance for the combination of capacitances shown in Fig. 28-14a, across which potential difference ΔV is applied. Assume

$$C_1 = 12.0 \mu\text{F}, \quad C_2 = 5.30 \mu\text{F}, \quad \text{and} \quad C_3 = 4.50 \mu\text{F}.$$

SOLUTION ■ The **Key Idea** here is that any capacitors connected in series can be replaced with their equivalent capacitor, and

any capacitors connected in parallel can be replaced with their equivalent capacitor. Therefore, we should first check whether any of the capacitors in Fig. 28-14a are in parallel or series.

Capacitors 1 and 3 are connected one after the other, but are they in series? No. The potential ΔV that is applied to the capacitors forces excess charge on the bottom plate of capacitor 3. That charge causes charge to shift from the top plate of capacitor 3. However, note that the shifting charge can move to the bottom

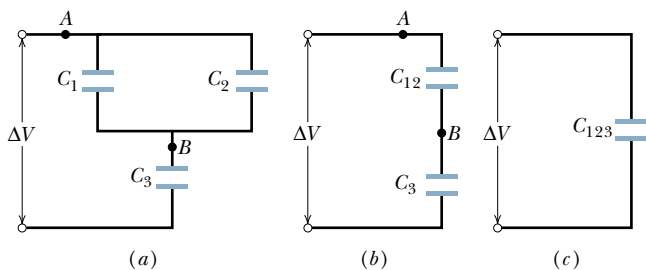

FIGURE 28-14 (a) Three capacitors. (b) C_1 and C_2 , a parallel combination, are replaced by C_{12} . (c) C_{12} and C_3 , a series combination, are replaced by the equivalent capacitance C_{123} .

plates of both capacitor 1 and capacitor 2. Because there is more than one route for the shifting charge, capacitor 3 is *not* in series with capacitor 1 (or capacitor 2).

Are capacitor 1 and capacitor 2 in parallel? Yes. Their top plates are directly wired together and their bottom plates are directly wired together, and electric potential is applied between the top-plate pair and the bottom-plate pair. Thus, capacitor 1 and capacitor 2 are in parallel, and Eq. 28-19 tells us that their equivalent capacitance C_{12} is

$$C_{12} = C_1 + C_2 = 12.0 \mu\text{F} + 5.30 \mu\text{F} = 17.3 \mu\text{F}.$$

In Fig. 28-14b, we have replaced capacitors 1 and 2 with their equivalent capacitor, call it capacitor 12 (say “one two”). (The connections at points A and B are exactly the same in Figs. 28-14a and b.)

Is capacitor 12 in series with capacitor 3? Again applying the test for series capacitances, we see that the charge that shifts from the top plate of capacitor 3 must entirely go to the bottom plate of capacitor 12. Thus, capacitor 12 and capacitor 3 are in series, and we can replace them with their equivalent C_{123} , as shown in Fig. 28-14c.

From Eq. 28-20, we have

$$\frac{1}{C_{123}} = \frac{1}{C_{12}} + \frac{1}{C_3} = \frac{1}{17.3 \mu\text{F}} + \frac{1}{4.50 \mu\text{F}} = 0.280 \mu\text{F}^{-1},$$

from which

$$C_{123} = \frac{1}{0.280 \mu\text{F}^{-1}} = 3.57 \mu\text{F}. \quad (\text{Answer})$$

(b) The potential difference that is applied to the input terminals in Fig. 28-14a is $V = 12.5 \text{ V}$. What is the excess charge on each plate of C_1 ?

SOLUTION ■ One **Key Idea** here is that, to get the excess charge q_1 on each plate of capacitor 1, we now have to work backward to that capacitor, starting with the equivalent capacitor 123. Since the given potential difference $\Delta V = 12.5 \text{ V}$ is applied across the actual combination of three capacitors in Fig. 28-14a, it is also applied across capacitor 123 in Fig. 28-14c. Thus, Eq. 28-1 ($|q| = C|\Delta V|$) gives us

$$|q_{123}| = C_{123}|\Delta V| = (3.57 \mu\text{F})(12.5 \text{ V}) = 44.6 \mu\text{C}.$$

A second **Key Idea** is that the series capacitors 12 and 3 in Fig. 28-1b have the same charge as their equivalent capacitor 123. Thus, capacitor 12 has charge $q_{12} = q_{123} = 44.6 \mu\text{C}$. From Eq. 28-1, the potential difference across capacitor 12 must be

$$|\Delta V_{12}| = \frac{|q_{12}|}{C_{12}} = \frac{44.6 \mu\text{C}}{17.3 \mu\text{F}} = 2.58 \text{ V}.$$

A third **Key Idea** is that the parallel capacitors 1 and 2 both have the same potential difference as their equivalent capacitor 12. Thus, capacitor 1 has the potential difference $\Delta V_1 = \Delta V_{12} = 2.58 \text{ V}$. Thus, from Eq. 28-1, the excess charge on each plate of capacitor 1 must be

$$\begin{aligned} |q_1| &= C_1|\Delta V_1| = (12.0 \mu\text{F})(2.58 \text{ V}) \\ &= 31.0 \mu\text{C}. \end{aligned} \quad (\text{Answer})$$

28-5 Energy Stored in an Electric Field

Work must be done by an external agent to charge a capacitor. Starting with an uncharged capacitor, for example, imagine—using “magic tweezers”—that you remove electrons from one plate and deposit them one at a time to the other plate. The electric field building up in the space between the plates has a direction that tends to oppose further separation of charge. As excess charge accumulates on the capacitor plates, you have to do increasingly larger amounts of work to transfer additional electrons. In practice, this work is done not by “magic tweezers” but by a battery, at the expense of its store of chemical energy.

We visualize the work required to charge a capacitor as being stored in the form of **electric potential energy** U in the electric field between the plates. You can recover this energy at will, by discharging the capacitor in a circuit, just as you can recover the potential energy stored in a stretched bow by releasing the bowstring to transfer the energy to the kinetic energy of an arrow. Another example is carrying rocks up a hill against gravity. Energy is stored because of the hill’s height and can be recovered by letting the rocks fall down again. In a capacitor, we can recover the stored energy by connecting wires to the ends.

Suppose that at a given instant, a charge $|q'|$ has been moved from one plate of a capacitor, through the wires in the circuit, to the other plate. The amount of the potential difference $|\Delta V'|$ between the plates at that instant will be $|q'|/C$. If an extra increment of charge $|dq'|$ is then removed from one plate and deposited on the other, the amount of the increment of work required will be (from Chapter 25)

$$|dW| = |\Delta V'| |dq'| = \frac{|q'|}{C} |dq'|.$$

The work required to bring the total capacitor charge separation up to a final value $|q|$ is

$$W = \int dW = \frac{1}{C} \int_0^q q' |dq'| = \frac{|q|^2}{2C}.$$

This work is stored as potential energy U in the capacitor, and since $q^2 = |q|^2$

$$U = \frac{q^2}{2C} \quad (\text{potential energy}). \quad (28-21)$$

From $|q| = C|\Delta V|$, we can also write this as

$$U = \frac{1}{2}C(\Delta V)^2 = \frac{1}{2}q\Delta V \quad (\text{potential energy}). \quad (28-22)$$

These relations hold no matter what the geometry of the capacitor is.

To gain some physical insight into energy storage, consider two parallel-plate capacitors identical except that capacitor 1 has twice the plate separation of capacitor 2. Then capacitor 1 has twice the volume between its plates and also, from Eq. 28-9, half the capacitance of capacitor 2. Equation 28-4 tells us that if both capacitors have the same amount of charge $|q|$, the electric fields between their plates are identical. Equation 28-21 tells us capacitor 1 has twice the stored potential energy of capacitor 2. Of two otherwise identical capacitors with the same charge and same electric field, the one with twice the volume between its plates has twice the stored potential energy. Arguments like this tend to verify our earlier assumption:

The potential energy of a charged capacitor may be viewed as being stored in the electric field between its plates.

A High-Speed Electronic Flash Unit

The ability of a capacitor to store potential energy is the basis of *high-speed electronic flash* devices, like those used in stop-action photography. In an electronic flash unit, a battery charges a capacitor relatively slowly to a high potential difference, storing a large amount of energy in the capacitor. The battery maintains only a modest potential difference; an electronic circuit repeatedly uses that potential difference to greatly increase the potential difference of the capacitor. The power, or rate of energy transfer, during this process is also modest.

When a high-speed flash unit fires, the capacitor releases its stored energy by sending a burst of electric current through a Xenon gas discharge tube that gives off a brief flash of white light. As an example, when a $200 \mu\text{F}$ capacitor in a high-speed flash unit is charged to 300 V, Eq. 28-22 gives the energy stored in the capacitor as

$$U = \frac{1}{2}C(\Delta V)^2 = \frac{1}{2}(200 \times 10^{-6} \text{ F})(300 \text{ V})^2 = 9 \text{ J}.$$

As mentioned in the puzzler at the beginning of this chapter, this should be more than enough energy to provide the illumination needed to take a photograph with ordinary film. Suppose the flashtube in the high-speed flash unit Edgerton used to take the photo of the bullet passing through the apple has a very rapid discharge rate. If the Xenon tube takes only one-third of a microsecond to discharge, then the power associated with the discharge is

$$P = \frac{U}{t} = \frac{9 \text{ J}}{0.33 \times 10^{-6} \text{ s}} = 27 \times 10^6 \text{ W} = 27 \text{ MW}.$$

Energy Density

In a parallel-plate capacitor, neglecting fringing, the electric field has the same value at all points between the plates. The **energy density** u —that is, the potential energy per unit volume between the plates—should also be uniform. We can find u by dividing the total potential energy by the volume Ad of the space between the plates. Using Eq. 28-22, we obtain

$$u = \frac{U}{Ad} = \frac{C(\Delta V)^2}{2Ad}.$$

With Eq. 28-9 ($C = \epsilon_0 A/d$), this result becomes

$$u = \frac{1}{2}\epsilon_0 \left(\frac{\Delta V}{d}\right)^2.$$

However, from Eq. 25-39, $\Delta V/d$ equals the electric field magnitude $|\vec{E}| = E$, so

$$u = \frac{1}{2}\epsilon_0 E^2 \quad (\text{energy density}). \quad (28-23)$$

Although we derived this result for the special case of a parallel-plate capacitor, it holds generally, whatever may be the source of the electric field. If an electric field \vec{E} exists at any point in space, we can think of that point as a site of electric potential energy whose amount per unit volume is given by Eq. 28-23.

TOUCHSTONE EXAMPLE 28-2: Redistributing Charge

(a) Capacitor 1, with $C_1 = 3.55 \mu\text{F}$, is charged to a potential difference $\Delta V_0 = 6.30 \text{ V}$, using a 6.30 V battery. The battery is then removed and the capacitor is connected as in Fig. 28-15 to an uncharged capacitor 2, with $C_2 = 8.95 \mu\text{F}$. When switch S is closed, charge flows between the capacitors until they have the same potential difference ΔV . Find ΔV .

SOLUTION ■ The situation here differs from Touchstone Example 28-1 because an applied electric potential is *not* maintained

FIGURE 28-15 ■ A potential difference ΔV_0 is applied to capacitor 1 and the charging battery is removed. Switch S is then closed so that the charge on capacitor 1 is shared with capacitor 2.

across a combination of capacitors by a battery or some other source. Here, just after switch S is closed, the only applied electric potential is that of capacitor 1 on capacitor 2, and that potential is decreasing. Thus, although the capacitors in Fig. 28-15 are connected end to end, in this situation they are not *in series*; and although they are drawn parallel, in this situation they are not *in parallel*.

To find the final electric potential (when the system comes to equilibrium and charge stops flowing), we use this **Key Idea**: After the switch is closed, the original excess charge $|q_0|$ on each plate of capacitor 1 is redistributed (shared) between capacitor 1 and capacitor 2. When equilibrium is reached, we can relate the original charge $|q_0|$ with the final charges $|q_1|$ and q_2 by writing

$$|q_0| = |q_1| + |q_2|.$$

Applying the relation $|q| = C|\Delta V|$ (Eq. 28-1) to each term of this equation yields

$$C_1|\Delta V_0| = C_1|\Delta V| + C_2|\Delta V|,$$

from which

$$\begin{aligned} |\Delta V| &= |\Delta V_0| \frac{C_1}{C_1 + C_2} = \frac{(6.30 \text{ V})(3.55 \mu\text{F})}{3.55 \mu\text{F} + 8.95 \mu\text{F}} \\ &= 1.79 \text{ V}. \end{aligned} \quad (\text{Answer})$$

When the capacitors reach this steady value of electric potential difference, the charge flow stops.

(b) How much energy is stored in the original capacitor when it is first charged up?

SOLUTION ■ The **Key Idea** here is that the potential energy stored in a capacitor, given by Eq. 28-22, is just

$$\begin{aligned} U &= \left(\frac{1}{2}\right)C(\Delta V)^2 \\ &= \left(\frac{1}{2}\right)(3.55 \mu\text{F})(6.30 \text{ V})^2 \\ &= 70.4 \mu\text{J}. \end{aligned} \quad (\text{Answer})$$

(c) How much energy is stored in the two capacitors after they are connected together?

SOLUTION ■ The **Key Idea** here is that the potential energy stored in *each* capacitor, given by Eq. 28-22, so that

$$\begin{aligned} U^{\text{total}} &= U_1 + U_2 = \left(\frac{1}{2}\right)C_1(\Delta V_1)^2 + \left(\frac{1}{2}\right)C_2(\Delta V_2)^2 \\ &= \left(\frac{1}{2}\right)((3.55 \mu\text{F}) + (8.95 \mu\text{F}))(1.79 \text{ V})^2 \\ &= 20.0 \mu\text{J}. \end{aligned} \quad (\text{Answer})$$

But how can this be? Before the second capacitor was placed across the first one, there was over 70 μJ of energy stored in the system. What happened to the 50 μJ of energy that seems to have vanished when the second capacitor was charged from the first one? You might argue that the “lost” energy must have been dissipated as heat in the resistance of the wires connecting the two capacitors. But suppose we used superconducting wires with zero resistance? Then where does the missing energy go? The answer, as you will learn in Chapters 33 and 34, is that the charge would oscillate back and forth between the two capacitors until the 50 μJ of “excess” energy was radiated away in the form of electromagnetic waves.

28-6 Capacitor with a Dielectric

If you fill the space between the plates of a capacitor with a *dielectric*, which is usually an insulating material such as mineral oil or plastic, what happens to the capacitance? Michael Faraday—to whom the whole concept of capacitance is largely due and for whom the SI unit of capacitance is named—first looked into this matter in 1837. Using simple equipment much like that shown in Fig. 28-16, he found that the capacitance *increased* by a numerical factor κ , which he called the dielectric constant of the insulating material. Table 28-3 shows some dielectric materials and their dielectric constants. The dielectric constant of a vacuum is unity by definition. Because air is mostly empty space, its measured dielectric constant is only slightly greater than unity.

Another effect of the introduction of a dielectric is to limit the potential difference that can be applied between the plates to a certain value ΔV^{max} , called the *breakdown potential*. If this value is substantially exceeded, the dielectric material will break down and form a conducting path between the plates. That is, when the capacitor is filled with a dielectric, the charge separation you can maintain with a given potential difference increases. Every dielectric material has a characteristic *dielectric strength*, which is the maximum value of the electric field that it can tolerate without breakdown. A few such values are listed in Table 28-3.

As we discussed in connection with Eq. 28-18, the capacitance of any capacitor can be written in the form

$$C = \epsilon_0 L, \quad (28-24)$$

in which L has the dimensions of a length. For example, $L = A/d$ for a parallel-plate capacitor. Faraday’s discovery was, with a dielectric *completely* filling the space between the plates, Eq. 28-24 becomes

$$C = \kappa\epsilon_0 L = \kappa C_{\text{air}}, \quad (28-25)$$

where C_{air} is the value of the capacitance with only air between the plates.

FIGURE 28-16 ■ The simple electrostatic apparatus used by Faraday. An assembled apparatus (second from left) forms a spherical capacitor consisting of a central brass ball and a concentric brass shell. Faraday placed dielectric materials in the space between the ball and the shell.

TABLE 28-3

Some Properties of Dielectrics^a

Material	Dielectric Constant κ	Dielectric Strength (kV/mm)
Air (1 atm)	1.00054	3
Polystyrene	2.6	24
Paper	3.5	16
Transformer oil	4.5	
Pyrex	4.7	14
Ruby mica	5.4	
Porcelain	6.5	
Tantalum oxide	11.6	
Silicon	12	
Germanium	16	
Ethanol	25	
Water (20°C) ^b	80.4	
Water (25°C) ^b	78.5	
Titania ceramic	130	
Strontium titanate	310	8
For a vacuum, $\kappa = \text{unity}$.		

^aMeasured at room temperature, except for the water.^bNote that water is not an insulating material. It is listed because it has dielectric properties.

FIGURE 28-17 (a) If the potential difference between the plates of a capacitor is maintained, as by battery B, the effect of a dielectric is to increase the excess charge on each plate. (b) If the charge on the capacitor plates is maintained, as in this case, the effect of a dielectric is to reduce the potential difference between the plates. The scale shown is that of a *potentiometer*, a device used to measure potential difference (here, between the plates). A capacitor cannot discharge through a potentiometer.

Figure 28-17 provides some insight into Faraday's experiments. In Fig. 28-17a the battery ensures that the potential difference ΔV between the plates will remain constant. When a dielectric slab is inserted between the plates, the excess amount of charge $|q|$ on the plates increases by a factor of κ , where κ is always greater than 1; the additional charge is delivered to the capacitor plates by the battery. In Fig. 28-17b there is no battery and therefore the amount of excess charge $|q|$ must remain constant when the dielectric slab is inserted; then the potential difference ΔV between the plates decreases by a factor of κ . Both these observations are consistent (through the relation $|q| = C|\Delta V|$) with the increase in capacitance caused by the dielectric.

Comparison of Eqs. 28-24 and 28-25 suggests that the effect of a dielectric can be summed up in more general terms:

In a region completely filled by a dielectric material of dielectric constant κ , all electrostatic equations containing the permittivity constant ϵ_0 are to be modified by replacing ϵ_0 with $\kappa\epsilon_0$.

A point charge inside a dielectric produces an electric field that, by Coulomb's law, has the magnitude

$$|\vec{E}| = \frac{1}{4\pi\kappa\epsilon_0} \frac{|q|}{r^2}. \quad (28-26)$$

Also, the expression for the electric field just outside an isolated conductor immersed in a dielectric (see Eq. 24-20) becomes

$$|\vec{E}| = \frac{|\sigma|}{\kappa\epsilon_0}. \quad (28-27)$$

Both these equations show that for a fixed distribution of charges, the effect of a dielectric is to weaken the magnitude of the electric field that would otherwise be present. In

addition, the amount of energy stored is reduced because work must be done by the field to pull in the dielectric.

TOUCHSTONE EXAMPLE 28-3: A Dielectric's Energetics

A parallel-plate capacitor whose capacitance C is 13.5 pF is charged by a battery to a potential difference $\Delta V = 12.5$ V between its plates. The charging battery is now disconnected and a porcelain slab ($\kappa = 6.50$) is slipped between the plates. What is the potential energy of the device, both before and after the slab is put into place?

SOLUTION ■ The **Key Idea** here is that we can relate the potential energy U of the capacitor to the capacitance C and either the potential ΔV (with Eq. 28-22) or the capacitor charge $|q|$ (with Eq. 28-21):

$$U_1 = \frac{1}{2}C\Delta V^2 = \frac{q^2}{2C}.$$

Because we are given the initial potential $\Delta V (=12.5\text{V})$, we use Eq. 28-22 to find the initial stored energy:

$$\begin{aligned} U_1 &= \frac{1}{2}CV^2 = \frac{1}{2}(13.5 \times 10^{-12} \text{ F})(12.5 \text{ V})^2 \\ &= 1.055 \times 10^{-9} \text{ J} = 1055 \text{ pJ} \approx 1100 \text{ pJ}. \quad (\text{Answer}) \end{aligned}$$

To find the final potential energy U_2 (after the slab is introduced), we need another **Key Idea**: Because the battery has been

disconnected, the amount of excess charge on each capacitor plate cannot change when the dielectric is inserted. However, the potential *does* change. Thus, we must now use Eq. 28-21 (based on q) to write the final potential energy U_2 , but now that the slab is within the capacitor, the capacitance is κC . We then have

$$U_2 = \frac{q^2}{2\kappa C} = \frac{U_1}{\kappa} = \frac{1055 \text{ pJ}}{6.50} = 162 \text{ pJ} \approx 160 \text{ pJ}. \quad (\text{Answer})$$

When the slab is introduced, the potential energy decreases by a factor of κ .

The “missing” energy, in principle, would be apparent to the person who introduced the slab. The capacitor would exert a tiny tug on the slab and would do work on it, in amount

$$W = U_1 - U_2 = (1055 - 162) \text{ pJ} = 893 \text{ pJ}.$$

If the slab were allowed to slide between the plates with no restraint and if there were no friction, the slab would oscillate back and forth between the plates with a (constant) mechanical energy of 893 pJ, and this system energy would transfer back and forth between kinetic energy of the moving slab and potential energy stored in the electric field.

28-7 Dielectrics: An Atomic View

What happens, in atomic and molecular terms, when we put a dielectric in an electric field? There are two possibilities, depending on the nature of the molecules:

1. **Polar dielectrics.** The molecules of some dielectrics, like water, have permanent electric dipole moments. In such materials (called *polar dielectrics*), the electric dipoles tend to line up with an external electric field as in Fig. 28-18. Because the molecules are continuously jostling each other as a result of their random thermal motion, this alignment is not complete, but it becomes more complete as the magnitude of the applied field is increased (or as the temperature, and thus the jostling, is decreased). The alignment of the electric dipoles produces an electric field directed opposite the applied field and smaller in magnitude.
2. **Nonpolar dielectrics.** Regardless of whether they have permanent electric dipole moments, molecules acquire dipole moments by induction when placed in an external electric field. In Section 25-9 (see Fig. 25-16), we saw that this occurs because the external field tends to “stretch” the molecules, slightly separating the centers of negative and positive charge.

Figure 28-19a shows a nonpolar dielectric slab with no external electric field applied. An electric field \vec{E}_0 is present due to the excess charges shown on the capacitor plates in Fig. 28-19a. The result is a slight separation of the centers of the positive and negative charge distributions within the slab, producing positive charge on one face of the slab (due to the positive ends of dipoles there) and negative charge on the opposite

FIGURE 28-18 ■ (a) Molecules with a permanent electric dipole moment, showing their random orientation in the absence of an external electric field. (b) An electric field is applied, producing partial alignment of the dipoles. Thermal agitation prevents complete alignment.

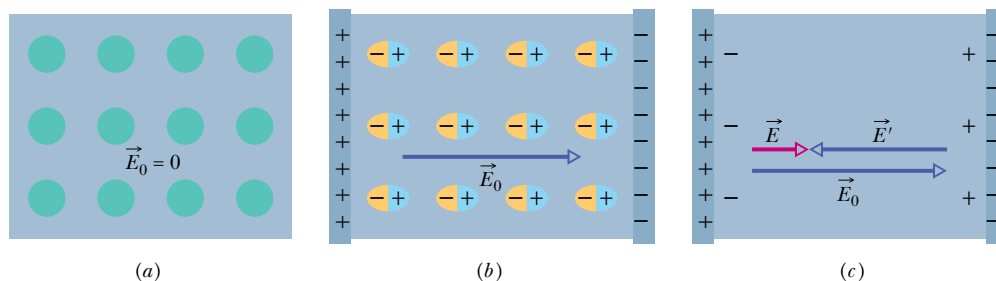

FIGURE 28-19 (a) A nonpolar dielectric slab. The circles represent the electrically neutral atoms within the slab. (b) An electric field is applied via charged capacitor plates; the field slightly stretches the atoms, separating the centers of positive and negative charge. (c) The separation produces surface charges on the slab faces. These charges set up a field \vec{E}' , which opposes the applied field \vec{E}_0 . The resultant field \vec{E} inside the dielectric (the vector sum of \vec{E}_0 and \vec{E}') has the same direction as \vec{E}_0 but smaller magnitude.

face (due to the negative ends of dipoles there). The slab as a whole remains electrically neutral and—within the slab—there is no excess charge in any volume element.

Figure 28-19c shows that the induced surface charges on the faces produce an electric field \vec{E}' , in the direction opposite the applied electric field \vec{E}_0 . The resultant field \vec{E} inside the dielectric (the vector sum of fields \vec{E}_0 and \vec{E}') has the direction of \vec{E}_0 but is smaller in magnitude.

Both the field \vec{E}' produced by the surface charges in Fig. 28-19c and the electric field produced by the permanent electric dipoles in Fig. 28-18 act in the same way—they oppose the applied field \vec{E} . (Inside the material, the \vec{E} field fluctuates wildly, depending on whether you are close to one side of a molecule or another. The effects we are looking at are the average effects of the molecules.) Thus, the effect of both polar and nonpolar dielectrics is to weaken any applied field within them, as between the plates of a capacitor. As a result, a given charge separation can be maintained at a lower potential difference, ΔV , with a dielectric than with a vacuum. This means that a capacitor with a dielectric added has a higher capacitance.

We can now see why the dielectric porcelain slab in Touchstone Example 28-3 is pulled into the capacitor: As it enters the space between the plates, the excess surface charge appearing on each slab face has a sign that is opposite to that of the excess charge on the nearby capacitor plate. Thus, slab and plates attract each other.

FIGURE 28-20 (a) A parallel-plate capacitor (a) without and (b) with a dielectric slab inserted. The excess charge q on the plates is assumed to be the same in both cases.

28-8 Dielectrics and Gauss' Law

In our discussion of Gauss' law in Chapter 24, we assumed that the charges existed in a vacuum. Here we shall see how to modify and generalize that law if dielectric materials, such as those listed in Table 28-3, are present. Figure 28-20 shows a parallel-plate capacitor of plate area A , both with and without a dielectric. We assume the amount of excess charge $|q|$ on the plates is the same in both situations. Note the field between the plates induces charge buildup on the faces of the dielectric by one of the methods discussed in Section 28-7.

For the situation of Fig. 28-20a, without a dielectric, we can find the electric field \vec{E}_0 between the plates as we did in Fig. 28-9: We enclose the excess charge q on the top plate with a Gaussian surface and then apply Gauss' law. Letting $E_0 = |\vec{E}_0|$ represent the magnitude of the field, we find

$$|\epsilon_0 \oint \vec{E} \cdot d\vec{A}| = \epsilon_0 E_0 A = |q^{\text{net}}| = |q|, \quad (28-28)$$

or

$$E_0 = \frac{|q|}{\epsilon_0 A}. \quad (28-29)$$

In Fig. 28-20*b*, with the dielectric in place, we can find the electric field between the plates (and within the dielectric) by using the same Gaussian surface. However, now the surface encloses two types of charge: it still encloses a net charge q on the top plate but it now also encloses the induced charge q' on the top face of the dielectric. The excess charge on each conducting plate is said to be *free charge* because it can move through the circuit if we change the electric potential of the plate. The induced charge on the surfaces of the dielectric is bound charge. It's stuck to the molecules of an insulator. It can only be displaced from its original position by microscopic amounts and cannot move from the surface.

The amount of net charge enclosed by the Gaussian surface in Fig. 28-20*b* is $|q + q'|$, so Gauss' law now gives

$$|\epsilon_0 \oint \vec{E} \cdot d\vec{A}| = \epsilon_0 EA = |q + q'|, \quad (28-30)$$

or

$$E = \frac{|q + q'|}{\epsilon_0 A}. \quad (28-31)$$

Since q' and q have different signs, this means that the effect of the dielectric is to weaken the original field E_0 by a factor of κ , so we may write

$$E = \frac{E_0}{\kappa} = \frac{|q|}{\kappa \epsilon_0 A}. \quad (28-32)$$

Comparison of Eqs. 28-31 and 28-32 shows

$$|q^{\text{net}}| = |q + q'| = \frac{|q|}{\kappa}. \quad (28-33)$$

Equation 28-33 shows correctly that the amount of induced surface charge is less than that of the excess free charge and is zero if no dielectric is present (then, $\kappa = 1$ in Eq. 28-33).

By substituting for $|q + q'|$ from Eq. 28-33 in Eq. 28-30, we can write Gauss' law in the form

$$\epsilon_0 \oint \kappa \vec{E} \cdot d\vec{A} = q \quad (\text{Gauss' law with dielectric}), \quad (28-34)$$

where q is the net free charge on the plate of interest. Here we drop the absolute value sign to account for the fact that the excess charge on a plate of interest, q , can be either positive or negative.

This important equation, although derived for a parallel-plate capacitor, is true generally and is the most general form in which Gauss' law can be written. Note the following:

1. The flux integral now involves $\kappa \vec{E}$, not just \vec{E} . (The vector $\epsilon_0 \kappa \vec{E}$ is sometimes called the electric displacement \vec{D} , so Eq. 28-34 can be written in the form $\oint \vec{D} \cdot d\vec{A} = q$).
2. The amount of excess charge $|q|$ enclosed by the Gaussian surface is now taken to be the free charge only. The induced surface charge is deliberately ignored on the right side of Eq. 28-34, having been taken fully into account by introducing the dielectric constant κ on the left side.
3. Equation 28-34 differs from Eq. 24-7, our original statement of Gauss' law, only in that ϵ_0 in the latter equation has been replaced by $\kappa \epsilon_0$. We keep κ inside the integral of Eq. 28-34 to allow for cases in which κ is not constant over the entire Gaussian surface.

Gauss's law still holds when charged molecules are present, but it's hard to use, since we don't know where those molecular charges are. We only know their average effect, which is summarized by the measured constant κ . Here, we saw how to create a form of Gauss's law including the effect of the molecules automatically, and this allows us to work only with the charges we control directly—the “free” charges.

TOUCHSTONE EXAMPLE 28-4: Adding a Dielectric

Figure 28-21 shows a parallel-plate capacitor of plate area A and plate separation d . A potential difference ΔV_0 is applied between the plates. The battery is then disconnected, and a dielectric slab of thickness b and dielectric constant κ is placed between the plates as shown. Assume

$$A = 115 \text{ cm}^2, \quad d = 1.24 \text{ cm}, \quad \Delta V_0 = 85.5 \text{ V}, \\ b = 0.780 \text{ cm}, \quad \text{and} \quad \kappa = 2.61.$$

FIGURE 28-21 A parallel-plate capacitor containing a dielectric slab that only partially fills the space between the plates.

(a) What is the capacitance C_0 before the dielectric slab is inserted?

SOLUTION From Eq. 28-9 we have

$$C_0 = \frac{\epsilon_0 A}{d} = \frac{(8.85 \times 10^{-12} \text{ F/m})(115 \times 10^{-4} \text{ m}^2)}{1.24 \times 10^{-2} \text{ m}} \\ = 8.21 \times 10^{-12} \text{ F} = 8.21 \text{ pF.} \quad (\text{Answer})$$

(b) What is the amount of free excess charge that appears on each plate?

SOLUTION From Eq. 28-1,

$$|q| = C_0 |\Delta V_0| = (8.21 \times 10^{-12} \text{ F})(85.5 \text{ V}) \\ = 7.02 \times 10^{-10} \text{ C} = 702 \text{ pC.} \quad (\text{Answer})$$

Because the charging battery was disconnected before the slab was introduced, the free charge remains unchanged as the slab is put into place.

(c) What is the magnitude of the electric field E_0 in the gaps between the plates and the dielectric slab?

SOLUTION A **Key Idea** here is to apply Gauss' law, in the form of Eq. 28-34, to Gaussian surface I in Fig. 28-21—that surface

passes through the gap, and so it encloses *only* the free charge on the upper capacitor plate. Because the area vector $d\vec{A}$ and the field vector \vec{E}_0 are both directed downward, the dot product in Eq. 28-34 becomes

$$\vec{E}_0 \cdot d\vec{A} = |\vec{E}_0| dA \cos 0^\circ = E_0 dA.$$

Equation 28-34 then becomes

$$\epsilon_0 \kappa E_0 \oint dA = q.$$

The integration now simply gives the surface area A of the plate. Thus, we obtain

$$\epsilon_0 \kappa |\vec{E}_0| \oint dA = q,$$

or

$$E_0 = \frac{q}{\epsilon_0 \kappa A}.$$

One more **Key Idea** is needed before we evaluate E_0 ; that is, we must put $\kappa = 1$ here because Gaussian surface I does not pass through the dielectric. Since the charge q on the upper plate is positive, we have

$$E_0 = \frac{q}{\epsilon_0 \kappa A} = \frac{7.02 \times 10^{-10} \text{ C}}{(8.85 \times 10^{-12} \text{ F/m})(1)(115 \times 10^{-4} \text{ m}^2)} \\ = 6900 \text{ V/m} = 6.90 \text{ kV/m.} \quad (\text{Answer})$$

Note that the value of E_0 does not change when the slab is introduced because the amount of charge enclosed by Gaussian surface I in Fig. 28-21 does not change.

(d) What is the magnitude of the electric field E_1 in the dielectric slab?

SOLUTION The **Key Idea** here is to apply Eq. 28-34 to Gaussian surface II in Fig. 28-21. That surface encloses free charge $-q$ and induced charge $-q'$, but we ignore the latter when we use Eq. 28-34. We find

$$\oint \kappa \vec{E}_1 \cdot d\vec{A} = -\epsilon_0 \kappa E_1 A = -q. \quad (28-35)$$

(The first minus sign in this equation comes from the dot product $\vec{E}_1 \cdot d\vec{A}$, because now the field vector \vec{E}_1 is directed downward and the area vector $d\vec{A}$ is directed upward.) Equation 28-35 gives us

$$E_1 = \frac{q}{\epsilon_0 \kappa A} = \frac{E_0}{\kappa} = \frac{6.90 \text{ kV/m}}{2.61} = 2.64 \text{ kV/m.} \quad (\text{Answer})$$

(e) What is the potential difference ΔV between the plates after the slab has been introduced?

SOLUTION ■ The **Key Idea** here is to find ΔV by integrating along a straight-line path extending directly from the bottom plate to the top plate. Within the dielectric, the path length is b and the electric field is E_1 . Within the two gaps above and below the dielectric, the total path length is $d - b$ and the electric field is E_0 . Equation 28-6 then yields

$$\begin{aligned}\Delta V &= \int_{-}^{+} |\vec{E}| |d\vec{s}| = E_0(d - b) + E_1 b \\ &= (6900 \text{ V/m})(0.0124 \text{ m} - 0.00780 \text{ m}) \\ &\quad + (2640 \text{ V/m})(0.00780 \text{ m}) \\ &= 52.3 \text{ V.} \quad (\text{Answer})\end{aligned}$$

This is less than the original potential difference of 85.5 V.

(f) What is the capacitance with the slab in place?

SOLUTION ■ The **Key Idea** now is that the capacitance C is related to the free charge q and the potential difference ΔV via Eq. 28-1, just as when a dielectric is not in place. Taking q from (b) and ΔV from (e), we have

$$\begin{aligned}C &= \frac{|q|}{|\Delta V|} = \frac{7.02 \times 10^{-10} \text{ C}}{52.3 \text{ V}} \\ &= 1.34 \times 10^{-11} \text{ F} = 13.4 \text{ pF.} \quad (\text{Answer})\end{aligned}$$

This is greater than the original capacitance of 8.21 pF.

28-9 RC Circuits

In preceding sections we dealt only with circuits in which the currents did not vary with time. Here we begin a discussion of time-varying currents.

Charging a Capacitor

The capacitor of capacitance C in Fig. 28-22 is initially uncharged. To charge it, we close switch S on point a . This completes an *RC series circuit* consisting of the capacitor, an ideal battery of emf \mathcal{E} , and a resistance R . Since an ideal battery has no internal resistance, its emf is the same as the potential difference across the battery, ΔV_B .

From Section 28-2, we already know that as soon as the circuit is complete, charge begins to flow (current exists) between a capacitor plate and a battery terminal on each side of the capacitor. This current increases the amount of excess charge on the plates, q and the size of the potential difference $|\Delta V_C| = |q|/C$ across the capacitor. When that potential difference across the capacitor equals the potential difference across the battery (which here is equal to the emf of the battery, ΔV_B), the current is zero. From Eq. 28-1 ($|q| = C|\Delta V_C|$), the *equilibrium* (final) amount of excess charge on each plate of the fully charged capacitor is equal to $C|\Delta V_B|$.

Here we want to examine the charging process. In particular we want to know how the amount of excess charge $|q(t)|$ on each capacitor plate, the potential difference $\Delta V_C(t)$ across the capacitor, and the current $i(t)$ in the circuit vary with time during the charging process. We begin by applying the loop rule to the circuit, traversing it clockwise from the negative terminal of the battery. We find

$$\Delta V_B - iR - \frac{q}{C} = 0, \quad (28-36)$$

where q represents the excess charge on the top plate of the capacitor, which is positive in this case.

The last term on the left side represents the potential difference across the capacitor. The term is negative because the capacitor's top plate, which is connected to the battery's positive terminal, is at a higher potential than the lower plate. Thus, there is a drop in potential as we move down through the capacitor.

FIGURE 28-22 ■ When switch S is closed on a , the capacitor is *charged* through the resistor. When the switch is afterward closed on b , the capacitor *discharges* through the resistor.

FIGURE 28-23 (a) A plot of Eq. 28-39, which shows the buildup of excess charge on the capacitor plates of Fig. 28-22. (b) A plot of Eq. 28-40. The charging current in the circuit of Fig. 28-22 declines as the capacitor becomes more fully charged. The curves are plotted for $R = 2000 \, \Omega$, $C = 1 \, \mu\text{F}$, and $\Delta V_B = 10 \, \text{V}$. The small triangles represent successive intervals of one time constant τ .

We cannot immediately solve Eq. 28-36 because it contains two variables, i and q . However, those variables are not independent but are related by

$$i = \frac{dq}{dt}. \quad (28-37)$$

Substituting this for i and rearranging, we find

$$R \frac{dq}{dt} + \frac{q}{C} = \Delta V_B \quad (\text{charging equation}). \quad (28-38)$$

This differential equation describes the time variation of the excess positive charge q on the top plate of the capacitor shown in Fig. 28-23. To solve it, we need to find the function $q(t)$ that satisfies this equation and also satisfies the condition the capacitor be initially uncharged: $q = 0 \, \text{C}$ at $t = 0 \, \text{s}$.

The solution to Eq. 28-38 is

$$q = C\Delta V_B(1 - e^{-t/RC}) \quad (\text{charging a capacitor}). \quad (28-39)$$

(Here e is the exponential base, $2.718 \dots$, and not the elementary charge.) You can verify by substitution that Eq. 28-39 is indeed a solution to Eq. 28-38. We can see that this expression does indeed satisfy our required initial condition, because at $t = 0$ the term $e^{-t/RC}$ is unity, so the equation gives $q = 0$. Note also that as t goes to ∞ (that is, a long time later), the term $e^{-t/RC}$ goes to zero; so the equation gives the proper value for the full (equilibrium) excess charge on the positive plate of the capacitor—namely, $q = C\Delta V_B$. A plot of $q(t)$ for the charging process is given in Fig. 28-23a.

The derivative of $q(t)$ is the positive current $i(t)$ charging the capacitor:

$$i = \frac{dq}{dt} = \left(\frac{\Delta V_B}{R} \right) e^{-t/RC} \quad (\text{charging a capacitor}). \quad (28-40)$$

A plot of $i(t)$ for the charging process is given in Fig. 28-23b. Note that the current has the initial value $\Delta V_B/R$ and it decreases to zero as the capacitor becomes fully charged.

A capacitor being charged initially acts like ordinary connecting wire relative to the charging current. A long time later, it acts like a broken wire.

By combining $|q| = C|\Delta V_C|$ (Eq. 28-1) and $q = C\Delta V_B(1 - e^{-t/RC})$ (Eq. 28-39), we find the potential difference $\Delta V_C(t)$ across the capacitor during the charging process is

$$|\Delta V_C| = \frac{q}{C} = |\Delta V_B(1 - e^{-t/RC})| \quad (\text{charging a capacitor}). \quad (28-41)$$

This tells us $\Delta V_C = 0$ at $t = 0$ and $\Delta V_C = \Delta V_B$ when the capacitor is fully charged as the time approaches infinity ($t \rightarrow \infty$).

The Time Constant

The product RC appearing in the equations above has the dimensions of time (both because the argument of an exponential must be dimensionless and because, in fact, $1.0 \, \Omega \times 1.0 \, \text{F} = 1.0 \, \text{s}$). RC is called the **capacitive time constant** of the circuit and is represented with the symbol τ .

$$\tau = RC \quad (\text{time constant}). \quad (28-42)$$

From the expression for the excess charge as a function of time on one plate of a charging capacitor $q = C\Delta V_B(1 - e^{-t/RC})$ (Eq. 28-39), we can now see that at time $t = \tau (=RC)$, the excess charge on the top plate of the initially uncharged capacitor of Fig. 28-22 has increased from zero to

$$q = C\Delta V_B(1 - e^{-1}) = 0.63C\Delta V_B. \quad (28-43)$$

In words, after the first time constant, τ , the amount of excess charge has increased from zero to 63% of its final value, $C\Delta V_B$. In Fig. 28-22, the small triangles along the time axes mark successive intervals of one time constant during the charging of the capacitor. The charging times for RC circuits are often stated in terms of τ . The greater τ is, the greater is the charging time.

Discharging a Capacitor

Assume that now the capacitor of Fig. 28-22 is fully charged to a potential ΔV_0 equal to the potential difference, ΔV_B , of the battery. At a new time $t = 0$, switch S is thrown from a to b so the capacitor can *discharge* through resistance R . How do the excess charge $q(t)$ on the top plate of the capacitor and the current $i(t)$ through the discharge loop of capacitor and resistance now vary with time?

The differential equation describing $q(t)$ in this case is similar to the one we worked with for the case of charging Eq. 28-38, except now there is no battery in the discharge loop and so $\Delta V_B = 0$. Thus,

$$R \frac{dq}{dt} + \frac{q}{C} = 0 \quad (\text{discharging equation}), \quad (28-44)$$

where the current term, dq/dt , and the voltage across the capacitor, q/C , can be positive or negative. The solution to this differential equation is

$$q = q_0 e^{-t/RC} \quad (\text{discharging a capacitor}), \quad (28-45)$$

where $|q_0| (=C|\Delta V_0|)$ is the initial amount of excess charge on the capacitor plates. You can verify by substitution that Eq. 28-45 is indeed a solution of Eq. 28-44.

Equation 28-45 tells us that the amount of excess charge on each capacitor plate decreases exponentially with time, at a rate set by the capacitive time constant $\tau = RC$. At time $t = \tau$, the capacitor's excess charge has been reduced to $|q_0|e^{-1}$, or about 37% of the initial value. That is, the amount of excess charge on the plates has decreased by 63%. Note that a greater τ means a greater discharge time.

Differentiating Eq. 28-45 gives us the current $i(t)$:

$$i = \frac{dq}{dt} = -\left(\frac{q_0}{RC}\right)e^{-t/RC} \quad (\text{discharging a capacitor}). \quad (28-46)$$

This tells us the current also decreases exponentially with time, at a rate set by τ . The initial current i_0 is equal to q_0/RC . Note that you can find i_0 by simply applying the loop rule to the circuit at $t = 0$ the moment when the capacitor's initial potential ΔV_0 is connected across the resistance R . So the current must be

$$i_0 = \frac{\Delta V_0}{R} = \frac{(q_0/C)}{R} = \frac{q_0}{RC}.$$

The minus sign in the discharging capacitor expression (Eq. 28-46) can be ignored; it merely means the amount of excess charge on the plate is decreasing.

READING EXERCISE 28-5: The table gives four sets of values for the circuit elements in Fig. 28-22. Rank the sets according to (a) the initial current (as the switch is closed on *a*) and (b) the time required for the current to decrease to half its initial value, greatest first.

	1	2	3	4
ΔV_B (V)	12.0	12.0	10.0	10.0
R (Ω)	2.0	3.0	10.0	5.0
C (μF)	3.0	2.0	0.5	2.0

■

TOUCHSTONE EXAMPLE 28-5: Discharging a Capacitor

A capacitor of capacitance C is discharging through a resistor of resistance R .

(a) In terms of the time constant $\tau = RC$, when will the excess charge on each plate of the capacitor be half its initial value?

SOLUTION ■ The **Key Idea** here is that the excess charge on each plate of the capacitor varies according to Eq. 28-45,

$$q = q_0 e^{-t/RC},$$

in which q_0 is the initial charge. We are asked to find the time t at which $q = \frac{1}{2}q_0$ or at which

$$\frac{1}{2}q_0 = q_0 e^{-t/RC}. \quad (28-47)$$

After canceling q_0 , we realize that the time t we seek is “buried” inside an exponential function. To expose the symbol t in Eq. 28-47, we take the natural logarithms of both sides of the equation. (The natural logarithm is the inverse function of the exponential function.) We find

$$\ln \frac{1}{2} = \ln(e^{-t/RC}) = -\frac{t}{RC},$$

or
$$t = (-\ln \frac{1}{2})RC = 0.69RC = 0.69\tau. \quad (\text{Answer})$$

(b) When will the energy stored in the capacitor be half its initial value?

SOLUTION ■ There are two **Key Ideas** here. First, the energy U stored in a capacitor is related to the charge $|q|$ on the each plate according to Eq. 28-21 ($U = q^2/2C$). Second, that charge is decreasing according to Eq. 28-45. Combining these two ideas gives us

$$U = \frac{q^2}{2C} = \frac{q_0^2}{2C} e^{-2t/RC} = U_0 e^{-2t/RC},$$

in which U_0 is the initial stored energy. We are asked to find the time at which $U = \frac{1}{2}U_0$, or at which

$$\frac{1}{2}U_0 = U_0 e^{-2t/RC}.$$

Canceling U_0 and taking the natural logarithms of both sides, we obtain

$$\ln \frac{1}{2} = -\frac{2t}{RC},$$

or
$$t = -RC \frac{\ln \frac{1}{2}}{2} = 0.35RC = 0.35\tau. \quad (\text{Answer})$$

It takes longer (0.69τ versus 0.35τ) for the *charge* to fall to half its initial value than for the *stored energy* to fall to half its initial value. Does this result surprise you?

Problems

SEC. 28-2 ■ CAPACITANCE

1. Electrometer An electrometer is a device used to measure static charge—an unknown excess charge is placed on the plates of the meter’s capacitor, and the potential difference is measured. What minimum charge can be measured by an electrometer with a capacitance of 50 pF and a voltage sensitivity of 0.15 V?

FIGURE 28-24 ■ Problem 2.

2. Two Metal Objects The two metal objects in Fig. 28-24 have net

(or excess) charges of +70 pC and –70 pC, which result in a 20 V potential difference between them.

(a) What is the capacitance of the system? (b) If the excess charges are changed to +200 pC and –200 pC, what does the capacitance become? (c) What does the potential difference become?

FIGURE 28-25 ■ Problem 3.

3. Initially Uncharged The capacitor in Fig. 28-25 has a capacitance of

25 μF and is initially uncharged. The battery provides a potential difference of 120 V. After switch S is closed, how much charge will pass through it?

SEC. 28-3 ■ CALCULATING THE CAPACITANCE

4. Show That If we solve Eq. 28-9 for ϵ_0 we see that its SI unit is the farad per meter. Show that this unit is equivalent to that obtained earlier for ϵ_0 —namely, the coulomb squared per newton-meter squared ($\text{C}^2/\text{N}\cdot\text{m}^2$).

5. Circular Plates A parallel-plate capacitor has circular plates of 8.2 cm radius and 1.3 mm separation. (a) Calculate the capacitance. (b) What excess charge will appear on each of the plates if a potential difference of 120 V is applied?

6. Two Flat Metal Plates You have two flat metal plates, each of area 1.00 m^2 , with which to construct a parallel-plate capacitor. If the capacitance of the device is to be 1.00 F, what must be the separation between the plates? Could this capacitor actually be constructed?

7. Spherical Drop of Mercury A spherical drop of mercury of radius R has a capacitance given by $C = 4\pi\epsilon_0 R$. If two such drops combine to form a single larger drop what is its capacitance?

8. Spherical Capacitor The plates of a spherical capacitor have radii 38.0 mm and 40.0 mm. (a) Calculate the capacitance. (b) What must be the plate area of a parallel-plate capacitor with the same plate separation and capacitance?

9. Two Spherical Shells Suppose that the two spherical shells of a spherical capacitor have approximately equal radii. Under these conditions the device approximates a parallel-plate capacitor with $b - a = d$. Show that Eq. 28-17 does indeed reduce to Eq. 28-9 in this case.

SEC. 28-4 ■ CAPACITORS IN PARALLEL AND IN SERIES

10. Equivalent In Fig. 28-26, find the equivalent capacitance of the combination. Assume that $C_1 = 10.0 \mu\text{F}$, $C_2 = 5.00 \mu\text{F}$, and $C_3 = 4.00 \mu\text{F}$.

11. How Many How many 1.00 μF capacitors must be connected in parallel to store an excess charge of 1.00 C with a potential of 110 V across the capacitors?

12. Each Uncharged Each of the uncharged capacitors in Fig. 28-27 has a capacitance of 25.0 μF . A potential difference of 4200 V is established when the switch is closed. How many coulombs of charge then pass through meter A?

13. Combo In Fig. 28-28 find the equivalent capacitance of the combination. Assume that $C_1 = 10.0 \mu\text{F}$, $C_2 = 5.00 \mu\text{F}$, and $C_3 = 4.00 \mu\text{F}$.

14. Breaks Down In Fig. 28-28 suppose that capacitor 3 breaks down electrically, becoming equivalent to

FIGURE 28-26 ■ Problems 10 and 30.

FIGURE 28-27 ■ Problem 12.

FIGURE 28-28 ■ Problems 13, 14, and 28.

a conducting path. What changes in (a) the amount of excess charge and (b) the potential difference occur for capacitor 1? Assume that $\Delta V = 100 \text{ V}$.

15. Two in Series Figure 28-29 shows two capacitors in series; the center section of length b is movable vertically. Show that the equivalent capacitance of this series combination is independent of the position of the center section and is given by $C = \epsilon_0 A / (a - b)$, where A is the plate area.

FIGURE 28-29 ■ Problem 15.

16. Battery Potential In Fig. 28-30, the battery has a potential difference of 10 V and the five capacitors each have a capacitance of 10 μF . What is the excess charge on (a) capacitor 1 and (b) capacitor 2?

17. Parallel with Second 100 pF capacitor is charged to a potential difference of 50 V, and the charging battery is disconnected. The capacitor

is then connected in parallel with a second (initially uncharged) capacitor. If the potential difference across the first capacitor drops to 35 V, what is the capacitance of this second capacitor?

18. Charge Stored In Fig. 28-31, the battery has a potential difference of 20 V. Find (a) the equivalent capacitance of all the capacitors and (b) the excess charge stored by that equivalent capacitance. Find the potential across and charge on (c) capacitor 1, (d) capacitor 2, and (e) capacitor 3.

19. Opposite Polarity In Fig. 28-32, the capacitances are $C_1 = 1.0 \mu\text{F}$ and $C_2 = 3.0 \mu\text{F}$ and both capacitors are charged to a potential difference of $\Delta V = 100 \text{ V}$ but with opposite polarity as shown. Switches S_1 and S_2 are now closed. (a) What is now the potential difference between points a and b ? What are now the amounts of excess charge on capacitors (b) 1 and (c) 2?

20. Battery Supplies In Fig. 28-33, battery B supplies 12 V. Find the excess charge on each capacitor (a) first when only switch S_1

FIGURE 28-30 ■ Problem 16.

FIGURE 28-31 ■ Problem 18.

FIGURE 28-32 ■ Problem 19.

FIGURE 28-33 ■ Problem 20.

switch S_2 is also closed. Take $C_1 = 1.0 \mu\text{F}$, $C_2 = 2.0 \mu\text{F}$, $C_3 = 3.0 \mu\text{F}$, and $C_4 = 4.0 \mu\text{F}$.

21. Switch Is Thrown When switch S is thrown to the left in Fig. 28-34, the plates of capacitor 1 acquire a potential difference ΔV_0 . Capacitors 2 and 3 are initially uncharged. The switch is now thrown to the right. What are the final amounts of excess charge $|q_1|$, $|q_2|$, and $|q_3|$ on the capacitors?

FIGURE 28-34 ■ Problem 21.

SEC. 28-5 ■ ENERGY STORED IN AN ELECTRIC FIELD

22. Air How much energy is stored in one cubic meter of air due to the “fair weather” electric field of magnitude 150 V/m ?

23. Capacitance Required What capacitance is required to store an energy of $10 \text{ kW} \cdot \text{h}$ at a potential difference of 1000 V ?

24. Air-Filled Capacitor A parallel-plate air-filled capacitor having area 40 cm^2 and plate spacing 1.0 mm is charged to a potential difference of 600 V . Find (a) the capacitance, (b) the amount of excess charge on each plate, (c) the stored energy, (d) the electric field between the plates, and (e) the energy density between the plates.

25. Two Capacitors Two capacitors, of 2.0 and $4.0 \mu\text{F}$ capacitance, are connected in parallel across a 300 V potential difference. Calculate the total energy stored in the capacitors.

26. Connected Bank A parallel-connected bank of $5.00 \mu\text{F}$ capacitors is used to store electric energy. What does it cost to charge the 2000 capacitors of the bank to $50,000 \text{ V}$ assuming $12.0\text{¢/kW} \cdot \text{h}$?

27. One Capacitor One capacitor is charged until its stored energy is 4.0 J . A second uncharged capacitor is then connected to it in parallel. (a) If the charge distributes equally, what is now the total energy stored in the electric fields? (b) Where did the excess energy go?

28. Find In Fig. 28-28 find (a) the excess charge, (b) the potential difference, and (c) the stored energy for each capacitor. Assume the numerical values of Problem 13, with $\Delta V = 100 \text{ V}$.

29. Plates of Area A A parallel-plate capacitor has plates of area A and separation d and is charged to a potential difference ΔV . The charging battery is then disconnected, and the plates are pulled apart until their separation is $2d$. Derive expressions in terms of A , d , and ΔV for (a) the new potential difference; (b) the initial and final stored energies, U_i and U_f and (c) the work required to separate the plates.

30. Find the Charge In Fig. 28-26, find (a) the excess charge, (b) the potential difference, and (c) the stored energy for each capacitor. Assume the numerical values of Problem 10, with $\Delta V = 100 \text{ V}$.

31. Cylindrical Capacitor A cylindrical capacitor has radii a and b as in Fig. 28-10. Show that half the stored electric potential energy lies within a cylinder whose radius is $r = \sqrt{ab}$.

32. Metal Sphere A charged isolated metal sphere of diameter 10 cm has a potential of 8000 V relative to $V = 0$ at infinity. Calculate the energy density in the electric field near the surface of the sphere.

33. Force of Magnitude (a) Show that the plates of a parallel-plate capacitor attract each other with a force of magnitude given by $F = q^2/2\epsilon_0 A$. Do so by calculating the work needed to increase the

plate separation from x to $x + dx$, with the excess charge $|q|$ remaining constant. (b) Next show that the magnitude of the force per unit area (the *electrostatic stress*) acting on either capacitor plate is given by $\frac{1}{2}\epsilon_0 E^2$. (Actually, this is the force per unit area on any conductor of any shape with an electric field \vec{E} at its surface.)

SEC. 28-6 ■ CAPACITOR WITH A DIELECTRIC

34. Wax An air-filled parallel-plate capacitor has a capacitance of 1.3 pF . The separation of the plates is doubled and wax is inserted between them. The new capacitance is 2.6 pF . Find the dielectric constant of the wax.

35. Convert It Given a 7.4 pF air-filled capacitor, you are asked to convert it to a capacitor that can store up to $7.4 \mu\text{J}$ with a maximum potential difference of 652 V . What dielectric in Table 28-3 should you use to fill the gap in the air capacitor if you do not allow for a margin of error?

36. Separation A parallel-plate air-filled capacitor has a capacitance of 50 pF . (a) If each of its plates has an area of 0.35 m^2 , what is the separation? (b) If the region between the plates is now filled with material having $\kappa = 5.6$, what is the capacitance?

37. Coaxial Cable A coaxial cable used in a transmission line has an inner radius of 0.10 mm and an outer radius of 0.60 mm . Calculate the capacitance per meter for the cable. Assume that the space between the conductors is filled with polystyrene.

38. Construct a Capacitor You are asked to construct a capacitor having a capacitance near 1 nF and a breakdown potential in excess of $10\,000 \text{ V}$. You think of using the sides of a tall Pyrex drinking glass as a dielectric, lining the inside and outside curved surfaces with aluminum foil to act as the plates. The glass is 15 cm tall with an inner radius of 3.6 cm and an outer radius of 3.8 cm . What are the (a) capacitance and (b) breakdown potential of this capacitor?

39. Certain Substance A certain substance has a dielectric constant of 2.8 and a dielectric strength of 18 MV/m . If it is used as the dielectric material in a parallel-plate capacitor, what minimum area should the plates of the capacitor have to obtain a capacitance of $7.0 \times 10^{-2} \mu\text{F}$ and to ensure that the capacitor will be able to withstand a potential difference of 4.0 kV ?

40. Two Dielectrics A parallel-plate capacitor of plate area A is filled with two dielectrics as in Fig. 28-35a. Show that the capacitance is

$$C = \frac{\epsilon_0 A}{d} \frac{\kappa_1 + \kappa_2}{2}.$$

Check this formula for limiting cases. (*Hint:* Can you justify this arrangement as being two capacitors in parallel?)

FIGURE 28-35 ■ Problems 40 and 41.

41. Limiting Cases A parallel-plate capacitor of plate area A is filled with two dielectrics as in Fig. 28-35*b*. Show that the capacitance is

$$C = \frac{2\epsilon_0 A}{d} \frac{\kappa_1 \kappa_2}{\kappa_1 + \kappa_2}.$$

Check this formula for limiting cases. (*Hint*: Can you justify this arrangement as being two capacitors in series?)

FIGURE 28-36 ■ Problem 42.

42. What is Capacitance What is the capacitance of the capacitor, of plate area A , shown in Fig. 28-36? (*Hint*: See Problems 40 and 41.)

SEC. 28-8 ■ DIELECTRICS AND GAUSS' LAW

43. Mica A parallel-plate capacitor has a capacitance of 100 pF, a plate area of 100 cm², and a mica dielectric ($\kappa = 5.4$) completely filling the space between the plates. At 50 V potential difference, calculate (a) the electric field magnitude E in the mica, (b) the amount of excess free charge on each plate, and (c) the amount of induced surface charge on the mica.

44. Electric Field Two parallel plates of area 100 cm² are given excess charges of equal amounts 8.9×10^{-7} C but opposite signs. The electric field within the dielectric material filling the space between the plates is 1.4×10^6 V/m. (a) Calculate the dielectric constant of the material. (b) Determine the amount of bound charge induced on each dielectric surface.

45. Concentric Conducting Shells The space between two concentric conducting spherical shells of radii b and a (where $b > a$) is filled with a substance of dielectric constant κ . A potential difference ΔV exists between the inner and outer shells. Determine (a) the capacitance of the device, (b) the excess free charge q on the inner shell, and (c) the charge q' induced along the surface of the inner shell.

SEC. 28-9 ■ RC CIRCUITS

46. Initial Charge A capacitor with initial excess charge of amount $|q_0|$ is discharged through a resistor. In terms of the time constant τ , how long is required for the capacitor to lose (a) the first one-third of its charge and (b) two-thirds of its charge?

47. How Many Time Constants How many time constants must elapse for an initially uncharged capacitor in an RC series circuit to be charged to 99.0% of its equilibrium charge?

48. Leaky Capacitor The potential difference between the plates of a leaky (meaning that charges leak directly across the “insulated” space between the plates) 2.0 μ F capacitor drops to one-fourth its initial value in 2.0 s. What is the equivalent resistance between the capacitor plates?

49. Time Constant A 15.0 k Ω resistor and a capacitor are connected in series and then a 12.0 V potential difference is suddenly applied across them. The potential difference across the capacitor rises to 5.00 V in 1.30 μ s. (a) Calculate the time constant of the circuit. (b) Find the capacitance of the capacitor.

50. Flashing Lamp Figure 28-37 shows the circuit of a flashing lamp, like those attached to barrels at highway construction sites. The fluorescent lamp L (of negligible capacitance) is connected in parallel across the capacitor C of an RC circuit. There is a current through the lamp only when the potential difference across it reaches the breakdown voltage V_L ; in this event, the capacitor discharges completely through the lamp and the lamp flashes briefly.

FIGURE 28-37 ■ Problem 50.

Suppose that two flashes per second are needed. For a lamp with breakdown voltage $\Delta V_L = 72.0$ V, wired to a 95.0 V ideal battery and a 0.150 μ F capacitor, what should be the resistance R ?

51. Initial Potential Difference A capacitor with an initial potential difference of 100 V is discharged through a resistor when a switch between them is closed at $t = 0$. At $t = 10.0$ s, the potential difference across the capacitor is 1.00 V. (a) What is the time constant of the circuit? (b) What is the potential difference across the capacitor at $t = 17.0$ s?

52. Electronic Arcade Game A controller on an electronics arcade games consists of a variable resistor connected across the plates of a 0.220 μ F capacitor. The capacitor is charged to 5.00 V, then discharged through the resistor. The time for the potential difference across the plates to decrease to 0.800 V is measured by a clock inside the game. If the range of discharge times that can be handled effectively is from 10.0 μ s to 6.00 ms, what should be the resistance range of the resistor?

53. Initial Stored Energy A 1.0 μ F capacitor with an initial stored energy of 0.50 J is discharged through a 1.0 M Ω resistor. (a) What is the initial amount of excess charge on the capacitor plates? (b) What is the current through the resistor when the discharge starts? (c) Determine ΔV_C , the potential difference across the capacitor, and ΔV_R , the potential difference across the resistor, as functions of time. (d) Express the production rate of thermal energy in the resistor as a function of time.

Additional Problems

54. Capacitance (a) What is the physical definition and description of a capacitor? (b) What is the mathematical definition of capacitance? (c) Based on the physical description of a capacitor, why would you expect it to hold more excess charge on each of its conducting surfaces when the voltage difference between the two pieces of conductor increases?

55. Net Charge What is the net charge on a capacitor in a circuit? Is it ever possible for the amount of excess charge on one conductor to be different from the amount of excess charge on the other conductor? Explain.

56. Attraction and Repulsion Consider the attraction and repulsion of different types of charge. (a) Explain why you expect to find

that the amount of excess charge a battery can pump onto a parallel-plate capacitor will double if the area of each plate doubles. (b) Explain why you expect to find that the amount of excess charge a battery can pump onto a parallel-plate capacitor will be cut in half if the distance between each plate doubles.

57. Three Parallel-Plate Capacitors

Suppose you have three parallel-plate capacitors as follows:

Capacitor 1: Area A , spacing d

Capacitor 2: Area A , spacing $2d$

Capacitor 3: Area $2A$, spacing d

The three graph lines (labeled a , b , and c) in Fig. 28-38 represent data for the amounts of excess of charge on the plates of each capacitor as a function of the potential difference across it. Which capacitor {1, 2, or 3} belongs to which line { a , b , and c }? Explain your reasoning carefully.

FIGURE 28-38 ■ Problem 57.

58. Capacitors in Series Give as clear an explanation as possible as to why it is physically reasonable to expect that two identical parallel-plate capacitors that are placed in series ought to have half the capacitance as one capacitor. *Hints:* What happens to the effective spacing between the first plate of capacitor 1 and the second plate of capacitor 2 when they are wired in series? What does the fact that like charges repel and opposites attract have to do with anything?

59. Capacitors in Parallel Give as clear an explanation as possible as to why it is physically reasonable to expect that two identical parallel-plate capacitors placed in parallel ought to have twice the capacitance as one capacitor. *Hints:* What happens to the effective area of capacitors wired in parallel? What does the fact that like charges repel and opposites attract have to do with anything?

60. Charge Ratios on Capacitors (Adapted from a TYC WS Project ranking task by D. Takahashi). Eight capacitor circuits are

FIGURE 28-39 ■ Problem 60.

shown in Fig. 28-39. All of the capacitors are identical and all are fully charged. The batteries are also identical. In each circuit, one capacitor is labeled C_1 and another is labeled C_2 . Assuming $|q_1|$ denotes the amount of excess charge on C_1 , $|q_2|$ denotes the amount of excess charge on C_2 , and the value of the ratio is denoted $|q_1/q_2|$, rank the circuit in which the value of the ratio $|q_1/q_2|$ is largest *first*, and rank the circuit in which the value of the ratio is the smallest *last*. If two or more circuits result in identical values for the ratio, give these circuits equal ranking. Express your ranking symbolically. (For example, suppose the ratio was highest for D and G and lowest for A and E with the in-between ratios being equal, then the symbolic ranking would be

$$D = G > B = C = H = F > A = E$$

(*Beware:* This is only a sample, not a correct answer!)

61. Physicists Claim Physicists claim that charge never flows *through* an ideal capacitor. Yet when an uncharged capacitor is first placed in series with a resistor and a battery, current flows through the battery and the resistor. Explain how this is possible.

FIGURE 28-40 ■ Problem 62.

62. Voltage Graphs

Figure 28-40 shows plots of voltage across the capacitor as a function of time for three different capacitors that have each been separately discharged through the same resistor. Rank the plots according to the capacitances, the greatest first. Explain the reasons for your rankings.

63. A Cell Membrane The inner and outer surfaces of a cell membrane carry excess negative and positive charge, respectively. Because of these charges, a potential difference of about 70 mV exists across the membrane. The thickness of the membrane is 8 nm.

(a) If the membrane were empty (filled with air), what would be the magnitude of the electric field inside the membrane?

(b) If the dielectric constant of the membrane were $\kappa = 3$ what would the field be inside the membrane?

(c) Cells can carry ions across a membrane *against the field* (“up-hill”) using a variety of active transport mechanisms. One mechanism does so by using up some of the cell’s stored energy converting ATP to ADP. How much work does it take to carry one sodium ion (charge = $+e$) across the membrane against the field? Calculate your answer in eV, joules, and kcal/mole (the last for 1 mole of sodium ions).

29

Magnetic Fields

Ocean water contains huge quantities of the light atomic nuclei found in “heavy water” needed to produce fusion power. If we could produce a cost-effective fusion reactor, the world’s power problems could be solved. We have known this for over 50 years and still not produced fusion power. Why? A key problem is that it takes a temperature of at least 100 million degrees Celsius to force two light nuclei to fuse together. At this temperature, any material we tried to squeeze together to fuse would be so hot that it would vaporize any material it touches. The torus-shaped chamber of the large Tokomak reactor in this photo was built in an attempt to contain fusion reactions.

How can this Tokomak contain matter at 100 million degrees Celsius?

The answer is in this chapter.

FIGURE 29-1 ■ A large electromagnet is used to collect and transport scrap metal at a steel mill.

29-1 A New Kind of Force?

In Chapter 14 we studied gravitational interaction forces that we experience on an everyday basis. Gravitational forces are so weak that it takes a source the size of a planet or star to produce a noticeable effect. This made the study of the effects of gravity near the Earth's surface relatively simple. In most cases, we treat the gravitational force on an object as a constant.

Then, in Chapter 22, we studied the electrostatic force—a long-range force that is much stronger than the gravitational force. If you run a comb through your hair, a bit of paper near the comb hops up and sticks to the comb. The electrostatic force exerted on the paper by the comb is somewhat larger than the gravitational force that the whole Earth exerts on the paper.

Are there any other long-range (or, action-at-a-distance) forces, or are we done? If you think about your personal experiences, you probably have had the opportunity to play with small disk-shaped refrigerator magnets or pairs of bar magnets. On a larger scale, **electromagnets** are used for sorting scrap metal (Fig. 29-1) and many other things. Magnets are fun because they behave in such an unusual way. You can use one magnet to chase a second magnet around a table without even touching it. But if you come at the magnet from a slightly different direction, it will suddenly seem to change what it's doing and will be pulled toward the other. A refrigerator magnet will seem to leap to the door of the refrigerator, being drawn to it from a distance. Clearly a long-range force is at work here. But is it a new kind of force? Or is it merely a form of gravitational or electrical force?

29-2 Probing Magnetic Interactions

We know from our everyday experiences with small bar magnets that we can *feel* a force on one bar magnet as it interacts with another. This means we can use a bar magnet as a test object for investigating the nature of magnetic interactions. In order to answer the question of whether magnetic interactions are really gravitational or electrostatic forces, let's investigate what happens when a small bar magnet or disk-shaped refrigerator magnet experiences a significant force.

Is the Magnetic Force a Type of Gravitational Force?

The force on our test magnet near the Earth's surface is clearly *in addition* to the gravitational attraction of the Earth. The fact that a refrigerator magnet can stick to the refrigerator and not fall means that it is experiencing a force that is stronger than the gravitational force exerted on it by the entire Earth.

What happens if we replace our test magnet with another *nonmagnetic* object of equal mass and the same shape? We find that the magnetic force disappears. Hence, we must surmise that the force we detected with the bar magnet is not a gravitational force associated with the presence of another object. It is too strong and exists only for certain probe objects. Furthermore, we know from playing with magnets that the force can be attractive or repulsive. As we know, this is not true for the gravitational force.

Is the Magnetic Force a Type of Electrostatic Force?

Could the magnetic force be the electrostatic force we have learned about? After all, the magnetic force, like the electrostatic force, is sometimes attractive and sometimes repulsive. To test this idea, we replace our test magnet with a test charge (such as a tiny Styrofoam ball charged by a rubber rod) at the former location of our test

magnet. Again, we find that our new probe (the charge) is only weakly attracted—as is any charged object to a neutral object. So, we must also surmise that *the force the bar magnet detects is not a type of electrostatic force.*

The Magnetic Force and a Moving Charge

We have just described observations that show that forces between magnets are fundamentally different from either electrostatic or gravitational forces. So it appears that we have a new action-at-a-distance force to learn about. This force can be either attractive or repulsive. We can detect this force with a magnet, and so we will refer to it as a **magnetic force**.

Having completed our investigations of electric force in earlier chapters, we now take the electric charge we had been using as a probe and move it rapidly away from a magnet. When we do this, we find something strange. When we *move* the charge, we do detect a force!

OBSERVATION: A magnet exerts a force on a moving charged object, but not on a stationary charged object.

Furthermore, when we try moving the charge at different velocities, we find that the larger the magnitude of the velocity, the larger is the force exerted on the charge. Is the same true for *uncharged*, nonmagnetic masses? Experimentation shows the same is *not* true for uncharged masses. No magnetic force is detected when an uncharged, nonmagnetic mass is used as a probe—regardless of whether the probe is moving or stationary.

In the early 19th century, both Oersted and Ampère discovered that magnets interact with moving charges. In fact, these two scientists showed that current-carrying wires both exert forces on and feel forces from bar magnets. Their observations provide us with important information in our quest to understand the magnetic force. We have found that magnetic forces are not just exerted on other magnets. Magnetic forces are also exerted on a nonmagnetic small charged particle in rough proportion to the degree to which the particle is *both* charged and moving. What is the simplest relationship between magnetic force, charge, and velocity that is consistent with our observations? Mathematically stated, it is a proportional relationship given by

$$|\vec{F}^{\text{mag}}| \propto |q|v,$$

where $|q|$ represents the amount of electric charge on the particle and v is the particle's speed.

Is this relationship correct? Well, if it is, we should see a doubling of the force when we double the velocity of the charged particle we are using as a probe. Experimentally, this does turn out to be the case. Furthermore, we also find that doubling the charge on the probe doubles the force detected. Hence, the linear relationship expressed above is a good start toward a more precise mathematical description of the magnetic force on a moving charged particle. We will return to experimentation as a means for developing a precise expression for the magnetic force in just a moment.

29-3 Defining a Magnetic Field \vec{B}

When we play with two bar magnets, we quickly see that the magnetic force can be attractive or repulsive. Furthermore, if we observe more carefully, we find that the strength of the force decreases as the distance between the two magnets is increased. These observations are distinctly reminiscent of our observations of the

electrostatic force between two charges. So our first guess in developing a model of the magnetic force might turn out to be somewhat similar to our model of the electrostatic force.

In order to develop a model of magnetism that parallels our model of electrostatics, we should have two different kinds of “magnetic charges.” These conceptual objects are referred to as **magnetic monopoles**. We can model our bar magnet as containing a south and a north pole with at least some separation between them. If we assume that like poles repel and unlike poles attract, then this model allows us to correctly predict all our observations. Playing with bar magnets informs us that poles of the same kind repel one another and poles of different kinds attract one another. This is just as we found for electric charges. However, careful observation of the interaction between bar magnets shows that their behavior is similar to that of electric dipoles. Recall that an electric dipole consists of two charges of opposite sign with a small spacing between them. If two electric dipoles that are placed with all their charges lying on the same line are brought together, they will attract. Why? Because a negative charge from the end of one dipole will be closest to the positive charge of the other dipole. However, if we turn one of the electric dipoles around so the dipoles are anti-aligned, then the two like charges will be closest together. Now the dipoles will repel.

Two bar magnets when aligned and then anti-aligned will behave just like electric dipoles. For this reason, we often refer to magnets as *magnetic dipoles*. That is, one end appears to be one kind of magnetic charge and the other end appears to be the other kind of magnetic charge. By convention, we can assign names to the poles of a bar magnet as follows. If we suspend a bar magnet by a string placed halfway between its ends and take other magnetic sources away from its vicinity, one pole of the magnet will point more or less north and the other more or less south. We can call the north-pointing end the north pole of the magnet and the other end the south pole of the magnet.

FIGURE 29-2 ■ Whenever a magnet is broken into pieces between its poles, the pieces behave like smaller, weaker magnets.

This idea that a bar magnet is a magnetic dipole with a north charge at one end and a south charge at the other end provides us with a start in describing magnetic interactions. However, to continue with the analogy between the magnetism and electricity, we would like to isolate a magnetic charge. After all, we can separate a negative charge from a positive charge. So we need to be able to separate the north pole of a bar magnet from the south pole of a bar magnet. To do this, we take our bar magnet and cut it in half. But, when we do this we find a surprising thing. The result of breaking the bar magnet in half is simply that we have two weaker half-sized bar magnets. Each one still behaves as a dipole with both a north and a south pole. If we again try to break the magnet in half, we find we have a still smaller magnet, but still with a north and south pole (Fig. 29-2). In fact, if we break the magnet down into subatomic parts, we find that even the electrons, protons, and neutrons within atoms behave as magnetic dipoles (that is, *very* little bar magnets).

As it turns out, the magnetic effect of a bar magnet arises from the combination of the effects of the little bar magnets in the electrons in iron, nickel, and cobalt aligning with each other and producing a strong effect. Each electron’s magnet is small, but when you turn them in the same direction and add them all up, the total effect is strong—the full magnetic effect of the bar magnet. So, in short, although the existence of separate magnetic charges (or magnetic monopoles) have been predicted by some physicists, they have never actually been found.

Does the fact that we cannot find an isolated magnetic monopole mean that we must abandon our effort to find parallels between magnetic and electrostatic forces? Not at all. In Chapter 23, we found that the concept of an electric field was quite useful. With so many different possible sources of significant electrostatic forces, it was helpful to think about the force field associated with a given charge (the source of electrostatic force)—without having to decide on what object the force will be exerted on. That is, we wanted to separate the discussion of the source of the force

from the discussion of the object the force is exerted on. So we defined the electric field \vec{E} as

$$\vec{E} = \frac{\vec{F}^{\text{elec}}}{q}. \quad (\text{Eq. 23-4})$$

We determined the electric field \vec{E} at a point by putting a test particle of charge q at rest at that point and measuring the electrostatic force \vec{F}^{elec} acting on the particle. We saw that *electric charges* set up an electric field that can then affect other electric charges.

Perhaps the same idea could be useful to us in describing magnetic forces. If we could develop a parallel concept of a magnetic field, we could separate the issue of sources of magnetic forces from discussions of the objects that magnetic forces are exerted on. This would be helpful since the concept of a magnetic monopole is so problematic. If a magnetic monopole were available, we could define the magnetic field \vec{B} in a way similar to that used for electric fields. However, because such particles have not been found, we must use another method to define a magnetic field \vec{B} .

For nonmagnetic particles, we have already observed that the magnetic force is proportional to the charge and the magnitude of the velocity of the particle being acted on (the probe). We can use this information and define the magnetic field in terms of the force \vec{F}^{mag} exerted on a moving, electrically charged test particle. The magnitude of the force seems to depend on the direction of the particle's velocity \vec{v} as well. We will examine this effect in more detail in the next section, but for now we define the magnetic field \vec{B} in terms of the *maximum* force magnitude we measure after trying all different directions for \vec{v} . So we can express the *magnitude* of the magnetic field \vec{B} in terms of this maximum force magnitude as:

$$B = \frac{F_{\text{max}}^{\text{mag}}}{|q|v}, \quad (29-1)$$

where q is the particle's charge and v is its speed.

Having defined the magnitude of the magnetic field is a big step forward. It is a concept that will turn out to be extremely useful. Right now, it is helpful because we have not identified the source of the force exerted on our probe. But, having defined the magnitude of the magnetic field in this way, we can at least say that we know that there is a vector magnetic field in the region of space we have been probing. We make extensive use of the concept of a magnetic field in this chapter. Next we turn our attention to this issue of how to define the direction of the magnetic field.

29-4 Relating Magnetic Force and Field

In order to determine the direction of the magnetic field, we can fire a charged particle through a region of space where a magnetic field \vec{B} is known to exist. If we shoot the charged particle in various directions, we find something surprising—the direction of \vec{F}^{mag} is always perpendicular to the direction of \vec{v} (Fig. 29-3). After many such trials we find that when the particle's velocity \vec{v} is along a particular axis through the region of space, force \vec{F}^{mag} is zero. Furthermore, we find that for all other directions of \vec{v} , the *magnitude* of \vec{F}^{mag} depends on the direction of \vec{v} . In fact, it is proportional to $|\vec{v}|\sin\phi$ where ϕ is the angle between the zero-force axis and the direction of \vec{v} . Thinking back to our work on torque and angular momentum, these observations suggest that a cross product is involved. But a cross product of what two vectors?

Clearly, one of the two vectors involved in the cross product is the velocity vector. Our observation that the force is zero when the velocity is along a certain axis implies

FIGURE 29-3 ■ (a) An electron beam is accelerated by a voltage source and travels through an evacuated glass tube to the center of a phosphorescent screen. (b) If a magnet is oriented vertically and placed just below the beam (along the $+z$ axis), the electrons are deflected horizontally along the $-x$ axis.

that the other vector must be aligned with this “zero magnetic force” axis. Referring back to our definition of the magnetic field magnitude, B , in Eq. 29-1, we note that the magnitude of the observed magnetic force is given by

$$F_{\text{max}}^{\text{mag}} = |q|vB,$$

where v is the particle speed and $|q|$ is the amount of charge the particle has. Suppose the direction of the magnetic field is taken to be along the “zero magnetic force” axis. We could then represent all of our observations with the following vector equation, known as the *magnetic force law* or **Lorentz force law**:

$$\vec{F}^{\text{mag}} = q\vec{v} \times \vec{B} \quad (\text{magnetic force law}). \quad (29-2)$$

That is, the force \vec{F}^{mag} on the particle is equal to the charge q times the cross product of its velocity \vec{v} and the magnetic field \vec{B} . If this expression is correct, the force on a negatively charged particle should be opposite in direction from the force on a positively charged particle. This does in fact turn out to be the case.

Furthermore, expressing the magnetic force on a charged particle moving through a magnetic field as $\vec{F}^{\text{mag}} = q\vec{v} \times \vec{B}$ requires that we adopt a standard convention for the *direction* of the magnetic field. That is,

The direction of a magnetic field is defined to be related to the direction of the force on and the velocity of a positively charged particle by $\vec{F}^{\text{mag}} = q\vec{v} \times \vec{B}$.

Although this is not a very intuitive statement of how one goes about finding the direction of a magnetic field, we are forced to use it if we want to use $\vec{F}^{\text{mag}} = q\vec{v} \times \vec{B}$ to determine the magnitude and direction of the magnetic force on a moving charged particle.

Using the mathematical definition of a cross product to evaluate this expression, we see that we can write the magnitude of the magnetic force as

$$F^{\text{mag}} = |q\vec{v}||\vec{B}|\sin\phi = |q|vB\sin\phi, \quad (29-3)$$

where ϕ is the smaller angle (the one whose value lies between 0° and 180°) between the directions of velocity \vec{v} and magnetic field \vec{B} .

We have seen that magnetic force and electric force are not the same. However, a magnetic force *is* exerted on a moving charged particle as well as on bar magnets. This suggests that there is a profound connection between electricity and magnetism—even though they are *not* the same thing. As it turns out, the theory of relativity, treated in Chapter 38, reveals a deep underlying connection between \vec{E} and \vec{B} . Furthermore, much of the technology that makes our lives more comfortable today results from an understanding of this relationship. In Chapter 30, we show how moving electrical charges can create magnetic fields and in Chapter 31 we show an even deeper and more surprising link between electricity and magnetism (called Faraday's law). What we find is that a magnetic field can, if it changes in time, create an electric field without any electric charge present!

Finding the Magnetic Force on a Moving Charged Particle

Equation 29-3 reveals that the magnitude of the force \vec{F}^{mag} acting on a particle in a magnetic field is proportional to the amount of charge $|q|$ and speed v of the particle. Thus, the force is equal to zero if the charge is zero or if the particle is stationary. Equation 29-3 also tells us that the magnitude of the force is zero if \vec{v} and \vec{B} are either parallel ($\phi = 0^\circ$) or antiparallel ($\phi = 180^\circ$), and the force is a maximum when \vec{v} and \vec{B} are perpendicular to each other.

Equation 29-2 tells us all this and the direction of \vec{F}^{mag} . From Section 12-4, we know that the cross product $\vec{v} \times \vec{B}$ in Eq. 29-2 is a vector that is perpendicular to the two vectors \vec{v} and \vec{B} . The right-hand rule (Fig. 29-4a) specifies that the thumb of the right hand points in the direction of $\vec{v} \times \vec{B}$ when the fingers sweep \vec{v} into \vec{B} . If q is positive, then (by Eq. 29-2) the force \vec{F}^{mag} has the same sign as $\vec{v} \times \vec{B}$ and thus must be in the same direction. That is, for positive q , \vec{F}^{mag} is directed along the thumb as in Fig. 29-4b. If q is negative, then the force \vec{F}^{mag} and the cross product $\vec{v} \times \vec{B}$ have opposite signs and thus must be in opposite directions. For negative q , \vec{F}^{mag} is directed opposite the thumb as in Fig. 29-4c.

Regardless of the sign of the charge, however,

The force \vec{F}^{mag} acting on a charged particle moving with velocity \vec{v} through a magnetic field \vec{B} is *always* perpendicular to \vec{v} and \vec{B} .

Thus, \vec{F}^{mag} *never* has a component parallel to \vec{v} . This means that \vec{F}^{mag} cannot change the particle's speed $v = |\vec{v}|$ (and thus it cannot change the particle's kinetic energy). The force can change only the direction of \vec{v} (and thus the direction of travel); only in this sense can \vec{F}^{mag} accelerate the particle. If there are no other forces acting on the charged particle and the velocity of the particle is perpendicular to the direction of the magnetic field, this means that the particle will move in a circle. If the particle has a component perpendicular to the magnetic field *and* a component of velocity parallel

FIGURE 29-4 (a) The right-hand rule (in which \vec{v} is swept into \vec{B} through the smaller angle ϕ between them) gives the direction of $\vec{v} \times \vec{B}$ as the direction of the thumb. (b) If q is positive, then the direction of $\vec{F}^{\text{mag}} = q\vec{v} \times \vec{B}$ is in the direction of $\vec{v} \times \vec{B}$. (c) If q is negative, then the direction of \vec{F}^{mag} is opposite that of $\vec{v} \times \vec{B}$.

FIGURE 29-5 ■ Color enhanced tracks showing two electrons (e^-) and a positron (e^+) in a bubble chamber that is immersed in a uniform magnetic field that is directed out of the plane of the page.

to the magnetic field, the particle will move along a *helix* of constant radius. These paths are discussed in more detail in Section 29-5.

To develop a feeling for the relationship between the magnetic force on a moving charged particle and the magnetic field, $\vec{F}^{\text{mag}} = q\vec{v} \times \vec{B}$, consider Fig. 29-5. This figure shows some tracks left by charged particles moving rapidly through a *bubble chamber* at the Lawrence Berkeley Laboratory. The chamber, which is filled with liquid hydrogen, is immersed in a strong uniform magnetic field that is directed out of the plane of the figure. An incoming gamma ray particle—which leaves no track because it is uncharged—transforms into an electron (spiral track marked e^-) and a positron (track marked e^+) while it knocks an electron out of a hydrogen atom (long track marked e^-). At first these newly created charged particles are moving in the same direction as the gamma ray. As they move, they each experience a magnetic force of magnitude $F^{\text{mag}} = |q|vB$ and begin to move in a circular path given by $F^{\text{mag}} = mv^2/r$. Since $qvB = mv^2/r$, a particle has a path of radius $r = mv/|q|B$. You can use Eq. 29-2 and Fig. 29-4 to confirm that the three tracks made by these two negative particles and one positive particle curve in the proper directions. It is interesting to note that the electrons and positron do not move in a pure circle. Instead, they move in a shrinking spiral because they are slowed down through their interaction with the gas in the bubble chamber. This makes sense because $r = mv/|q|B$ and as each particle's speed, v , becomes smaller, so does its radius r . When this happens, the magnetic force, which is proportional to the particle's velocity, decreases and so the radius of the particle's path decreases.

What Produces a Magnetic Field?

We have discussed how a charged plastic rod produces a vector field—the electric field \vec{E} —at all points in the space around it. Similarly, a magnet produces a vector field—the **magnetic field** \vec{B} —at all points in the space around it. You get a hint of that magnetic field whenever you attach a note to a refrigerator door with a small magnet, or accidentally erase a computer disk by bringing it near a strong magnet. The magnet acts on the door or disk *by means of* its magnetic field.

In a common type of magnet, a wire coil is wound around an iron core and a current is sent through the coil; the strength of the magnetic field is determined by the size of the current. In industry, such **electromagnets** are used for sorting scrap metal (Fig. 29-1) among many other things. You are probably more familiar with **permanent magnets**—magnets, like the refrigerator-door type, that do not need current to have a magnetic field.

How then are magnetic fields set up? We know about two ways to create magnetic fields. (1) We observe that moving electrically charged particles, such as the current in a wire or charged beams of cosmic rays create magnetic fields. (2) We find that elementary particles such as protons, neutrons, and electrons have *intrinsic* magnetic moments that create magnetic fields. In Chapter 30 we discuss how moving charges create magnetic fields, and in Chapter 32 we consider the role of intrinsic magnetic moments in the creation of magnetic fields. In this chapter we stay focused on how to represent magnetic fields and how they influence charged particles that are moving.

The SI unit for \vec{B} that follows from Eqs. 29-2 and 29-3 is the newton per coulomb-meter per second. For convenience, the SI unit for magnetic field is called the tesla (T):

$$1 \text{ tesla} = 1 \text{ T} = 1 \frac{\text{newton}}{(\text{coulomb})(\text{meter/second})}.$$

Recalling that a coulomb per second is an ampere, we have

$$1 \text{ T} = 1 \frac{\text{newton}}{(\text{coulomb/second})(\text{meter})} = 1 \frac{\text{N}}{\text{A} \cdot \text{m}}. \quad (29-4)$$

TABLE 29-1
Some Approximate Magnetic Fields

At the surface of a neutron star	10^8 T
Near a big electromagnet	1.5 T
Near a small bar magnet	10^{-2} T
At Earth's surface	10^{-4} T
In interstellar space	10^{-10} T
Smallest value in a magnetically shielded room	10^{-14} T

An earlier (non-SI) unit for \vec{B} , that is still in common use is the *gauss* (G), and

$$1 \text{ tesla} = 10^4 \text{ gauss.} \quad (29-5)$$

Table 29-1 lists the magnetic fields that occur in a few situations. Note that Earth's magnetic field near the planet's surface is about 10^{-4} T (= $100 \mu\text{T}$ or 1 gauss).

READING EXERCISE 29-1: The figure shows three situations in which a charged particle with velocity \vec{v} travels through a uniform magnetic field \vec{B} . In each situation, what is the direction of the magnetic force \vec{F}^{mag} on the particle?

Magnetic Field Lines

We can represent magnetic fields with field lines, as we did for electric fields. Similar rules apply; that is, (1) the direction of the tangent to a magnetic field line at any point gives the direction of \vec{B} at that point, and (2) the spacing of the lines represents the magnitude of \vec{B} —the magnetic field is stronger where the lines are closer together, and conversely.

Figure 29-6a shows how the magnetic field near a *bar magnet* (a permanent magnet in the shape of a bar) can be represented by magnetic field lines. The lines all pass through the magnet, and they all form closed and continuous loops (even those that are not shown closed in the figure). They don't start or end anywhere. Since electric field lines begin and end on electric charges, this is consistent with our assumption that there are no magnetic charges (monopoles). As shown with field lines, the external magnetic effects of a bar magnet are strongest near its ends, where the field lines are most closely spaced. Thus, the magnetic field of the bar magnet in Fig. 29-6b collects the iron filings mainly near the two ends of the magnet. Overall, outside of the bar magnet the field lines look just like they would for an electric dipole, but inside the magnet they point in the opposite direction.

The (closed) field lines enter one end of a magnet and exit the other end. The end of a magnet from which the field lines emerge is called the *north pole* of the magnet; the other end, where field lines enter the magnet, is called the *south pole*. (Remember that the direction of the field line is related to the direction of the force on a moving positively charged particle.) Some of the magnets we use to fix notes on refrigerators

FIGURE 29-6 (a) The magnetic field lines for a bar magnet. (b) A “cow magnet”—a bar magnet that is intended to be slipped down into the rumen (first stomach) of a cow to prevent accidentally ingested bits of scrap iron from reaching the cow's intestines. The iron filings at its ends reveal the directions of the magnetic field lines in the vicinity of the magnet.

FIGURE 29-7 ■ (a) A horseshoe magnet and (b) a C-shaped magnet. (Only a few of the possible of the external field lines are shown.)

are short bar magnets. Figure 29-7 shows two other common shapes for magnets: a *horseshoe magnet* and a magnet that has been bent around into the shape of a C so that the *pole faces* are facing each other. (The magnetic field between the pole faces can then be approximately uniform.) Regardless of the shape of the magnets, if we place two of them near each other we find:

Opposite magnetic poles attract each other, and like magnetic poles repel each other.

Earth has a magnetic field that is produced in its core. We discuss current theories about the nature and origin of the Earth's magnetic field in Section 32-9. On Earth's surface, we can detect this magnetic field with a compass, which is essentially a slender bar magnet on a low-friction pivot. This bar magnet, or this needle, turns because its north pole end is attracted toward the Arctic region, or North Pole, of Earth. Thus, the *south* pole of Earth's magnetic field must be located toward the North Pole. Logically, we then should call the pole there a south pole. However, because we call that direction north, we are trapped into the statement that Earth has a *geomagnetic north pole* in that direction.

With more careful measurement we would find that in the northern hemisphere, the magnetic field lines of Earth generally point down into Earth and toward the Arctic. In the southern hemisphere, they generally point up out of Earth and away from the Antarctic—that is, away from Earth's *geomagnetic south pole*.

TOUCHSTONE EXAMPLE 29-1: Proton in a Magnetic Field

A uniform magnetic field \vec{B} , with magnitude 1.2 mT, is directed vertically upward throughout the volume of a laboratory chamber. A proton with kinetic energy 5.3 MeV enters the chamber, moving horizontally from south to north. What is the magnitude of the magnetic deflecting force acting on the proton as it enters the chamber? The proton mass is 1.67×10^{-27} kg. (Neglect Earth's magnetic field.)

SOLUTION ■ Because the proton is charged and moving through a magnetic field, a magnetic force \vec{F}^{mag} can act on it. The **Key Idea** here is that, because the initial direction of the proton's velocity is not along a magnetic field line, \vec{F}^{mag} is not simply zero. To find the magnitude of \vec{F}^{mag} , we can use Eq. 29-3 provided we first find the proton's speed $|\vec{v}| = v$. We can find v from the given

kinetic energy, since $K = \frac{1}{2}mv^2$. Solving for $|\vec{v}|$, we find

$$v = \sqrt{\frac{2K}{m}} = \sqrt{\frac{(2)(5.3 \text{ MeV})(1.60 \times 10^{-13} \text{ J/MeV})}{1.67 \times 10^{-27} \text{ kg}}} \\ = 3.2 \times 10^7 \text{ m/s.}$$

Equation 29-3 then yields

$$F^{\text{mag}} = |q|vB_{\sin\phi} \\ = (1.60 \times 10^{-19} \text{ C})(3.2 \times 10^7 \text{ m/s}) \\ \times (1.2 \times 10^{-3} \text{ T})(\sin 90^\circ) \\ = 6.1 \times 10^{-15} \text{ N.} \quad (\text{Answer})$$

This may seem like a small force, but it acts on a particle of small mass, producing a large magnitude of acceleration; namely,

$$a = \frac{F^{\text{mag}}}{m} = \frac{6.1 \times 10^{-15} \text{ N}}{1.67 \times 10^{-27} \text{ kg}} = 3.7 \times 10^{12} \text{ m/s}^2.$$

To find the direction of \vec{F}^{mag} , we use the **Key Idea** that \vec{F}^{mag} has the direction of the cross product $q\vec{v} \times \vec{B}$. Because the charge q is positive, \vec{F}^{mag} must have the same direction as $\vec{v} \times \vec{B}$, which can be determined with the right-hand rule for cross products (as in Fig. 29-4b). We know that \vec{v} is directed horizontally from south to north and \vec{B} is directed vertically up. The right-hand rule shows us that the deflecting force \vec{F}^{mag} must be directed horizontally from west to east, as Fig. 29-8 shows. (The array of dots in the figure represents a magnetic field directed out of the plane of the

figure. An array of Xs would have represented a magnetic field directed into that plane.)

If the charge of the particle were negative, the magnetic deflecting force would be directed in the opposite direction—that is, horizontally from east to west. This is predicted automatically by Eq. 29-2, if we substitute a negative value for q .

FIGURE 29-8 ■ An overhead view of a proton moving from south to north with velocity \vec{v} in a chamber. A magnetic field is directed vertically upward in the chamber, as represented by the array of dots (which resemble the tips of arrows). The proton is deflected toward the east.

29-5 A Circulating Charged Particle

Remember that when we studied projectile motion we found that the (vertical) gravitational acceleration had no effect on the horizontal velocity of the projectile. Furthermore, when we studied uniform circular motion, we found that the (radial) centripetal acceleration only changed the direction of the object's velocity (keeping it moving in a circle), but did not speed it up or slow it down. This is a general relationship: The component of acceleration that is perpendicular to the direction of velocity only changes the direction of the velocity, not the magnitude.

We have a similar situation here. If we have a charged particle whose size is small enough to ignore, the magnetic force the particle feels is always perpendicular to its velocity and not its magnitude. As we established earlier, if the velocity and magnetic field are perpendicular (and there are no other forces on the particle), the particle will move in a circle.

If a particle moves in a circle at constant speed, we can be sure that the net force acting on the particle is constant in magnitude and is centripetal. That is, the force points toward the center of the circle, always perpendicular to the particle's velocity. Think of a stone tied to a string and whirled in a circle on a smooth horizontal surface, or of a satellite moving in a circular orbit around the Earth. In the first case, the tension in the string provides the necessary force and centripetal acceleration. In the second case, Earth's gravitational attraction provides the force and acceleration.

Figure 29-9 shows another example of a centripetal magnetic force: A beam of electrons is projected into a chamber by an *electron gun* G. The electrons enter in the plane of the page with speed v and move in a region of uniform magnetic field \vec{B} directed out of the plane of the figure. As a result, a magnetic force $\vec{F}^{\text{mag}} = q\vec{v} \times \vec{B}$ continually deflects the electrons, and because the particle's velocity, \vec{v} , and the magnetic field it passes through, \vec{B} , are always perpendicular to each other, this deflection causes the electrons to follow a circular path. The path is visible in the photo because atoms of gas in the chamber emit light when some of the circulating electrons collide with them.

We would like to determine the parameters that characterize the circular motion of these electrons, or of any particle having an amount of charge $|q|$ and mass m moving perpendicular to a uniform magnetic field \vec{B} at speed v . From Eq. 29-3, the force acting on the particle has a magnitude of $|q|vB$. From Newton's Second Law ($\vec{F} = m\vec{a}$) applied to uniform circular motion (Eq. 5-34),

$$F^{\text{mag}} = m \frac{v^2}{r}, \quad (29-6)$$

FIGURE 29-9 ■ Electrons circulating in a chamber containing gas at low pressure (their path is the glowing circle). A uniform magnetic field \vec{B} , pointing directly out of the plane of the page, fills the chamber. Note the radially directed magnetic force \vec{F}^{mag} ; for circular motion to occur, \vec{F}^{mag} must point toward the center of the circle. Use the right-hand rule for cross products to confirm that $\vec{F}^{\text{mag}} = q\vec{v} \times \vec{B}$ gives \vec{F}^{mag} the proper direction. (Don't forget to include the sign of q .)

we have

$$|q|vB = \frac{mv^2}{r}. \quad (29-7)$$

Solving for r , we find the radius of the circular path as

$$r = \frac{mv}{|q|B} \quad (\text{radius of circular path}). \quad (29-8)$$

The period T (the time for one full revolution) is equal to the circumference divided by the speed:

$$T = \frac{2\pi r}{v} = \frac{2\pi}{v} \frac{mv}{|q|B} = \frac{2\pi m}{|q|B} \quad (\text{period}). \quad (29-9)$$

The frequency f (the number of revolutions per unit time) is

$$f = \frac{1}{T} = \frac{|q|B}{2\pi m} \quad (\text{frequency}). \quad (29-10)$$

The angular frequency ω of the motion is then

$$\omega = 2\pi f = \frac{|q|B}{m} \quad (\text{angular or cyclotron frequency}). \quad (29-11)$$

The quantities T , f , and ω do not depend on the speed of the particle (provided that speed is much less than the speed of light). Fast particles move in large circles and slow ones in small circles, but all particles with the same charge-to-mass ratio q/m take the same time T (the period) to complete one round trip. A bigger velocity makes the particle travel in a larger circle. The increase in speed is exactly compensated by the increase in distance, so the time it takes to go around the circle is the same. We see later that this plays an important role in the construction of a charged particle accelerator known as a **cyclotron**. Using Eq. 29-2, you can show that if you are looking in the direction of \vec{B} , the direction of rotation for a positive particle is always counterclockwise; the direction for a negative particle is always clockwise.

FIGURE 29-10 (a) A charged particle moves in a uniform magnetic field \vec{B} , its velocity \vec{v} making an angle ϕ with the field direction. (b) The particle follows a helical path, of radius r and pitch p . (c) A charged particle spiraling in a nonuniform magnetic field. (The particle can become trapped, spiraling back and forth between the strong field regions at either end.) Note that the magnetic force vectors at the left and right sides have a component pointing toward the center of the figure.

Helical Paths

As we discussed in regard to the electrons and positron in the bubble chamber of Figure 29-5, if the velocity of a charged particle moving through a magnetic field is changing, the particle will move in a shrinking spiral, rather than a circle. One way this can happen is for the particle to be slowed by frictional or other forces. Furthermore, if the velocity of a charged particle has a component parallel to the (uniform) magnetic field, the particle will move in a helical path about the direction of the field vector. Figure 29-10a, for example, shows the velocity vector \vec{v} of such a particle resolved into two components, one parallel to \vec{B} and one perpendicular to it:

$$v_{\parallel} = |\vec{v}| \cos \phi \quad \text{and} \quad v_{\perp} = |\vec{v}| \sin \phi. \quad (29-12)$$

The parallel component determines the *pitch* p of the helix—that is, the distance between adjacent turns (Fig. 29-10b). The perpendicular component determines the radius of the helix and is the quantity to be substituted for $|\vec{v}|$ in Eq. 29-8.

Figure 29-10c shows a charged particle spiraling in a nonuniform magnetic field. The more closely spaced field lines at the left and right sides indicate that the magnetic field is stronger there. When the field at an end is strong enough, the particle “reflects” from that end. If the particle reflects from both ends, it is said to be trapped in a *magnetic bottle*.

Confining Particles in a Tokamak Reactor

In the chapter opener we explained that in order to induce fusion reactions capable of releasing large amounts of energy, we must fuse light atoms together. To do this we need to confine ions having very high energy, and hence high temperature. Magnetic fields are ideal for containing the ions because both the ions and the electrons are charged and will spiral along magnetic field lines instead of hitting the walls of a containment vessel.

Scientists have not yet been able to confine charged particles at high enough temperatures to achieve controlled fusion. However, experiments reveal that one of the most effective configurations of magnetic field lines for containing the light atomic ions is shaped like a torus. A torus is basically a donut shape. The containment vessel of the Joint European Torus, commonly known as a tokamak, is shown at the beginning of this chapter. In a tokamak reactor, the magnetic field is produced by a series of magnetic coils that are evenly spaced around the torus-shaped containment vessel as shown in Fig. 29-11. The magnetic field lines form continuous loops inside the ring of the torus. In theory, when a tokamak is working properly, the high temperature ions and electrons should revolve in helical paths around the field lines. An ion can then travel in a continuous loop until it undergoes a fusion reaction with another ion.

FIGURE 29-11 A cutaway drawing of the JET tokamak showing the donut shaped containment vessel and surrounding magnetic coils.

Particles Trapped in the Earth's Magnetic Field

The terrestrial magnetic field acts as a magnetic bottle, trapping electrons and protons; the trapped particles form the *Van Allen radiation belts*, which loop well above the Earth's atmosphere between Earth's north and south geomagnetic poles. These particles bounce back and forth, from one end of this magnetic bottle to the other, within a few seconds.

When a large solar flare shoots additional energetic electrons and protons into the radiation belts, an electric field is produced in the region where electrons normally reflect. This field eliminates the reflection and instead drives electrons down into the atmosphere, where they collide with atoms and molecules of air, causing that air to emit light. This light forms the aurora—a curtain of light that hangs down to an altitude of about 100 km. Green light is emitted by oxygen atoms, and pink light is emitted by nitrogen molecules, but often the light is so dim that we perceive only white light.

READING EXERCISE 29-2: The figure shows the circular paths of two particles that travel at the same speed in a uniform magnetic field \vec{B} , which is directed into the page. One particle is a proton; the other is an electron (which is less massive). The relative sizes of the circles are not to scale. (a) Which particle follows the smaller circle, and (b) does that particle travel clockwise or counterclockwise?

TOUCHSTONE EXAMPLE 29-2: Mass Spectrometer

Figure 29-12 shows the essentials of a *mass spectrometer*, which can be used to measure the mass of an ion; an ion of mass m (to be measured) and charge q is produced in source S . The initially stationary ion is accelerated by the electric field due to a potential difference ΔV . The ion leaves S and enters a separator chamber in which a uniform magnetic field \vec{B} is perpendicular to the path of the ion. The magnetic field causes the ion to move in a semicircle, striking (and thus altering) a photographic plate at distance x from the entry slit. Suppose that in a certain trial $B = 80.000$ mT and $\Delta V = 1000.0$ V, and ions of charge $q = +1.6022 \times 10^{-19}$ C strike

FIGURE 29-12 ■ Essentials of an early model of a mass spectrometer. A positive ion, after being accelerated from its source S by potential difference ΔV , enters a chamber of uniform magnetic field \vec{B} . There it travels through a semicircle of radius r and strikes a photographic plate at a distance x from where it entered the chamber.

the plate at $x = 1.6254$ m. What is the mass m of the individual ions, in unified atomic mass units ($1 \text{ u} = 1.6605 \times 10^{-27}$ kg)?

SOLUTION ■ One **Key Idea** here is that, because the (uniform) magnetic field causes the (charged) ion to follow a circular path, we can relate the ion's mass m to the path's radius r with Eq. 29-8 ($r = m|\vec{v}|/|q\vec{B}|$). From Fig. 29-12 we see that $r = x/2$, and we are given the magnitude $|\vec{B}|$ of the magnetic field. However, we don't know the ion's speed v in the magnetic field, after it has been accelerated due to the potential difference ΔV .

To relate v and ΔV , we use the **Key Idea** that mechanical energy ($E^{\text{mec}} = K + U$) of the mass spectrometer system is conserved during the acceleration. When the ion emerges from the source, its kinetic energy is approximately zero. At the end of the acceleration, its kinetic energy is $\frac{1}{2}mv^2$. Also, during the acceleration, the positive ion moves through a change in potential of $-\Delta V$. Thus, because the ion has positive charge q , its potential energy changes by $-q\Delta V$. If we now write the conservation of the system's mechanical energy as

$$\Delta K + \Delta U = 0,$$

we get

$$\frac{1}{2}mv^2 - q\Delta V = 0$$

or

$$v = \sqrt{\frac{2|q\Delta V|}{m}}. \quad (29-13)$$

Substituting this into Eq. 29-8 gives us

$$r = \frac{m v}{|q \vec{B}|} = \frac{m}{|q| B} \sqrt{\frac{2|q \Delta V|}{m}} = \frac{1}{B} \sqrt{\frac{2m|\Delta V|}{|q|}}.$$

Thus,
$$x = 2r = \frac{2}{B} \sqrt{\frac{2m|\Delta V|}{|q|}}.$$

Solving this for m and substituting the given data yield

$$\begin{aligned} m &= \frac{B^2 |q| x^2}{8 |\Delta V|} \\ &= \frac{(0.080000 \text{ T})^2 (1.6022 \times 10^{-19} \text{ C})(1.6254 \text{ m})^2}{8(1000.0 \text{ V})} \\ &= 3.3863 \times 10^{-25} \text{ kg} = 203.93 \text{ u}. \end{aligned} \quad (\text{Answer})$$

29-6 Crossed Fields: Discovery of the Electron

As we have seen, both an electric field \vec{E} and a magnetic field \vec{B} can produce a force on a charged particle. When the two fields are perpendicular to each other, they are said to be *crossed fields*. Here we shall examine what happens to charged particles—namely, electrons—as they move through crossed fields. We use as our example the experiment that led to the discovery of the electron in 1897 by J. J. Thomson at Cambridge University.

Figure 29-13 shows a modern, simplified version of Thomson's experimental apparatus—a *cathode ray tube* (which is like the picture tube in a standard television set). Charged particles (which we now know as electrons) are emitted by a hot filament at the rear of the evacuated tube and are accelerated by an applied potential difference ΔV . After the electrons pass through a slit in screen C, they form a narrow beam. They then pass through a region of crossed \vec{E} and \vec{B} fields, headed toward a fluorescent screen S, where they produce a spot of light (on a television screen the spot is part of the picture). The forces on the charged particles in the crossed-fields region can deflect them from the center of the screen. By controlling the magnitudes and directions of the fields, Thomson could thus control where the spot of light appeared on the screen. Recall that the force on a negatively charged particle due to an electric field is directed opposite the field. Thus, for the particular field arrangement of Fig. 29-13, electrons are forced up the page by the electric field \vec{E} and down the page by the magnetic field \vec{B} ; that is, the forces are *in opposition*. Thomson's procedure was equivalent to the following series of steps:

1. Set $\vec{E} = 0 \text{ N/C}$ and $\vec{B} = 0 \text{ T}$ and note the position of the spot on screen S due to the undeflected beam.
2. Turn on \vec{E} and measure the resulting beam deflection.
3. Maintaining \vec{E} , now turn on \vec{B} and adjust its value until the beam returns to the undeflected position. (With the forces in opposition, they can be made to cancel.)

FIGURE 29-13 ■ A modern version of J. J. Thomson's apparatus for measuring the ratio of mass to the amount of charge of an electron. The electric field \vec{E} is established by connecting a battery across the deflecting-plate terminals. The magnetic field \vec{B} is set up by means of a current in a system of coils (not shown). The magnetic field shown is into the plane of the figure, as represented by the array of Xs (which resemble the feathered ends of arrows).

We discussed the deflection of a charged particle moving perpendicular to an electric field \vec{E} between two plates (step 2 here) in Touchstone Example 23-4. We found that the magnitude of the deflection of the particle at the far end of the plates is

$$|\Delta y| = \frac{|q|EL^2}{2mv^2}, \quad (29-14)$$

where v is the particle's initial speed (which was v_x in Touchstone Example 23-4), m its mass, and q its charge, and L is the length of the plates. So long as the particle's deflection is small, we can apply this same equation to the beam of electrons in Fig. 29-13; if necessary, we can calculate the deflection by measuring the deflection of the beam on screen S and then working back to calculate the deflection y at the end of the plates. (Because the direction of the deflection is set by the sign of the particle's charge, Thomson was able to show that the particles lighting up his screen were negatively charged.)

When the two fields in Fig. 29-13 are adjusted so that the two deflecting forces cancel (step 3), we have from Eqs. 29-1 and 29-3,

$$|q|E = |q|vB \sin(90^\circ) = |q|vB,$$

so the particle speed v is given by the ratio of the field magnitudes

$$v = \frac{E}{B}. \quad (29-15)$$

Thus, the crossed fields allow us to measure the speed of the charged particles passing through them. Substituting Eq. 29-15 for $|\vec{v}|$ in Eq. 29-14 and rearranging yield

$$\frac{m}{|q|} = \frac{B^2 L^2}{2|\Delta y|E}, \quad (29-16)$$

in which all quantities on the right can be measured. Thus, the crossed fields allow us to measure the mass-charge amount ratio $m/|q|$ of the particles moving through Thomson's apparatus.

Thomson claimed that these particles are found in all matter. He also claimed that they are lighter than the lightest known atom (hydrogen) by a factor of more than 1000. (The exact ratio proved later to be 1836.15.) His $m/|q|$ measurement, coupled with the boldness of his two claims, is considered to be the moment of "discovery of the electron."

READING EXERCISE 29-3: The figure shows four directions for the velocity vector \vec{v} of a positively charged particle moving through a uniform electric field \vec{E} (directed out of the page and represented by an encircled dot) and a uniform magnetic field \vec{B} (pointing to the left). (a) Rank directions 1, 2, 3, and 4 according to the magnitude of the net force on the particle, greatest first. (b) Of all four directions, which might result in a net force of zero?

29-7 The Hall Effect

In Chapters 22 and 26 we claimed that currents in solid conductors are due to moving electrons, and that the positive nuclei are at rest. What evidence do we have for this claim? In the late 1870s, Edwin H. Hall, a 24-year-old graduate student at the

Johns Hopkins University, investigated the deflection of electric current passing through copper wire when the wire is placed in a magnetic field. The result of his work, which is called the **Hall effect** after him, allows us to answer important questions about the nature of charge carriers. For example, Hall's findings allowed him to determine whether charge carriers in a conductor are positive or negative. In addition, Hall's measurements enabled him to deduce the number of charge carriers per unit volume contained in a given conductor.

What happens to a current-carrying metal wire in a magnetic field if the charge carriers are positive and negative charges are at rest? Figure 29-14a shows a copper strip of width d , carrying a current i that is assumed to be made up of positive charge carriers (the convention at the time) moving from the top of the figure to the bottom. The charge carriers drift (with an average speed $|\langle \vec{v} \rangle|$) in the direction of the current, from top to bottom. At the instant shown in Fig. 29-14a, an external magnetic field \vec{B} , pointing into the plane of the figure, has just been turned on. From Eq. 29-2 we see that a deflecting magnetic force \vec{F}^{mag} will act on each drifting positive charge, pushing it toward the right edge of the strip.

As time goes on, positive charges pile up on the right edge of the strip, leaving uncompensated negative charges in fixed positions at the left edge. The separation of positive and negative charges produces a constant electric field \vec{E} within the strip, pointing from right to left. This field exerts an average electrostatic force (\vec{F}^{elec}) on a typical positive charge, tending to push it back toward the left.

An equilibrium quickly develops in which the electric force on each positive charge (pushing left) builds up until it just cancels the magnetic force (pushing right). When this happens, as Fig. 29-14b shows, the force due to \vec{B} and the force due to \vec{E} are in balance. The drifting positive charges then move along the strip toward the bottom of the page at an average velocity $\langle \vec{v} \rangle$, with no further collection of positive charge on the right edge of the strip and thus no further increase in the electric field \vec{E} .

A *Hall potential difference* ΔV is associated with the electric field across strip width d . Because the field is constant, we use Eq. 25-39 to get

$$|\Delta V| = Ed. \quad (29-17)$$

By connecting a voltmeter across the width, we can measure the potential difference between the two edges of the strip. Moreover, the voltmeter can tell us which edge is at higher potential. This information, in turn, tells us whether our charge carriers are positive or negative.

So what do we find? For the situation of Fig. 29-14a, we find that the *left* edge is at *higher* potential, meaning we have a buildup of positive charge there. This result is inconsistent with our assumption that the charge carriers are positive.

Suppose we make the opposite assumption, that the charge carriers in current i are negative, as shown in Fig. 29-15. The negative charge carriers drift (with an average speed $|\langle \vec{v} \rangle|$) in the *opposite* direction of the conventional current, from bottom to top. You can use the magnetic force law (Eq. 29-2) to convince yourself that as these charge carriers move from bottom to top in the strip, they are pushed to the right edge by \vec{F}^{mag} and thus that the *left* edge is at higher potential. Because that last statement is in fact what we actually observe with a voltmeter, we conclude that the charge carriers must be negative.

Now for the quantitative part. When the electric and magnetic forces are in balance (Fig. 29-14b), Eqs. 29-1 and 29-3 give us a relationship between the magnitudes of the electric and magnetic fields:

$$eE = e|\langle \vec{v} \rangle|B, \quad (29-18)$$

FIGURE 29-14 ■ What would happen if a positive current were to flow through a strip of copper immersed in a magnetic field \vec{B} ? (a) As soon as the magnetic field is turned on, the positive charges follow a curved path as shown. (b) A short time later positive charges pile up on the right side of the strip. Thus, the right side of the strip has a higher potential than the left side. Since the higher potential is observed on the left not the right, we conclude that the *charge carriers are not positive*.

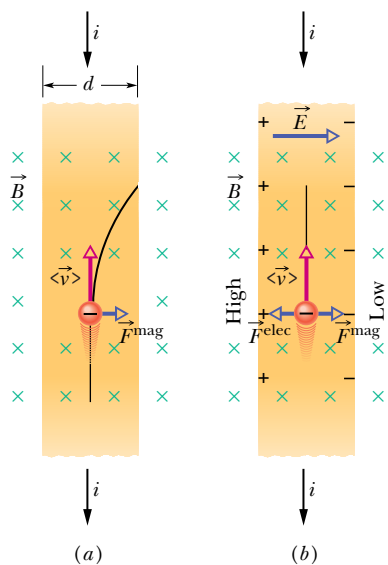

FIGURE 29-15 ■ What should happen when the conventional current, i , actually consists of a negative electron current flowing in the opposite direction? (a) As soon as the magnetic field is turned on, electrons follow the curved path shown. (b) A short time later negative charges pile up on the right side of the strip so that a higher potential develops on the left. Since this prediction matches experimental findings we must conclude that the *charge carriers are negative*.

where e is the amount of the charge on the electron. From Eq. 26-21, the average or drift speed $|\langle \vec{v} \rangle|$ is

$$|\langle \vec{v} \rangle| = \frac{|\vec{J}|}{ne} = \frac{|i|}{neA}, \quad (29-19)$$

in which $|\vec{J}| (= |i|/A)$ is the current density in the strip, A is the cross-sectional area of the strip, and n is the *number density* of charge carriers (their number per unit volume).

In Eq. 29-18, substituting $|\Delta V|/d$ for E (Eq. 29-17) and substituting for $|\langle \vec{v} \rangle|$ with the rightmost term in Eq. 29-19, we obtain

$$n = \frac{|i|B}{e\ell|\Delta V|}, \quad (29-20)$$

in which $\ell = A/d$ is the thickness of the strip. With this equation we can find n from measurable quantities.

It is also possible to use the Hall effect to measure directly the average or drift speed $|\langle \vec{v} \rangle|$ of the charge carriers, which you may recall is of the order of centimeters per hour. In this clever experiment, the metal strip is moved mechanically through the magnetic field in a direction opposite that of the drift velocity of the charge carriers. The speed of the moving strip is then adjusted until the Hall potential difference vanishes. At this condition, with no Hall effect, the velocity of the charge carriers *with respect to the laboratory frame* must be zero, so the velocity of the strip must be equal in magnitude but opposite in direction to the velocity of the negative charge carriers.

TOUCHSTONE EXAMPLE 29-3: Motional Potential Difference

Figure 29-16 shows a solid metal cube, of edge length $d = 1.5$ cm, moving in the positive y direction at a constant velocity \vec{v} of magnitude 4.0 m/s. The cube moves through a uniform magnetic field \vec{B} of magnitude 0.050 T directed toward positive z .

(a) Which cube face is at a lower electric potential and which is at a higher electric potential because of the motion through the field?

SOLUTION ■ One **Key Idea** here is that, because the cube is moving through a magnetic field \vec{B} , a magnetic force \vec{F}^{mag} acts on its charged particles, including its conduction electrons. A second **Key Idea** is how \vec{F}^{mag} causes an electric potential difference between certain faces of the cube. When the cube first begins to move

FIGURE 29-16 ■ A solid metal cube of edge length d moves at constant velocity \vec{v} through a uniform magnetic field \vec{B} .

through the magnetic field, its electrons do also. Because each electron has charge $q = -e$ and is moving through a magnetic field with velocity \vec{v} , the magnetic force \vec{F}^{mag} acting on it is given by Eq. 29-2. Because q is negative, the direction of \vec{F}^{mag} is opposite the cross product $\vec{v} \times \vec{B}$, which is in the positive direction of the x axis in Fig. 29-16. Thus, \vec{F}^{mag} acts in the negative direction of the x axis, toward the left face of the cube (which is hidden from view in Fig. 29-16).

Most of the electrons are fixed in place in the molecules of the cube. However, because the cube is a metal, it contains conduction electrons that are free to move. Some of those conduction electrons are deflected by \vec{F}^{mag} to the left cube face, making that face negatively charged and leaving the right face positively charged. This charge separation produces an electric field \vec{E} directed from the positively charged right face to the negatively charged left face. Thus, the left face is at a lower electric potential, and the right face is at a higher electric potential.

(b) What is the potential difference between the faces of higher and lower electric potential?

SOLUTION ■ The **Key Ideas** here are these:

1. The electric field \vec{E} created by the charge separation produces an electric force $\vec{F}^{\text{elec}} = q\vec{E}$ on each electron. Because q is

negative, this force is directed opposite the field \vec{E} —that is, toward the right. Thus on each electron, \vec{F}^{elec} acts toward the right and \vec{F}^{mag} acts toward the left.

- When the cube had just begun to move through the magnetic field and the charge separation had just begun, the magnitude of \vec{E} began to increase from zero. Thus, the magnitude of \vec{F}^{elec} also began to increase from zero and was initially smaller than the magnitude \vec{F}^{mag} . During this early stage, the net force on any electron was dominated by \vec{F}^{mag} , which continuously moved additional electrons to the left cube face, increasing the charge separation.
- However, as the charge separation increased, eventually magnitude $|\vec{F}^{\text{elec}}|$ became equal to magnitude $|\vec{F}^{\text{mag}}|$. The net force on any electron was then zero, and no additional electrons were moved to the left cube face. Thus, the magnitude of \vec{F}^{elec} could not increase further, and the electrons were then in equilibrium.

We seek the potential difference ΔV between the left and right cube faces after equilibrium was reached (which occurred quickly). We can obtain the magnitude of ΔV with Eq. 29-17 ($|\Delta V| = Ed$)

provided we first find the magnitude $|\vec{E}| = E$ of the electric field at equilibrium. We can do so with the equation for the balance of force magnitudes ($|\vec{F}^{\text{elec}}| = |\vec{F}^{\text{mag}}|$).

For F^{elec} , we substitute $|q|E$. For F^{mag} , we substitute $|q|vB \sin \phi$ from Eq. 29-3. From Fig. 29-16, we see that the angle ϕ between v and B is 90° ; so $\sin \phi = 1$. We can now write ($F^{\text{elec}} = F^{\text{mag}}$) as

$$|q|E = |q|vB \sin 90^\circ = |q|vB.$$

This gives us $E = vB$, so Eq. 29-17 ($|\Delta V| = Ed$) becomes

$$|\Delta V| = |V_{\text{left}} - V_{\text{right}}| = vBd. \quad (29-21)$$

Substituting known values gives us

$$\begin{aligned} |\Delta V| &= (4.0 \text{ m/s})(0.050 \text{ T})(0.015 \text{ m}) \\ &= 0.0030 \text{ V} = 3.0 \text{ mV}. \end{aligned}$$

Since the left face of the cube has excess negative charges, the right face is at a higher potential than the left face by 3.0 mV. (Answer)

29-8 Magnetic Force on a Current-Carrying Wire

We have just seen that a magnetic field exerts a sideways force on electrons moving in a wire. This force must then be transmitted to the wire itself, because the conduction electrons cannot escape sideways out of the wire.

In Fig. 29-17a, a vertical wire, carrying no current and fixed in place at both ends, extends through the gap between the vertical pole faces of a magnet represented by the shaded circle. The magnetic field between the faces is directed outward from the page. In Fig. 29-17b, a current is sent upward through the wire; the wire deflects to the right. In Fig. 29-17c, we reverse the direction of the current and the wire deflects to the left.

Figure 29-18 shows what happens inside the wire of Fig. 29-17. We see one of the conduction electrons, drifting downward with an assumed average (drift) speed $|\langle \vec{v} \rangle|$. Equation 29-3, in which we must put $\phi = 90^\circ$, tells us that a force of magnitude $F^{\text{mag}} = e|\langle \vec{v} \rangle|B$ must act on a typical electron. From Eq. 29-2 we see that this force must be directed to the right. We expect then that the wire as a whole will experience a force to the right, in agreement with Fig. 29-17b.

If, in Fig. 29-18, we were to reverse *either* the direction of the magnetic field *or* the direction of the current, the force on the wire would reverse, being directed now to the left. Note too that it does not matter whether we consider negative charges drifting downward in the wire (the actual case) or positive charges drifting upward. The direction of the deflecting force on the wire is the same. We are safe then in dealing with a current of positive charge.

Consider a length L of the wire in Fig. 29-18. All the conduction electrons in this section of wire will drift past a plane that is parallel to xx' (shown in Fig. 29-18) in a time $\Delta t = L/|\langle \vec{v} \rangle|$. Thus, in that time the charge that will pass through the plane is given by

$$q = i\Delta t = i \frac{L}{|\langle \vec{v} \rangle|}.$$

FIGURE 29-17 ■ A flexible wire passes between the pole faces of a magnet (only the farther pole face is shown). (a) Without current in the wire, the wire is straight. (b) With upward current, the wire is deflected rightward. (c) With downward current, the deflection is leftward. Connections for getting the current into one end of the wire and out of the other are not shown.

FIGURE 29-18 ■ A close-up view of a section of the wire of Fig. 29-17*b*. The current direction is upward, which means that electrons drift downward. A magnetic field that emerges from the plane of the page causes the electrons and the wire to be deflected to the right.

FIGURE 29-19 ■ A wire carrying current i makes an angle ϕ with magnetic field \vec{B} . The wire has length L in the field and length vector \vec{L} (in the direction of the current). A magnetic force $\vec{F}^{\text{mag}} = i\vec{L} \times \vec{B}$ acts on the wire.

Substituting this into Eq. 29-3 yields the following expressions for the magnitude of the magnetic force

$$F^{\text{mag}} = |q| |\langle \vec{v} \rangle| B \sin \phi = \frac{|i| L |\langle \vec{v} \rangle| B}{|\langle \vec{v} \rangle|} \sin 90^\circ$$

or
$$F^{\text{mag}} = |i| LB. \quad (29-22)$$

This equation gives the magnetic force that acts on a length L of straight wire carrying a current i and immersed in a magnetic field \vec{B} that is perpendicular to the wire.

If the magnetic field is *not* perpendicular to the wire, as in Fig. 29-19, the magnetic force is given by a generalization of Eq. 29-22:

$$\vec{F}^{\text{mag}} = |i| \vec{L} \times \vec{B} \quad (\text{force on a current}). \quad (29-23)$$

Here \vec{L} is a *length vector* that has magnitude $|\vec{L}|$ and is directed along the wire segment in the direction of the (conventional) current. The magnitude of the magnetic force is

$$F^{\text{mag}} = |i| LB \sin \phi, \quad (29-24)$$

where ϕ is the smaller angle between the directions of \vec{L} and \vec{B} . The direction of \vec{F}^{mag} is that of the cross product $\vec{L} \times \vec{B}$, because we take current i to be a positive quantity. Equation 29-23 tells us that \vec{F}^{mag} is always perpendicular to the plane defined by \vec{L} and \vec{B} , as indicated in Fig. 29-19.

Equation 29-23 is equivalent to Eq. 29-2 in that either can be taken as the defining equation for \vec{B} . In practice, we define \vec{B} from Eq. 29-23. It is much easier to measure the magnetic force acting on a wire than that on a single moving charge.

If a wire is not straight or the field is not uniform, we can imagine it broken up into small straight segments and apply Eq. 29-23 to each short segment $d\vec{L}$. The force on the wire as a whole is then the vector sum of all the forces on the segments that make it up. In the differential limit, we can write

$$d\vec{F}^{\text{mag}} = i d\vec{L} \times \vec{B}, \quad (29-25)$$

and we can find the resultant force on any given arrangement of currents by integrating Eq. 29-25 over that arrangement.

In using Eq. 29-25, bear in mind that there is no such thing as an isolated current-carrying wire segment of length $d\vec{L}$. There must always be a way to introduce the current into the segment at one end and take it out at the other end.

READING EXERCISE 29-4: The figure shows a current i through a wire in a uniform magnetic field \vec{B} , as well as the magnetic force \vec{F}^{mag} acting on the wire. The field is oriented so that the magnitude force is a maximum. In what direction is the field?

■

TOUCHSTONE EXAMPLE 29-4: Levitating a Wire

A straight, horizontal length of copper wire has a current $i = 28$ A through it. If this current is directed out of the page as shown in Fig. 29-20, what are the magnitude and direction of the minimum

magnetic field \vec{B} needed to suspend the wire—that is, to balance the gravitational force on it? The linear density (mass per unit length) is 46.6 g/m.

FIGURE 29-20 ■ A current-carrying wire (shown in cross section) can be made to “float” in a magnetic field. The current in the wire emerges from the plane of the page, and the magnetic field is directed to the right.

SOLUTION ■ One **Key Idea** is that, because the wire carries a current, a magnetic force \vec{F}^{mag} can act on the wire if we place it in a magnetic field \vec{B} . To balance the downward gravitational force \vec{F}^{grav} on the wire, we want \vec{F}^{mag} to be directed upward (Fig. 29-20).

A second **Key Idea** is that the direction of \vec{F}^{mag} is related to the directions of \vec{B} and the wire’s length vector \vec{L} by Eq. 29-23. Because \vec{L} is directed horizontally (and the current is taken to be positive), Eq. 29-23 and the right-hand rule for cross products tell us that \vec{B} must be horizontal and rightward (in Fig. 29-20) to give the required upward \vec{F}^{mag} .

The magnitude of \vec{F}^{mag} is given by Eq. 29-24 ($|\vec{F}^{\text{mag}}| = |i\vec{L}||\vec{B}|\sin\phi$). Because we want \vec{F}^{mag} to balance \vec{F}^{grav} , we want

$$|i|LB\sin\phi = mg, \quad (29-26)$$

where mg is the magnitude of \vec{F}^{grav} and m is the mass of the wire. We also want the minimal field magnitude B for \vec{F}^{mag} to balance \vec{F}^{grav} . Thus, we need to maximize $\sin\phi$ in Eq. 29-26. To do so, we set $\phi = 90^\circ$, thereby arranging for \vec{B} to be perpendicular to the wire. We then have $\sin\phi = 1$, so Eq. 29-26 yields a magnetic field magnitude of

$$|\vec{B}| = B = \frac{mg}{|i|L\sin\phi} = \frac{(m/L)g}{|i|}. \quad (29-27)$$

We write the result this way because we know m/L , the linear density of the wire. Substituting known data then gives us a magnitude of

$$B = \frac{(46.6 \times 10^{-3} \text{ kg/m})(9.8 \text{ m/s}^2)}{28 \text{ A}} = 1.6 \times 10^{-2} \text{ T}. \quad (\text{Answer})$$

This is about 160 times the strength of Earth’s magnetic field. As stated in the second paragraph of this solution, the right-hand rule tells us that B must point to the right.

29-9 Torque on a Current Loop

Much of the world’s work is done by electric motors. The forces that do this work are magnetic. In principle a direct current motor can be constructed from a single loop of current-carrying wire that is immersed in a magnetic field and is attached to a battery. If the current were to flow through the loop in the same direction all the time, the magnetic field would push on this loop in one direction at one instant of time, but would reverse the direction of the force when the loop was rotated halfway around. We would get a vibration that would quickly damp out. We can, however, get a continuous rotation if we use a connection, called a commutator, that reverses the current direction when the loop has gone halfway around (Fig. 29-21). Then, the force will continue to push the loop in the same direction and the motor will spin. Although many essential details have been omitted, the figure does suggest how the action of a magnetic field on a current loop produces rotary motion. To understand how the dc motor works in detail, we need to understand how a magnetic field can cause a current-carrying wire loop to rotate by exerting a torque on it.

How a Current Loop Can Experience a Torque

Figure 29-22a shows a front view of a rectangular loop of sides a and b . The loop is carrying a current i and is immersed in a uniform magnetic field \vec{B} . We start our consideration of the torque on the loop with a special case in which the plane of the loop is parallel to the magnetic field as shown in Fig. 29-22a.

Let’s use Eq. 29-24 to find the forces on each side of the loop for our special case. For sides 1 and 3 the vector \vec{L} points in the direction of the current and has magnitude a . The angle between \vec{L} and \vec{B} for these is $\phi = 0^\circ$. Thus, the magnitude of the forces acting on this side is

$$F_1^{\text{mag}} = F_3^{\text{mag}} = |i|aB\sin 0^\circ = 0 \text{ N}.$$

FIGURE 29-21 ■ The elements of an electric motor. A rectangular loop of wire, carrying a current and free to rotate about a fixed axis, is placed in a magnetic field. Magnetic forces on the wire produce a torque that rotates it. A commutator reverses the direction of the current every half-revolution so that the torque always acts in the same direction.

FIGURE 29-22 ■ A rectangular loop, of length a and width b and carrying a current i , is located in a uniform magnetic field. A torque $\vec{\tau}$ that is perpendicular to the magnetic field acts on the loop. The angle, ϕ , perpendicular or normal to the plane of the loop and the B -field varies. (a) The plane of the loop is aligned with the magnetic field so that $\phi = 90^\circ$. (b) A perspective drawing of the loop after it has rotated to $\phi = 0^\circ$ due to the torque exerted on it by the magnetic field. (c) A top view of the loop when it is part way between $\phi = 90^\circ$ (part a) and $\phi = 0^\circ$ (part b).

The situation is different for sides 2 and 4. For them, \vec{L} , which has magnitude b , is perpendicular to \vec{B} so $\phi = 90^\circ$. Thus, the forces \vec{F}_2 and \vec{F}_4 have the common magnitude given by

$$F_2^{\text{mag}} = F_4^{\text{mag}} = |i|bB \sin 90^\circ = |i|bB. \quad (29-28)$$

However, since the direction of the current is different on each of these sides, the right-hand rule tells us that these two forces point in opposite directions. The vector \vec{F}_2 points out of the page while the vector \vec{F}_4 points into the page. However, as Fig. 29-22a shows, these two forces do *not* share the same line of action so they *do* produce a net torque. The torque tends to rotate the loop toward an orientation for which the plane of the loop is perpendicular to the direction of the magnetic field \vec{B} . At $\phi = 90^\circ$ that torque has a moment arm of magnitude $a/2$ about the central axis of the loop. The magnitude of the torque due to forces \vec{F}_2 and \vec{F}_4 is then (see Fig. 29-22a),

$$\tau_{90} = \frac{a}{2}F_2 + \frac{a}{2}F_4 = |i|\frac{a}{2}(bB) + |i|\frac{a}{2}(bB) = |i|abB. \quad (29-29)$$

As the coil in Fig. 29-22a starts to rotate, the moment arm between sides 2 and 4 decreases, and it reaches zero when the loop is in the position shown in Fig. 29-22b. In general, the torque on the loop is given by

$$\tau' = |i|abB \sin \phi, \quad (29-30)$$

where ϕ is the smaller angle normal to the area subtended by the loop and the external magnetic field (Fig. 22-22c).

Suppose we replace the single loop of current with a *coil* of N loops, or *turns*. Further, suppose that the turns are wound tightly enough that they can be approximated as all having the same dimensions and lying in a plane. Then the turns form a *flat coil* and a torque $\vec{\tau}'$ with the magnitude found in Eq. 29-29 acts on each of the turns. The total torque on the coil then has magnitude

$$\tau = N\tau' = N|i|AB \sin \phi, \quad (29-31)$$

in which $A(= ab)$ is the area enclosed by the coil. Equation 29-31 holds for all flat coils, no matter what their shape, provided the magnetic field is uniform.

How a DC Motor Works

Consider the operation of a motor like that shown in Fig. 29-21. When the coil is at the point where the plane of the coil is perpendicular to the field direction so $\phi = 0^\circ$, the polarity of the battery is suddenly reversed. Since the coil is accelerated by the initial torque on it, it sails past the point where $\phi = 0^\circ$, and a new torque takes over and continues to rotate the coil in the same direction. This automatic reversal of the current occurs every half cycle and is accomplished with a commutator that electrically connects the rotating coil with the stationary contacts connected to the battery (or other power source).

29-10 The Magnetic Dipole Moment

We can describe the current-carrying coil of the preceding section with a single vector $\vec{\mu}$, its magnetic dipole moment. The direction of the magnetic dipole $\vec{\mu}$ is determined by another right hand rule similar to the one shown in Fig. 29-4. If you wrap your right

hand around the coil in the direction of the positive current, your thumb points in the direction of the magnetic dipole $\vec{\mu}$.

We define the magnitude of $\mu = |\vec{\mu}|$ as

$$\mu = N|i|A \quad (\text{magnetic moment magnitude}), \quad (29-32)$$

in which N is the number of turns in the coil, $|i|$ is the magnitude current through the coil, and A is the area enclosed by each turn of the coil. (Equation 29-32 tells us that the unit of $\vec{\mu}$ is the ampere-square meter.) Using $\vec{\mu}$, we can rewrite Eq. 29-31 for the magnitude of the torque on the coil due to a magnetic field as

$$\tau = |\vec{\mu}||\vec{B}|\sin\phi = \mu B \sin\phi, \quad (29-33)$$

in which ϕ is the smallest angle between the vectors $\vec{\mu}$ and \vec{B} .

We can generalize this to the vector relation

$$\vec{\tau} = \vec{\mu} \times \vec{B}, \quad (29-34)$$

which reminds us very much of the corresponding equation for the torque exerted by an *electric* field on an *electric* dipole—namely, Eq. 23-37:

$$\vec{\tau} = \vec{p} \times \vec{E}.$$

In each case the torque exerted by the external field—either magnetic or electric—is equal to the vector product of the corresponding dipole moment and the field vector.

A magnetic dipole in an external magnetic field has a **magnetic potential energy** that depends on the dipole's orientation in the field. For electric dipoles,

$$U(\theta) = -\vec{p} \cdot \vec{E}.$$

In strict analogy, we can write for the magnetic case

$$U(\theta) = -\vec{\mu} \cdot \vec{B}. \quad (29-35)$$

A magnetic dipole has its lowest energy ($-\mu B \cos\theta = -\mu B$) when its dipole moment $\vec{\mu}$ is lined up with the magnetic field (Fig. 29-23). It has its highest energy ($-\mu B \cos 180^\circ = +\mu B$) when the vector $\vec{\mu}$ is directed opposite the field.

When a magnetic dipole rotates in the presence of a magnetic field from an initial orientation θ_1 to another orientation θ_2 , the work $W_{B \rightarrow \mu}$ done on the dipole by the magnetic field is

$$W_{B \rightarrow \mu} = -\Delta U = -(U_2 - U_1), \quad (29-36)$$

where U_2 and U_1 are calculated with Eq. 29-35. If an external torque acts on the dipole during the change in its orientation, then work $W_{\text{ext} \rightarrow \mu}$ is done on the dipole by the external torque. *If the dipole is stationary* before and after the change in its orientation, then work $W_{\text{ext} \rightarrow \mu}$ is the negative of the work done on the dipole by the field. Thus,

$$W_{\text{ext} \rightarrow \mu} = -W_{B \rightarrow \mu} = U_2 - U_1. \quad (29-37)$$

So far, we have identified only a current-carrying coil as a magnetic dipole. However, a simple bar magnet is also a magnetic dipole, as is a rotating sphere of charge. Earth itself is (approximately) a magnetic dipole. And, most subatomic particles, including the electron, the proton, and the neutron, have magnetic dipole moments. As you will see in Chapter 32, all these quantities can be viewed as current loops. For comparison, some approximate magnetic dipole moments are shown in Table 29-2.

FIGURE 29-23 The orientations of highest and lowest energy of a magnetic dipole in an external magnetic field \vec{B} . In each case, the direction of the current i determines the direction of the magnetic dipole moment $\vec{\mu}$ shown in Fig. 29-23 via the right-hand rule.

TABLE 29-2
Some Magnetic Dipole Moments

A small bar magnet	5 J/T
Earth	8.0×10^{22} J/T
A proton	1.4×10^{-26} J/T
An electron	9.3×10^{-24} J/T

READING EXERCISE 29-5: The figure shows four orientations, at angle θ , of a magnetic dipole moment $\vec{\mu}$ in a magnetic field. Rank the orientations according to (a) the magnitude of the torque on the dipole and (b) the potential energy of the dipole, greatest first.

TOUCHSTONE EXAMPLE 29-5: Coil in an External Magnetic Field

Figure 29-24 shows a circular coil with 250 turns, an area A of $2.52 \times 10^{-4} \text{ m}^2$, and a current of $100 \mu\text{A}$. The coil is at rest in a uniform magnetic field of magnitude $|\vec{B}| = 0.85 \text{ T}$, with its magnetic dipole moment $\vec{\mu}$ initially aligned with \vec{B} .

(a) In Fig. 29-24, what is the direction of the current in the coil?

SOLUTION ■ The **Key Idea** here is to apply the right-hand rule to the coil by curling your fingers around the current in the coil so your right thumb points in the $\vec{\mu}$ direction. Thus, in the wires on the near side of the coil—those we see in Fig. 29-24—the current is from top to bottom.

(b) How much work would the torque applied by an external agent have to do on the coil to rotate it 90° from its initial orientation, so that $\vec{\mu}$ is perpendicular to \vec{B} and the coil is again at rest?

FIGURE 29-24 ■ A side view of a circular coil carrying a current and oriented so that its magnetic dipole moment $\vec{\mu}$ is aligned with magnetic field \vec{B} .

tation, so that $\vec{\mu}$ is perpendicular to \vec{B} and the coil is again at rest?

SOLUTION ■ The **Key Idea** here is that the work $W_{\text{ext} \rightarrow \mu}$ done by the applied torque would be equal to the change in the coil's potential energy due to its change in orientation. From Eq. 29-37 ($W_{\text{ext} \rightarrow \mu} = U_2 - U_1$), we find

$$\begin{aligned} W_{\text{ext} \rightarrow \mu} &= U(90^\circ) - U(0^\circ) \\ &= -\mu B \cos 90^\circ - (-\mu B \cos 0^\circ) = 0 + \mu B \\ &= \mu B. \end{aligned}$$

Substituting for $\vec{\mu}$ from Eq. 29-32 ($\mu = N|i|A$), we find that

$$\begin{aligned} W_{\text{ext} \rightarrow \mu} &= (N|i|AB) \\ &= (250)(100 \times 10^{-6} \text{ A})(2.52 \times 10^{-4} \text{ m}^2)(0.85 \text{ T}) \\ &= 5.356 \times 10^{-6} \text{ J} \approx 5.4 \mu\text{J}. \end{aligned} \quad \text{(Answer)}$$

29-11 The Cyclotron

Physicists have been able to use their understanding of how charged particles behave in magnetic fields to develop devices that can accelerate protons to high speeds. These high-energy protons are extremely useful to scientists for several reasons. Collisions between energetic protons and matter allow them to learn about the nature of atomic and subatomic particles. High-energy protons and ions can also be used to create new radioactive elements. In addition, physicians can use high-energy protons to destroy tumors in cancer patients. In 1939, E. O. Lawrence was awarded a Nobel Prize in physics for the development of the cyclotron—the first of many magnetic accelerators capable of accelerating protons, ions, and electrons.

The principles that govern the operation of the cyclotron are quite simple. Figure 29-9 showed experimental evidence that a charged particle projected into an evacuated chamber perpendicular to a uniform magnetic field moves in a circular orbit. We used the magnetic force law (Eq. 29-2) to derive the frequency of revolution of the orbit. In Eq. 29-10 we found that $f = |q|B/2\pi m$. This is known as the cyclotron frequency, and its derivation had a rather surprising outcome. The frequency, f , with which a charged particle moves in its circular orbit depends only on its charge, its mass, and the magnetic field strength. So f is independent of speed. This is because a particle with low speed moves in a small circle whereas one with a higher speed moves in a larger circle. The particle speeds and orbital sizes are related in such a way that all charged particles take the same amount of time to make a revolution in a uniform magnetic field. (At least this is true for all speeds that are well below the speed

of light.) Lawrence used the fact that the orbital frequency of a charged particle does not depend on its speed in the design of the cyclotron.

The original cyclotron was first used to accelerate protons. It consisted of two hollow semicircular disks shaped more or less like a capital D as shown in Fig. 29-25. In early cyclotrons, the dees, as they are called, were made of copper sheeting. The diameter of a dee was only about one meter. The dees were then placed in a vacuum chamber and oriented perpendicular to a large uniform magnetic field having a strength of a few teslas. There was a small gap between them. The dees were connected to an electrical oscillator that can alternate the potential difference across the gap between them at exactly the same frequency as an orbiting proton would have in the magnetic field. This arrangement is shown in Fig. 29-26.

To begin the operation of the original cyclotron, an oscillator was set at the cyclotron frequency. Then hydrogen gas was leaked into the vacuum chamber. Next a beam of high-energy electrons was injected into the center of the chamber so that other electrons were knocked out of hydrogen atoms. This ionization process produced protons. At a time when the oscillator caused the left dee to be at a lower potential than the right dee, the proton received a kick in the direction of the right dee. It moved into the right dee where the electric field was zero. However, the magnetic field penetrated the dee and caused the proton to start into a small, low-speed orbit. Only half a cycle later the proton reached the gap again. Since the oscillator was tuned to the cyclotron frequency, the potential of the right dee was now lower than that of the left dee and the proton got another kick as it crossed the gap. The proton then proceeded into another circular orbit that involved a larger speed and radius, given by Eq. 29-8,

$$r = \frac{mv}{|q|B}.$$

When the proton reached the gap again it completed one full cycle but so had the alternating voltage oscillator. Thus the proton got another kick. This process continued, with the circulating proton always being in step with the oscillations of the dee potential. When the proton finally spiraled out to the edge of the dee system, a deflector plate sent it out through a portal. The path of such a proton is shown in Fig. 29-27.

Recall that the key to the operation of the cyclotron is that the frequency f at which the proton circulates in the field (and that does not depend on its speed) must be equal to the fixed frequency f_{osc} of the electrical oscillator, or

$$f = f_{\text{osc}} \quad (\text{resonance condition}). \quad (29-38)$$

This *resonance condition* says that, if the energy of the circulating proton is to increase, energy must be fed to it at a frequency f_{osc} that is equal to the natural frequency f at which the proton circulates in the magnetic field.

Combining Eqs. 29-10 and 29-38 allows us to write the resonance condition as

$$|q|B = 2\pi m f_{\text{osc}}. \quad (29-39)$$

For the proton, q and m are fixed. The oscillator (we assume) is designed to work at a single fixed frequency f_{osc} . We can then either “tune” the cyclotron by varying either \vec{B} or f_{osc} until Eq. 29-39 is satisfied. Then many protons can circulate through the magnetic field and emerge as a beam.

If the cyclotron is powerful enough to accelerate protons, electrons, or ions to speeds close to that of light, relativistic effects come into play. In such cases the simple resonance condition between orbital and oscillator frequencies no longer hold. More sophisticated magnetic field-based high-energy accelerators called synchrotrons and betatrons have been designed. We introduce relativistic effects in Chapter 38 where we discuss special relativity.

FIGURE 29-25 Cyclotron dees are hollow semicircular metal containers that are open along their diameters.

FIGURE 29-26 Cutaway view of dees placed between the poles of a large electromagnet. The dotted line shows the plane in which the paths of the particles orbit.

FIGURE 29-27 Top view of dees showing the path of a charged particle beam in a cyclotron. Each time the particle passes through the gap three things happen: (1) the particle gets a kick and is accelerated to a higher speed, (2) the oscillator changes the sign of the gap’s potential difference, and (3) the particle goes into a new semicircular orbit with a larger radius than before.

TOUCHSTONE EXAMPLE 29-6: Cyclotron

Suppose a cyclotron is operated at an oscillator frequency of 12 MHz and has a dee radius $R = 53$ cm.

(a) What is the magnitude of the magnetic field needed for deuterons to be accelerated in the cyclotron? A deuteron is the nucleus of deuterium, an isotope of hydrogen. It consists of a proton and a neutron and thus has the same charge as a proton. Its mass is $m = 3.34 \times 10^{-27}$ kg.

SOLUTION ■ The **Key Idea** here is that, for a given oscillator frequency f_{osc} , the magnetic field magnitude B required to accelerate any particle in a cyclotron depends on the ratio m/q of mass to charge for the particle, according to Eq. 29-39. For deuterons and the oscillator frequency $f_{\text{osc}} = 12$ MHz, we find

$$B = \frac{2\pi m f_{\text{osc}}}{q} = \frac{(2\pi)(3.34 \times 10^{-27} \text{ kg})(12 \times 10^6 \text{ s}^{-1})}{1.60 \times 10^{-19} \text{ C}}$$

$$= 1.57 \text{ T} \approx 1.6 \text{ T}. \quad (\text{Answer})$$

Note that, to accelerate protons, B would have to be reduced by a factor of 2, providing the oscillator frequency remained fixed at 12 MHz.

(b) What is the resulting kinetic energy of the deuterons?

SOLUTION ■ One **Key Idea** here is that the kinetic energy $\frac{1}{2}mv^2$ of a deuteron exiting the cyclotron is equal to the kinetic energy it had just before exiting, when it was traveling in a circular path with a radius approximately equal to the radius R of the cyclotron dees. A second **Key Idea** is that we can find the speed v of the deuteron in that circular path with Eq. 29-8 ($r = mv/|q|B$). Solving that equation for v , substituting R for r , and then substituting known data, we find

$$v = \frac{RqB}{m} = \frac{(0.53 \text{ m})(1.60 \times 10^{-19} \text{ C})(1.57 \text{ T})}{3.34 \times 10^{-27} \text{ kg}}$$

$$= 3.99 \times 10^7 \text{ m/s}.$$

This speed corresponds to a kinetic energy of

$$K = \frac{1}{2}mv^2$$

$$= \frac{1}{2}(3.34 \times 10^{-27} \text{ kg})(3.99 \times 10^7 \text{ m/s})^2 \quad (\text{Answer})$$

$$= 2.7 \times 10^{-12} \text{ J},$$

or about 17 MeV.

Problems

SEC. 29-3 ■ DEFINING A MAGNETIC FIELD \vec{B}

1. Alpha Particle An alpha particle travels at a velocity \vec{v} of magnitude 550 m/s through a uniform magnetic field \vec{B} of magnitude 0.045 T. (An alpha particle has a charge of $+3.2 \times 10^{-19}$ C and a mass of 6.6×10^{-27} kg.) The angle between \vec{v} and \vec{B} is 52° . What are the magnitudes of (a) the force \vec{F}^{mag} acting on the particle due to the field and (b) the acceleration of the particle due to \vec{F}^{mag} ? (c) Does the speed of the particle increase, decrease, or remain equal to 550 m/s?

2. TV Camera An electron in a TV camera tube is moving at 7.20×10^6 m/s in a magnetic field of strength 83.0 mT. (a) Without knowing the direction of the field, what can you say about the greatest and least magnitudes of the force acting on the electron due to the field? (b) At one point the electron has an acceleration of magnitude 4.90×10^{14} m/s². What is the angle between the electron's velocity and the magnetic field?

3. Proton Traveling A proton traveling at 23.0° with respect to the direction of a magnetic field of strength 2.60 mT experiences a magnetic force of 6.50×10^{-17} N. Calculate (a) the proton's speed and (b) its kinetic energy in electron-volts.

4. Force on Charges An electron that has velocity

$$\vec{v} = (2.0 \times 10^6 \text{ m/s})\hat{i} + (3.0 \times 10^6 \text{ m/s})\hat{j}$$

moves through the magnetic field $\vec{B} = (0.030 \text{ T})\hat{i} - (0.15 \text{ T})\hat{j}$. (a) Find the force on the electron. (b) Repeat your calculation for a proton having the same velocity.

5. Television Tube Each of the electrons in the beam of a television tube has a kinetic energy of 12.0 keV. The tube is oriented so that the electrons move horizontally from geomagnetic south to geomagnetic north. The vertical component of Earth's magnetic field points down and has a magnitude of $55.0 \mu\text{T}$. (a) In what direction will the beam deflect? (b) What is the magnitude of the acceleration of a single electron due to the magnetic field? (c) How far will the beam deflect in moving 20.0 cm through the television tube?

SEC. 29-5 ■ A CIRCULATING CHARGED PARTICLE

6. Accelerated from Rest An electron is accelerated from rest by a potential difference of 350 V. It then enters a uniform magnetic field of magnitude 200 mT with its velocity perpendicular to the field. Calculate (a) the speed of the electron and (b) the radius of its path in the magnetic field.

7. Field Perpendicular to Beam A uniform magnetic field is applied perpendicular to a beam of electrons moving at 1.3×10^6 m/s. What is the magnitude of the field if the electrons travel in a circular arc of radius 0.35 m?

8. Heavy Ions Physicist S. A. Goudsmit devised a method for measuring the masses of heavy ions by timing their periods of revolution in a known magnetic field. A singly charged ion of iodine makes 7.00 rev in a field of 45.0 mT in 1.29 ms. Calculate its mass, in atomic mass units. (Actually, the method allows mass measurements to be carried out to much greater accuracy than these approximate data suggest.)

9. Kinetic Energy An electron with kinetic energy 1.20 keV circles in a plane perpendicular to a uniform magnetic field. The orbit radius is 25.0 cm. Find (a) the speed of the electron, (b) the magnetic field, (c) the frequency, and (d) the period of the motion.

10. Circular Path An alpha particle ($q = +2e$, $m = 4.00$ u) travels in a circular path of radius 4.50 cm in a uniform magnetic field with magnitude $B = 1.20$ T. Calculate (a) its speed, (b) its period of revolution, (c) its kinetic energy in electron-volts, and (d) the potential difference through which it would have to be accelerated to achieve this energy.

11. Frequency of Revolution (a) Find the frequency of revolution of an electron with an energy of 100 eV in a uniform magnetic field of magnitude $35.0 \mu\text{T}$. (b) Calculate the radius of the path of this electron if its velocity is perpendicular to the magnetic field.

12. Source of Electrons A source injects an electron of speed $v = 1.5 \times 10^7$ m/s into a uniform magnetic field of magnitude $B = 1.0 \times 10^{-3}$ T. The velocity of the electron makes an angle $\theta = 10^\circ$ with the direction of the magnetic field. Find the distance d from the point of injection at which the electron next crosses the field line that passes through the injection point.

13. Beam of Electrons A beam of electrons whose kinetic energy is K emerges from a thin-foil “window” at the end of an accelerator tube. There is a metal plate a distance d from this window and perpendicular to the direction of the emerging beam (Fig. 29-28). Show that we can prevent the beam from hitting the plate if we apply a uniform magnetic field \vec{B} such that its magnitude is

FIGURE 29-28 ■ Problem 13.

$$B \geq \sqrt{\frac{2mK}{e^2 d^2}},$$

in which m and e are the electron mass and charge. How should \vec{B} be oriented?

14. Proton, Deuteron, Alpha A proton, a deuteron ($q = +e$, $m = 2.0$ u), and an alpha particle ($q = +2e$, $m = 4.0$ u) with the same kinetic energies enter a region of uniform magnetic field \vec{B} , moving perpendicular to \vec{B} . Compare the radii of their circular paths.

15. Nuclear Experiment In a nuclear experiment a proton with kinetic energy 1.0 MeV moves in a circular path in a uniform magnetic field. What energy must (a) an alpha particle ($q = +2e$, $m = 4.0$ u) and (b) a deuteron ($q = +e$, $m = 2.0$ u) have if they are to circulate in the same circular path?

16. Uniform Magnetic Field A proton of charge $+e$ and mass m enters a uniform magnetic field $\vec{B} = B\hat{i}$ with an initial velocity $\vec{v} = v_{1x}\hat{i} + v_{1y}\hat{j}$. Find an expression in unit-vector notation for its velocity \vec{v} at any later time t .

17. Mass Spectrometer A certain commercial mass spectrometer (see Touchstone Example 29-2) is used to separate uranium ions of mass 3.92×10^{-25} kg and charge 3.20×10^{-19} C from related species. The ions are accelerated through a potential difference of 100 kV and then pass into a uniform magnetic field, where they are bent in a path of radius 1.00 m. After traveling through 180° and passing through a slit of width 1.00 mm and height 1.00 cm, they are collected in a cup. (a) What is the magnitude of the (perpendicular)

magnetic field in the separator? If the machine is used to separate out 100 mg of material per hour, calculate (b) the current of the desired ions in the machine and (c) the thermal energy produced in the cup in 1.00 h.

18. Half Circle In Fig 29-29, a charged particle moves into a region of uniform magnetic field B , goes through half a circle, and then exits that region. The particle is either a proton or an electron (you must decide which). It spends 130 ns within the region.

FIGURE 29-29 ■ Problem 18.

(a) What is the magnitude $|\vec{B}|$? (b) If the particle is sent back through the magnetic field (along the same initial path) but with 2.00 times its previous kinetic energy, how much time does it spend within the field?

19. Positron A positron with kinetic energy 2.0 keV is projected into a uniform magnetic field \vec{B} of magnitude 0.10 T, with its velocity vector making an angle of 89° with \vec{B} . Find (a) the period, (b) the pitch p , and (c) the radius r of its helical path.

20. Neutral Particle A neutral particle is at rest in a uniform magnetic field \vec{B} . At time $t = 0$ it decays into two charged particles, each of mass m . (a) If the charge of one of the particles is $+q$, what is the charge of the other? (b) The two particles move off in separate paths, both of which lie in the plane perpendicular to \vec{B} . At a later time the particles collide. Express the time from decay until collision in terms of m , $|\vec{B}|$, and $|q|$.

SEC. 29-6 ■ CROSSED FIELDS: DISCOVERY OF THE ELECTRON

21. Horizontal Motion An electron with kinetic energy 2.5 keV moves horizontally into a region of space in which there is a downward-directed uniform electric field of magnitude 10 kV/m. (a) What are the magnitude and direction of the (smallest) uniform magnetic field that will cause the electron to continue to move horizontally? Ignore the gravitational force, which is small. (b) Is it possible for a proton to pass through the combination of fields undeflected? If so, under what circumstances?

22. At One Instant A proton travels through uniform magnetic and electric fields. The magnetic field is $\vec{B} = (-2.5 \text{ mT})\hat{i}$. At one instant the velocity of the proton is $\vec{v} = (2000 \text{ m/s})\hat{j}$. At that instant, what is the magnitude of the net force acting on the proton if the electric field is (a) $(4.0 \text{ V/m})\hat{k}$ and (b) $(4.0 \text{ V/m})\hat{i}$?

23. Potential Difference An electron is accelerated through a potential difference of 1.0 kV and directed into a region between two parallel plates separated by 20 mm with a potential difference of 100 V between them. The electron is moving perpendicular to the electric field of the plates when it enters the region between the plates. What magnitude of uniform magnetic field, applied perpendicular to both the electron path and the electric field, will allow the electron to travel in a straight line?

24. Electric and Magnetic Field An electric field of magnitude 1.50 kV/m and a magnetic field of 0.400 T act on a moving electron to produce no net force. (a) Calculate the minimum speed $|\vec{v}|$ of the electron. (b) Draw a set of vectors \vec{E} , \vec{B} , and \vec{v} that could yield the net force.

25. Ion Source An ion source is producing ions of ${}^6\text{Li}$ (mass = 6.0 u), each with a charge of $+e$. The ions are accelerated by a

potential difference of 10 kV and pass horizontally into a region in which there is a uniform vertical magnetic field of magnitude $|\vec{B}| = 1.2$ T. Calculate the strength of the smallest electric field, to be set up over the same region, that will allow the ${}^6\text{Li}$ ions to pass through undeflected.

26. Initial Velocity An electron has an initial velocity of $(12.0 \text{ km/s})\hat{j} + (15.0 \text{ km/s})\hat{k}$ and a constant acceleration of $(2.00 \times 10^{12} \text{ m/s}^2)\hat{i}$ in a region in which uniform electric and magnetic fields are present. If $\vec{B} = (400 \mu\text{T})\hat{i}$, find the electric field \vec{E} .

SEC. 29-7 ■ THE HALL EFFECT

27. Field Ratio (a) In Fig 29-14, show that the ratio of the magnitudes of the Hall electric field \vec{E} to the electric field \vec{E}^{curr} responsible for moving charge (the current) along the length of the strip is

$$\frac{E}{E^{\text{curr}}} = \frac{B}{ne\rho}$$

where ρ is the resistivity of the material and n is the number density of the charge carriers and e is the amount of charge on the electron. (b) Compute this ratio numerically for Problem 28. (See Table 26-2.)

28. Strip of Copper A strip of copper $150 \mu\text{m}$ wide is placed in a uniform magnetic field \vec{B} of magnitude 0.65 T, with \vec{B} perpendicular to the strip. A current $i = 23$ A is then sent through the strip such that a Hall potential difference ΔV appears across the width of the strip. Calculate ΔV . (The number of charge carriers per unit volume for copper is 8.47×10^{28} electrons/ m^3 .)

29. Metal Strip A metal strip 6.50 cm long, 0.850 cm wide, and 0.760 mm thick moves with constant velocity \vec{v} through a uniform magnetic field of magnitude $|\vec{B}| = 1.20$ mT directed perpendicular to the strip, as shown in Fig. 29-30. A potential difference of $3.90 \mu\text{V}$ is measured between points x and y across the strip. Calculate the speed $|\vec{v}|$.

FIGURE 29-30 ■ Problem 29.

SEC. 29-8 ■ MAGNETIC FORCE ON A CURRENT-CARRYING WIRE

30. A Wire Carries a Current A wire 1.80 m long carries a current of 13.0 A and makes an angle of 35.0° with a uniform magnetic field of magnitude $B = 1.50$ T. Calculate the magnitude of the magnetic force on the wire.

31. Horizontal Conductor A horizontal conductor that is part of a power line carries a current of 5000 A from south to north. The magnitude of the Earth's magnetic field is $60.0 \mu\text{T}$. The field is directed toward the north and is inclined downward at 70° to the horizontal. Find the magnitude and direction of the magnetic force on 100 m of the conductor due to Earth's field.

32. Along the x Axis A wire 50 cm long lying along the x axis carries a current of 0.50 A in the positive x direction. It passes through a magnetic field $\vec{B} = (0.0030 \text{ T})\hat{j} + (0.0100 \text{ T})\hat{k}$. Find the magnetic force on the wire.

33. A Wire of Length A wire of 62.0 cm length and 13.0 g mass is suspended by a pair of flexible leads in a uniform magnetic field of magnitude 0.440 T (Fig. 29-31). What are the magnitude and direction of the current required to remove the tension in the supporting leads?

FIGURE 29-31 ■ Problem 33.

34. Electric Train Consider the possibility of a new design for an electric train. The engine is driven by the force on a conducting axle due to the vertical component of Earth's magnetic field. To produce the force, current is maintained down one rail, through a conducting wheel, through the axle, through another conducting wheel, and then back to the source via the other rail. (a) What amount of current is needed to provide a modest force of magnitude 10 kN? Take the vertical component of Earth's field to be $10 \mu\text{T}$ and the length of the axle to be 3.0 m. (b) At what rate would electric energy be lost for each ohm of resistance in the rails? (c) Is such a train totally or just marginally unrealistic?

35. Copper Rod A 1.0 kg copper rod rests on two horizontal rails 1.0 m apart and carries a current of 50 A from one rail to the other. The coefficient of static friction between rod and rails is 0.60. What is the magnitude of the smallest magnetic field (not necessarily vertical) that would cause the rod to slide?

SEC. 29-9 ■ TORQUE ON A CURRENT LOOP

36. Current Loop A single-turn current loop, carrying a current of 4.00 A, is in the shape of a right triangle with sides 50.0, 120, and 130 cm. The loop is in a uniform magnetic field of magnitude 75.0 mT whose direction is parallel to the current in the 130 cm side of the loop. (a) Find the magnitude of the magnetic force on each of the three sides of the loop. (b) Show that the total magnetic force on the loop is zero.

37. Rectangular Coil Figure 29-32 shows a rectangular 20-turn coil of wire, of dimensions 10 cm by 5.0 cm. It carries a current of 0.10 A and is hinged along one long side. It is mounted in the xy plane, at 30° to the direction of a uniform magnetic field of magnitude 0.50 T. Find the magnitude and direction of the torque acting on the coil about the hinge line.

FIGURE 29-32 ■ Problem 37.

38. Arbitrarily Shaped Coil Prove that the relation $\tau = N|i|AB \sin \phi$ (Eq. 29-31) holds for closed loops of arbitrary shape and not only for rectangular loops as in Fig. 29-22. (*Hint:* Replace the loop of arbitrary shape with an assembly of adjacent long, thin, approximately rectangular loops that are nearly equivalent to the loop of arbitrary shape as far as the distribution of current is concerned.)

39. Show That A length L of wire carries a current i . Show that if the wire is formed into a circular coil, then the magnitude of the maximum torque in a given magnetic field is developed when the coil has one turn only. Also show that maximum torque has the magnitude $\tau = L^2 i B / 4\pi$.

40. Zero Total Force A closed wire loop with current i is in a uniform magnetic field \vec{B} , with the plane of the loop at angle θ to the direction of \vec{B} . Show that the total magnetic force on the loop is zero. Does your proof also hold for a nonuniform magnetic field?

41. Wire Ring Figure 29-33 shows a wire ring of radius a that is perpendicular to the general direction of a radially symmetric, diverging magnetic field. The magnetic field at the ring is everywhere of the same magnitude $|\vec{B}|$, and its direction at the ring everywhere makes an angle θ with a normal to the plane of the ring. The twisted lead wires have no effect on the problem. Find the magnitude and direction of the force the field exerts on the ring if the ring carries a positive current i .

FIGURE 29-33 ■ Problem 41.

42. Maximum Torque A particle of charge q moves in a circular wire loop of radius a with speed $|\vec{v}|$. Find the maximum torque exerted on the loop by a uniform magnetic field of magnitude $|\vec{B}|$.

43. Wooden Cylinder Figure 29-34 shows a wooden cylinder with mass $m = 0.250$ kg and length $L = 0.100$ m, with $N = 10.0$ turns of wire wrapped around it longitudinally, so that the plane of the wire coil contains the axis of the cylinder. Also the plane of the coil is parallel to the inclined plane. There is a vertical, uniform magnetic field of magnitude 0.500 T. What is the least amount of current $|i|$ through the coil that will prevent the cylinder from rolling down a plane inclined at an angle θ to the horizontal?

FIGURE 29-34 ■ Problem 43.

SEC. 29-10 ■ THE MAGNETIC DIPOLE MOMENT

44. Earth's Moment The magnitude of magnetic dipole moment of Earth is 8.00×10^{22} J/T. Assume that this is produced by charges flowing in Earth's molten outer core. If the radius of their circular path is 3500 km, calculate the amount of current associated with each moving charge.

45. Calculate the Current A circular coil of 160 turns has a radius of 1.90 cm. (a) Calculate the current that results in a magnetic dipole moment of 2.30 A \cdot m². (b) Find the maximum magnitude of torque that the coil, carrying this current, can experience in a uniform 35.0 mT magnetic field.

46. Moment and Torque A circular wire loop whose radius is 15.0 cm carries an amount of current of 2.60 A. It is placed so that the normal to its plane makes an angle of 41.0° with a uniform magnetic field of magnitude 12.0 T. (a) Calculate the magnitude of the

magnetic dipole moment of the loop. (b) What is the magnitude of torque that acts on the loop?

47. Right Triangle A current loop, carrying an amount of current of 5.0 A, is in the shape of a right triangle with sides 30 , 40 , and 50 cm. The loop is in a uniform magnetic field of magnitude 80 mT whose direction is parallel to the current in the 50 cm side of the loop. Find the magnitude of (a) the magnetic dipole moment of the loop and (b) the torque on the loop.

48. Wall Clock A stationary circular wall clock has a face with a radius of 15 cm. Six turns of wire are wound around its perimeter; the wire carries a current of 2.0 A in the clockwise direction. The clock is located where there is a constant, uniform external magnetic field of magnitude 70 mT (but the clock still keeps perfect time). At exactly $1:00$ P.M., the hour hand of the clock points in the direction of the external magnetic field. (a) After how many minutes will the minute hand point in the direction of the torque on the winding due to the magnetic field? (b) Find the torque magnitude.

FIGURE 29-35 ■ Problem 49.

49. Concentric Loops Two concentric, circular wire loops, of radii 20.0 and 30.0 cm, are located in the xy plane; each carries a clockwise current of 7.00 A (Fig. 29-35). (a) Find the magnitude of the net magnetic dipole moment of this system. (b) Repeat for reversed current in the inner loop.

50. ABCDEFA Figure 29-36 shows a current loop $ABCDEFA$ carrying a current $i = 5.00$ A. The sides of the loop are parallel to the coordinate axes, with $AB = 20.0$ cm, $BC = 30.0$ cm, and $FA = 10.0$ cm. Calculate the magnitude and direction of the magnetic dipole moment of this loop. (Hint: Imagine equal and opposite currents i in the line segment AD ; then treat the two rectangular loops $ABCD$ and $ADEFA$.)

FIGURE 29-36 ■ Problem 50.

51. Circular Loop A circular loop of wire having a radius of 8.0 cm carries a current of 0.20 A. A vector of unit length and parallel to the dipole moment $\vec{\mu}$ of the loop is given by $0.60\hat{i} - 0.80\hat{j}$. If the loop is located in a uniform magnetic field given by $\vec{B} = (0.25 \text{ T})\hat{i} + (0.30 \text{ T})\hat{k}$, find (a) the torque on the loop (in unit-vector notation) and (b) the magnetic potential energy of the loop.

Additional Problems

52. Permanent Magnet You can observe that a permanent magnet can exert forces on moving charges or currents. (a) If a magnet exerts

a force on a moving charge, would the magnet experience any forces? Explain. (b) In the case of the gravitational or electrostatic

interaction between two objects, each object has a common property, such as mass in the case of gravitational interaction or excess charge in the case of the electrostatic interaction. A permanent magnet and a moving electron seem very different. Can you think of any way that they might have a common property? Explain.

53. U-Shaped Magnet An electron having a velocity of magnitude v enters a region between the poles of a U-shaped magnet. This region has a uniform magnetic field, \vec{B} , pointing out of the paper in the positive z direction as shown in Fig. 29-37.

FIGURE 29-37 Problem 53.

(a) If the magnetic field points out of the paper, where is the north pole of the magnet—in front of or behind the image shown? (b) Use the right-hand rule to find the direction of force on the electron as it passes into the region where the magnetic field is uniform. (c) Sketch the path of the electron, assuming that the magnetic field is relatively weak. (d) If the speed of the electron is 4.79×10^6 m/s and the magnitude of the magnetic field is 0.234 T, what is the magnitude of the force on the electron?

54. A Velocity Selector A group of physicists at Argonne National Laboratory in Illinois wants to bombard metals with monoenergetic beams of alpha particles to study radiation damage. (Alpha particles are helium nuclei, which consist of two neutrons and two protons and thus have a net charge of $+2e$ where e is the amount of the charge on the electron.) They have managed to create a beam of alpha particles from the decay of radioactive elements, but some of the alpha particles lose energy as they collide with other atoms in the source. As a new physicist assigned to the group you have been asked to use a velocity selector to select only the alpha particles in the beam that are close to one velocity and get rid of the others. The velocity selector consists of: (1) a power supply capable of delivering large potential differences between capacitor plates and (2) a large permanent magnet that has a uniform magnetic field perpendicular to the beam. The setup for the velocity selector is shown in Fig. 29-38. The direction of the B-field is out of the paper. Your magnet has a field of 0.22 T and the capacitor plates have a spacing of 2.5 cm. You are asked to figure out how the velocity selector works and then tell your group what voltage to put across the capacitor plates to select a velocity of 4.2×10^6 m/s.

(a)

FIGURE 29-38a Problem 54.

This is your first job and you feel overwhelmed by the assignment, but you calm down and begin to analyze the situation one step at a time. You come up with the following:

(a) The magnet is oriented so its magnetic field is out of the paper in the diagram you are given, so you use the right-hand rule to determine the direction of the magnetic force on an alpha particle passing from left to right into the magnetic field. What direction did you come up with for the force?

FIGURE 29-38b Enlarged view of the region between the poles of the magnet showing a single alpha particle having a speed v entering the region of uniform magnetic field.

(b) You realize that by using $\vec{F}^{\text{mag}} = q\vec{v} \times \vec{B}$, you can calculate the magnitude of force on an alpha particle moving at speed v just as it enters the uniform magnetic field as a function of the charge on the alpha particle and the magnitude of the magnetic field B . What is the expression for the magnitude of the force in terms of e , v , and B ?

(c) You realize that you might be able to put just the right voltage across the two capacitor plates so that the electrical force on a given alpha particle will be equal in magnitude and opposite in direction to the Lorentz magnetic force. Then any alpha particles with just the right velocity will pass straight through the poles of the magnet without being deflected. First you think about whether the voltage on the upper capacitor plate should be positive or negative to give a canceling force. What do you decide?

(d) Next you realize that if you know the electric field between the plates and the charge on the alpha particle then you can compute the electrical force on it. What is the relationship between the electrical force \vec{F}^{elec} , charge, q , and electric field \vec{E} ?

(e) Finally, you use the fact that the magnitude of the electric field between capacitor plates is given by $E = |\Delta V|/d$ where d is the spacing between the plates. Show that the voltage needed to have the electrical force and the magnetic force be “equal and opposite” can be calculated using the equation $|\Delta V| = vBd$. Calculate the voltage needed.

55. Region A—Region B

Figure 29-39 shows a charged particle that is moving in the positive x direction when it encounters region A with a uniform magnetic field. Its path is bent in a half-circle and then moves into region B also with a uniform magnetic field. The particle undergoes another half revolution.

FIGURE 29-39 Problem 55.

Finally it passes between two charged capacitor plates and is deflected downward in the negative y direction.

- (a) Is the charge positive or negative? Explain.
 (b) What is the direction of the magnetic field in region A? Explain.
 (c) What is the direction of the magnetic field in region B? Explain.
 (d) Which region has the larger magnetic field, A or B? Explain.

56. A Mass Spectrometer It is possible to accelerate ions to a known kinetic energy in an electric field. Sometimes chemists and physicists do this as part of a method to identify the chemical elements present in a beam of ions by determining the mass of each ion. This can be done by bending the ion beam in a uniform magnetic field and measuring the radius of the semicircular path each ion takes. A device that does this is called a mass spectrometer. A schematic of a mass spectrometer is shown in Fig. 29-40.

Boron is the fifth element in the periodic table so it always has 5 protons. However, different isotopes of boron have 3, 5, 6, 7, or 8 neutrons in addition to the 5 protons to make up boron-8, boron-10, boron-11 and so on. As a research chemist for the Borax Company you have been asked

FIGURE 29-40 ■ Problem 56.

to use a mass spectrometer to determine the relative abundance of different isotopes of boron in a sample of boron obtained from a mine near Death Valley in California. You decide to accelerate a beam of singly charged boron ions (i.e., those that have lost one of their orbital electrons). You use an accelerating potential difference of -2.68×10^3 volts. The boron beam then enters a uniform magnetic field you set up to have a magnetic flux density of 0.182 T in a direction perpendicular to the direction of the boron beam. You observe two bright spots on your photographic plate with the spot corresponding to a radius of 13.0 cm having four times the intensity of the one corresponding to a radius of 13.6 cm. There are very faint spots at 11.6 cm, 14.2 cm, and 14.8 cm. Which isotope of boron has approximately 80% abundance? Which one has about 20% abundance? Which ones are present in only trace amounts? Please show all your reasoning and calculations. *Hints:* (1) An atomic mass unit is given by 1.66×10^{-27} kg, which is close to the mass of the proton and neutron. (2) Find the velocity of each isotope of boron in meters per second just after it has been accelerated by the potential difference of -2.68×10^3 volts. (3) It is helpful to do the calculations for each of the five isotopes on a spreadsheet.

57. Bubble Chamber Tracks Energetic gamma rays like those coming from outer space can disappear near a heavy nucleus producing a rapidly moving pair of particles consisting of an electron and a positron. (A positron is a small positively charged particle that has the same mass and amount of charge as an electron). This process is called pair production. A device called a bubble chamber allows one to observe the path taken by electron-positron pairs produced by gamma rays. The study of bubble chamber tracks in the presence of magnetic fields has revealed a great deal about high-energy gamma rays, the processes of pair production, and the loss of

energy by electrons and positrons. A sample bubble chamber track is shown in Fig. 29-41.

(a) If the magnetic field is uniform pointing into the paper, which trajectory (the upper one or the lower one) shows the motion of the positron? Explain your reasoning. (b) In which part of the spiral does the positron have the greatest energy—the large radius part or the small radius part? Explain the reasons for your answer. (c) Is the electron moving faster, slower, or at the same speed as the positron at the point in time when the two particles are created? Cite the evidence for your answer. (d) Suppose the bubble chamber photograph in Fig. 29-41 is an enlargement of the actual event so that the length L is actually only 2.4×10^{-3} m. Show that the radius of curvature of the electron path just after the electron is created is approximately 0.8×10^{-3} m. *Hint:* Measure L in picture units to find a scale factor and then measure the appropriate feature of the electron path in picture units and use the scale factor to find R in meters. (e) Use the Lorentz force law and the expression for centripetal force to find the equation relating the speed of the electron to B , R , e , and m . (f) Suppose the magnitude of the magnetic field in the bubble chamber is $B = 0.54$ T. Calculate the approximate speed of the electron when it is first created in the bubble chamber.

FIGURE 29-41 ■ Problem 57.

58. Three Force Fields We have studied three long-range forces: gravity, electricity, and magnetism. Compare and contrast these three forces giving at least one feature that all three forces have in common, and at least one feature that distinguishes each force.

59. Comparing \vec{E} and \vec{B} Fields We have studied two fields: electric and magnetic. Explain why we introduce the idea of field, and compare and contrast the electric and magnetic fields. In your comparison, be certain to discuss at least one similarity and one difference.

60. Anti-matter Ion Cosmic Rays An international consortium is presently building a device to look for anti-matter nuclei in cosmic rays to help us decide whether there are galaxies made of anti-matter. Anti-matter is just like ordinary matter except the basic particles (anti-protons and anti-electrons) have opposite charge from ordinary matter counterparts. Anti-protons are negative, and anti-electrons (positrons) are positive.

A schematic of the device is shown in Fig. 29-42. A cosmic ray—say, a carbon nucleus or an anti-carbon nucleus—enters the device at the left where its position and velocity are measured. It then passes through a (reasonably uniform) magnetic field. Its path is bent in one direction if its charge is positive and in the opposite direction if its charge is negative. Its deflection is measured as it goes out of the device.

- (a) In Fig. 29-42, what is the direction of the magnetic field? How do you know?
 (b) Which path is followed by each particle in the device? How do you know?
 (c) If you were given the magnetic field, B , the size of the device, D , the amount of charge on the incoming particle, q , and the mass of the incoming particle, M , would this be enough to calculate the displacement of the charge, d ? If so, describe briefly how you would

FIGURE 29-42 ■ Problem 60.

do it (but don't do it). If not, explain what additional information you would need (but don't estimate it).

61. Magnets and Charge A bar magnet is hung from a string through its center as shown in Fig. 29-43. A charged rod is brought up slowly into the position shown. In what direction will the magnet tend to rotate? Suppose the charged rod is replaced by a bar magnet with the north pole on top. In what direction will the magnet tend to rotate? Is there a difference between what happens to the hanging magnet in the two situations? Explain why you either do or do not think so.

FIGURE 29-43 ■ Problem 61.

* C14 is a radioactive isotope of carbon that behaves chemically almost identically to its more common but slightly lighter sibling, C12. The amount of C14 in the atmosphere stays about constant since it is being produced continually by cosmic rays. Once carbon from the air is bound into an organic substance, the C14 will decay with half of them vanishing every 5730 years. The ratio of C14 to C12 in an organic substance therefore tells how long ago it died.

62. Buying a Mass Spectrometer* You are assigned the task of working with a desktop-sized magnetic spectrometer for the purpose of measuring the ratio of C^{12} to C^{14} atoms in a sample in order to determine the sample's age. For this problem, let's concentrate on the magnet that will perform the separation of masses. Suppose you have burned and vaporized the sample so that the carbon atoms are in a gas. You now pass this gas through an "ionizer" that on the average strips one electron from each atom. You then accelerate the ions by putting them through an electrostatic accelerator—two capacitor plates with small holes that permit the ions to enter and leave. (From the University of Washington Physics Education Group)

The two plates are charged so that they are at a voltage difference of ΔV volts. The electric field produced by charges on the capacitor plates accelerates the ions to an energy of $q\Delta V$. These are then introduced into a nearly constant, vertical magnetic field. If we ignore gravity, the magnetic field will cause the charged particles to follow a circular path in a horizontal plane. The radius of the circle will depend on the atom's mass. (Assume the whole device will be placed inside a vacuum chamber.)

Answer these three questions about how the device works.

- We want to keep the voltage at a moderate level. If ΔV is 1000 volts, how big of a magnetic field would we require to have a plausible tabletop-sized instrument? Is this a reasonable magnetic field to have with a tabletop-sized magnet?
- Do the C^{12} and C^{14} atoms hit the collection plate far enough apart? (If they are not separated by at least a few millimeters at the end of their path, we will have trouble collecting the atoms in separate bins.)
- Can we get away with ignoring gravity? (*Hint:* Calculate the time it would take the atom to travel its semicircle and calculate how far it would fall in that time.)

30

Magnetic Fields Due to Currents

This is the way we presently launch materials into space. However, when we begin mining the Moon and the asteroids, where we will not have a source of fuel for such conventional rockets, we shall need a more effective way. Electromagnetic launchers may be the answer. A small prototype, the *electromagnetic rail gun*, can accelerate a projectile from rest to a speed of 10 km/s (36 000 km/h) within 1 ms.

How can such rapid acceleration possibly be accomplished?

The answer is in this chapter.

30-1 Introduction

When people first began to study magnetism scientifically (say, starting from Gilbert's *Treatise de Magnete* in 1600), they focused on the properties of magnets. For example, they studied lodestones (pieces of iron naturally magnetized by the Earth's magnetic field) and found that magnets interact with other magnets through an "action-at-a-distance" force that we now call magnetism. Magnetism was found to be a third distinct noncontact force to add to the list of the two already known: gravity and electricity.

As we learned in the previous chapter, *stationary* electric charges and magnets do not interact (except for the polarization effects that stationary charges can induce in all objects). However, *moving* electric charges do experience a force in the presence of a magnet. Since magnets can exert forces on other magnets, could it be that moving charges behave like magnets?

We have postulated the existence of an entity called the magnetic field in order to introduce a magnetic force law that provides a mathematical description of the force that a permanent magnet can exert on moving electrical charges. Newton's Third Law states that whenever one object exerts a force on another object, the latter object exerts an equal and opposite force on the former. So, if a magnet exerts a force on a current-carrying wire, shouldn't the wire exert an equal and opposite force on the magnet? The symmetry demanded by Newton's Third Law leads us to predict that if moving charges feel forces as they pass through magnetic fields, then they should be capable of exerting forces on the sources of these magnetic fields. In the early 19th century the Danish physicist Hans Christian Oersted demonstrated that an electric current does indeed exert forces on a magnet in its vicinity.

In this chapter we describe how to determine the magnetic fields associated with current-carrying wires and the forces they exert on other wires and magnets. We begin with a summary of Oersted's observations of magnetic phenomena associated with current-carrying wires. We also discuss the work of Biot and Savart, two French scientists. Biot and Savart made a series of careful observations to formulate a mathematical expression describing the magnetic field from a short segment of current-carrying wire, doing for magnetism what Coulomb did for electricity. Next we show how the Biot–Savart law and an alternative law known as Ampère's law (much as Gauss' law was an alternative to Coulomb's) can be used to calculate the magnetic fields and forces associated with various configurations of current-carrying wires. The ability to make such calculations has had a tremendous impact on the design of devices ranging from electric toothbrushes to gigantic particle accelerators.

30-2 Magnetic Effects of Currents – Oersted's Observations

The Earth has a relatively weak magnetic field that interacts with magnets. This phenomenon was exploited for navigational purposes through the development of the compass—a small bar magnet suspended so it pivots freely. Hence a compass is a sensitive magnetic field detector. Oersted and other scientists used the orientation of a compass to detect magnetic fields and determine their directions. By convention, the north-seeking pole of a magnet points in the direction of the magnetic field at its location.

In 1820, H. C. Oersted reported on a famous experiment connecting magnetism with electric currents. He placed a conducting wire along the north–south line of the Earth's magnetic field and laid a compass on top of the wire. The needle pointed

along the wire (and the Earth's north–south line). When Oersted connected the ends of the wire to the terminals of a battery, the compass needle swung *perpendicular* to the wire as shown in Fig. 30-1, demonstrating that moving charges in a wire affect a compass in the same way a magnet does. Oersted also noticed that when the direction of the current is reversed, the compass needle flips so it points in the opposite direction.

Oersted found that moving charged particles, such as a current in a wire, create magnetic fields. Oersted's observation was especially surprising because this was the first known instance in which the force on an object (in this case the compass) was not observed to act along a line connecting it with the source of the force (in this case the wire). Within a week of the time that Oersted announced his observations, a French physicist, André Marie Ampère, began to refine them. Ampère noted that the magnetic field lines lay in concentric circles around the wire. His careful observations revealed that a long current-carrying wire sets up a magnetic field that orients small compass magnets so they are tangent to a circle centered on the wire that lies in a plane perpendicular to the wire. The alignment of iron filings, which act like small compasses, is shown in Fig. 30-2. Drawing the direction of the compass needle alignments at many different points that completely surround the wire results in an image of concentric circles like those shown in Fig. 30-3.

Ampère also developed a graphic way of relating the direction of conventional current (that is, traveling from the positive to the negative terminal of a battery) and the orientation of the magnetic field, which is indicated by the direction of the north pole of a compass needle. Ampère stated his **right-hand rule** as follows:

Encircle the wire with the fingers of the right hand, thumb extended in the direction of positive current. The fingers then point in the direction of deflection of the north pole.

This right-hand rule is shown graphically in Fig. 30-4.

You can easily replicate the following observations made by Oersted, Ampère, and many others in the early 19th century using a battery, wire, a piece of cardboard, and one or more small compasses:

- The compass needles are more strongly deflected when they are close to the wire than when they are far from the wire.
- For a given current, the amount of needle deflection depends only on the needle's radial distance from the wire.
- At a given radial distance from the wire, increasing the current in the wire increases the needle deflection.
- The direction of the needle deflection flips (change by 180°) if you reverse the direction of the current flow.
- Drawing the directions of the needle orientations at many different points that completely surround the wire results in an image of concentric circles like those shown in Fig. 30-3.

READING EXERCISE 30-1: In each of the following situations, assume that the magnetic field associated with a current-carrying wire can point up, down, left, right, into the page, or out of the page. (a) If the direction of the conventional current in the wire is out of the page, what is the direction of the magnetic field it generates at point 1? (b) At point 2? (c) If the direction of the conventional current in the wire is into the page, what is the direction of the magnetic field it generates at point 1? (d) At point 2?

FIGURE 30-1 Oersted's experiment showing how a compass needle becomes aligned in a direction that is perpendicular to the direction of the current in a length of wire.

FIGURE 30-2 Iron filing slivers that have been sprinkled onto cardboard collect in concentric circles when a strong current is sent through the central wire. The filings are magnetized and align themselves like tiny compasses in the direction of the magnetic field produced by the current.

FIGURE 30-3 The magnetic field lines produced by a current in a long straight wire form concentric circles around the wire. Here the current is into the page, as indicated by the \times . The field lines are farther apart as the distance from the wire increases, signifying a decrease in the magnitude of the field with distance.

FIGURE 30-4 ■ Ampère's right-hand rule gives the direction of the magnetic field relative to the conventional current in a wire. (a) The situation of Fig. 30-3, seen from the side. The magnetic field \vec{B} at any point to the left of the wire is perpendicular to the dashed radial line and directed into the page, in the direction of the fingertips, as indicated by the \times . (b) If the current is reversed, \vec{B} at any point to the left is still perpendicular to the dashed radial line but now is directed out of the page, as indicated by the dot.

30-3 Calculating the Magnetic Field Due to a Current

It is very useful to be able to compute the net magnetic field created by a current-carrying wire. We would also like to be able to do this either for long straight wires or for any wire no matter how it bends around.

Two French physicists named Biot and Savart (rhymes with “Leo and bazaar”) were able to develop a mathematical description of the magnetic field in the vicinity of a short segment of current-carrying wire. To do this, these investigators made a set of very clever experimental measurements:

- First, the two investigators positioned magnets around their experimental setup in order to cancel out the local magnetic field of the Earth.
- Next they placed sharp bends in a current-carrying wire so they could observe the approximate effect that an “isolated” short element of wire would have.
- Then they ran a known current through the wire and measured the direction of the magnetic field produced by the small wire segment at various locations using the final orientation of the suspended compass needles.
- Finally, they measured the relative magnitude of the torque on the suspended compass needles before they reached their final orientation and thus the relative force applied to the needles. In doing this, they were actually making measurements of the strength of the field at various locations.

Given what we know of the observations summarized in the previous section, it is not surprising that Biot and Savart found that the magnitude of the magnetic field contribution $|d\vec{B}| = dB$ is directly proportional to the amount of the current $|i|$ and the length of the small segment of wire. They also found that the magnitude of the magnetic field at a point P in space decreases as the inverse square of the distance between the segment of wire and point P . The two investigators proposed that the magnitude of the field contribution $d\vec{B}$ produced at a point P by a segment of wire $d\vec{s}$ carrying a current i is

$$dB = \frac{\mu_0}{4\pi} \frac{|i ds| \sin \phi}{r^2}, \quad (30-1)$$

where $d\vec{s}$ is a vector of magnitude ds equal to the length of the piece of wire and direction given by the direction of the current. ϕ is the angle between the directions of $d\vec{s}$ and \vec{r} , where \vec{r} is the vector that extends from $d\vec{s}$ to point P . (See Figure 30-5b.) The symbol μ_0 is called the *magnetic constant* (or permeability). By definition its value in SI units is exactly

$$\mu_0 \equiv 4\pi \times 10^{-7} \text{ T} \cdot \text{m/A} \approx 1.26 \times 10^{-6} \text{ T} \cdot \text{m/A} \quad (\text{magnetic constant}). \quad (30-2)$$

Equation 30-1 is similar in many ways to that found for the differential electric field from a small segment of wire holding static charge described by Eq. 23-21. However, the perpendicular relationship between the direction of a segment of wire and the magnetic field it produces is a new phenomenon. Fortunately, it turns out that a vector crossproduct can be used to find the direction of the magnetic field contribution. The direction of $d\vec{B}$, shown as being into the page in Fig. 30-5b, is the same as that given by the cross product $d\vec{s} \times \vec{r}$. We can therefore recast Eq. 30-1 in vector form as

$$d\vec{B} = \frac{\mu_0}{4\pi} \frac{i d\vec{s} \times \vec{r}}{r^3} \quad (\text{Biot-Savart law}). \quad (30-3)$$

This vector equation is known as the **Biot–Savart law**. The law, which was experimentally deduced, is an inverse-square law (the exponent in the denominator of Eq. 30-3 is 3 only because of the factor \vec{r} in the numerator). How can we use this law to calculate the net magnetic field \vec{B} produced at a point by various distributions of current?

If our goal is to calculate the magnetic field that is produced by a given current *distribution* based on the field produced by *segments* of the distribution, perhaps we should use the same basic procedure we used in Chapter 23 to calculate the electric field produced by a given distribution of charged particles. Let us quickly review that basic procedure. We first mentally divide the charge distribution into charge elements dq , as is done for a charge distribution of arbitrary shape in Fig. 30-5a. We then calculate the field $d\vec{E}$ produced at some point P by a single charge element. Because the electric fields contributed by different elements can be superimposed, we calculate the net field \vec{E} at P by summing, via integration, the contributions $d\vec{E}$ from all the elements.

Recall that we express the magnitude of $d\vec{E}$ as

$$|dE| = k \frac{|dq|}{r^2}, \quad (30-4)$$

in which r is the distance between the charge element dq and point P . For a positively charged element, the direction of $d\vec{E}$ is that of \vec{r} , where \vec{r} is the vector that extends from the charge element dq to the point P . Using \vec{r} , we can rewrite Eq. 30-4 in vector form as

$$d\vec{E} = k \frac{dq}{r^3} \vec{r}, \quad (30-5)$$

which indicates that the direction of the vector $d\vec{E}$ produced by a positively charged element is the direction of the vector \vec{r} . Note that just as is the case for the Biot-Savart law this is an inverse-square law ($d\vec{E}$ depends on inverse r^2) in spite of the r^3 term in the denominator. This is because the \vec{r} term in the numerator cancels one of the r 's in the denominator.

We can use the same basic procedure to calculate the magnetic field due to a current. Figure 30-5b shows a wire of arbitrary shape carrying a current i . We want to find the magnetic field \vec{B} at a nearby point P . We first mentally divide the wire into differential elements ds and then define for each element a length vector $d\vec{s}$ that has length ds and whose direction is the direction of the current in ds . We can then define a differential *current-length element* to be $i d\vec{s}$; we wish to calculate the field $d\vec{B}$ produced at P by a single current-length element. From experiment we find that magnetic fields, like electric fields, can be superimposed to find a net field. Thus, we can calculate the net field \vec{B} at P by summing contributions for discrete sources or by integrating the contributions $d\vec{B}$ from all the current-length elements in a continuous source. However, this summation (or integration) is more challenging than the process associated with electric fields because of a complexity. The charge element dq that produces an electric field is a scalar, but a current-length element $i d\vec{s}$ that produces a magnetic field is the product of a scalar and a vector.

Magnetic Field Due to a Current in a Long Straight Wire

Shortly we shall use the law of Biot and Savart to prove that the magnitude of the magnetic field at a perpendicular distance R from a long (infinite) straight wire carrying a current i is given by

$$B = \frac{\mu_0 |i|}{2\pi R} \quad (\text{long straight wire}). \quad (30-6)$$

FIGURE 30-5 (a) A charge element dq produces a differential electric field $d\vec{E}$ at point P . (b) A current-length element $i d\vec{s}$, isolated by sharp bends in the wire, produces a differential magnetic field $d\vec{B}$ at point P . The \times (the tail of an arrow) at the dot for point P indicates that $d\vec{B}$ is directed into the page there for the special case where i and $d\vec{s}$ are parallel. If a small magnetic compass needle is used to detect the magnetic field, then its north pole points into the page.

The field magnitude $B = |\vec{B}|$ in Eq. 30-6 depends only on the amount of current and the perpendicular distance R of the point from the wire. We shall show in our derivation that the field lines of \vec{B} form concentric circles around the wire, as Fig. 30-3 shows and as the iron filings in Fig. 30-2 suggest. The increase in the spacing of the lines in Fig. 30-3 with increasing distance from the wire represents the $1/R$ decrease in the magnitude of \vec{B} predicted by $B = \mu_0 |i| / 2\pi R$ (Eq. 30-6). The lengths of the two vectors \vec{B} in Fig. 30-3 also show the $1/R$ decrease when we use Ampère's right-hand rule for finding the direction of the magnetic field set up by a current-length element, such as a section of a long wire. What we are really doing is describing the orientation of concentric circles centered on the wire. A careful review of Fig. 30-3 yields two additional points that are often quite useful in solving magnetic field problems. Namely, the magnetic field \vec{B} due to a current-carrying wire at any point is *tangent to a magnetic field line* and it is *perpendicular to a dashed radial line connecting the point and the current*.

Proof of Equation 30-6

Figure 30-6, which is just like Fig. 30-5b except that now the wire is straight and of infinite length, illustrates the task at hand; we seek the field \vec{B} at point P , a perpendicular distance R from the wire. The magnitude of the differential magnetic field produced at P by the current-length element $|i d\vec{s}|$ located a distance r from P is given by Eq. 30-1:

$$|d\vec{B}| = \frac{\mu_0}{4\pi} \frac{|i d\vec{s}| \sin \phi}{r^2}.$$

FIGURE 30-6 ■ Calculating the magnetic field produced by a current i in a long straight wire. Using either Ampère's right-hand rule or $d\vec{s} \times \vec{r}$, we find $d\vec{B}$ at P is directed into the page as shown.

Since the direction of $d\vec{s}$ is always in the direction of the current, we find that the direction of $d\vec{B}$ in Fig. 30-6 (given by $d\vec{s} \times \vec{r}$) is into the page.

Note that $d\vec{B}$ at point P has this same direction (into the page) for all the current-length elements into which the wire can be divided. Thus, we can find the magnitude of the magnetic field produced at P by the current-length elements in the upper half of the infinitely long wire by integrating dB in Eq. 30-1 from 0 to ∞ .

Now consider a current-length element in the lower half of the wire, one that is as far below P as $d\vec{s}$ is above P . By Eq. 30-6, the magnetic field produced at P by this current-length element has the same magnitude and direction as that from $i d\vec{s}$ in Fig. 30-6. Further, the magnetic field produced by the lower half of the wire is exactly the same as that produced by the upper half. To find the magnitude of the total magnetic field \vec{B} at P , we need only multiply the result of our integration by 2. We get

$$B = 2 \int_0^{\infty} dB = \frac{\mu_0 |i|}{2\pi} \int_0^{\infty} \frac{|\sin \phi| ds}{r^2}. \quad (30-7)$$

The variables ϕ , s , and r in this equation are not independent but (see Fig. 30-6) are related by

$$r = \sqrt{s^2 + R^2}$$

and

$$\sin \phi = \sin(\pi - \phi) = \frac{R}{\sqrt{s^2 + R^2}}.$$

Using these substitutions along with the solution to integral 19 in Appendix E, Eq. 30-7 describing the magnitude of the magnetic field becomes

$$B = \frac{\mu_0 |i|}{2\pi} \int_0^{\infty} \frac{R ds}{(s^2 + R^2)^{3/2}} = \frac{\mu_0 |i|}{2\pi R} \left[\frac{s}{(s^2 + R^2)^{1/2}} \right]_0^{\infty}.$$

Substituting the limits in the expression above gives a B -field magnitude of

$$B = \frac{\mu_0 |i|}{2\pi R}, \quad (\text{infinite straight wire}), \quad (30-8)$$

which is the relation we set out to prove. Note that the magnitude of the magnetic field at P due to either the lower half or the upper half of the infinite wire in Fig. 30-6 is half this value; that is,

$$B = \frac{\mu_0 |i|}{4\pi R}, \quad (\text{semi-infinite straight wire}). \quad (30-9)$$

Magnetic Field Due to a Current in a Circular Arc of Wire

To find the magnetic field produced at a point by a current in a curved wire, we would again use Eq. 30-1 to write the magnitude of the field produced by a single current-length element, and we would again integrate to find the net field produced by all the current-length elements. That integration can be difficult, depending on the shape of the wire; it is fairly straightforward, however, when the wire is a circular arc and the point is the center of curvature.

Figure 30-7a shows such an arc-shaped wire with central angle ϕ_C , radius R , and center C , carrying current i . At C , each current-length element $i d\vec{s}$ of the wire produces a magnetic field element of magnitude dB given by Eq. 30-1. Moreover, as Fig. 30-7b shows, no matter where the element is located on the wire, the angle ϕ between the vectors $d\vec{s}$ and \vec{r} is 90° ; also, $r = R$. Thus, by substituting R for r and 90° for ϕ , we obtain from Eq. 30-1,

$$dB = \frac{\mu_0}{4\pi} \frac{|i| ds \sin 90^\circ}{R^2} = \frac{\mu_0}{4\pi} \frac{|i| ds}{R^2}. \quad (30-10)$$

The field at C due to each current-length element in the circular arc has this same magnitude.

An application of the right-hand rule anywhere along the wire (as in Fig. 30-7c) will show that all the differential fields $d\vec{B}$ have the same direction at C —directly out of the page. Thus, the total field at C is simply the sum (via integration) of all the fields $d\vec{B}$. We use the identity $ds = R d\phi$ to change the variable of integration from ds to $d\phi$ and obtain, from Eq. 30-10, a magnitude of

$$B = \int dB = \int_0^{\phi_C} \frac{\mu_0}{4\pi} \frac{|i| R d\phi}{R^2} = \frac{\mu_0 |i|}{4\pi R} \int_0^{\phi_C} d\phi.$$

Integrating, we find that

$$B = \frac{\mu_0 |i| \phi_C}{4\pi R} \quad (\text{at center of circular arc}). \quad (30-11)$$

Note that this equation gives us the magnitude of the magnetic field *only* at the center of curvature of a circular arc of current. When you insert data into the equation, you must be careful to express ϕ_C in radians rather than degrees. For example, to find the magnitude of the magnetic field at the center of a full circle of current,

FIGURE 30-7 (a) A wire in the shape of a circular arc with center C carries current i . (b) For any element of wire along the arc, the angle between the directions of $d\vec{s}$ and \vec{r} is 90° . (c) Determining the direction of the magnetic field at the center C due to the current in the wire; the field is out of the page, in the direction of the fingertips, as indicated by the colored dot at C .

you would substitute 2π for ϕ_C in Eq. 30-11, finding

$$B = \frac{\mu_0 |i| (2\pi)}{4\pi R} = \frac{\mu_0 |i|}{2R} \quad (\text{at center of full circle}). \quad (30-12)$$

READING EXERCISE 30-2: A uniform magnetic field is directed toward the right in the plane of the paper as shown in the diagram that follows. A wire oriented perpendicular to the plane of the paper carries a current i . Suppose that the resultant magnetic field at point 1 due to a superposition of the uniform magnetic field of magnitude $|\vec{B}|$ and the magnetic field of the wire at point 1 is zero. (a) Is the direction of the current in the wire into or out of the paper? Explain how you arrived at your conclusion. (b) Assume that point 2 lies at the same distance from the center of the wire as point 1 and that the length of the vector assigned to represent the magnitude of the uniform external magnetic field is that shown to the left. Construct a vector arrow showing the length and direction of the resultant magnetic field vector at point 2. Explain how you deduced what the vector should be. (Adapted from A. Arons, *Homework and Test Questions for Introductory Physics Teaching*, John Wiley and Sons, 1947.)

TOUCHSTONE EXAMPLE 30-1: An Arc and Two Straight Lines

The wire in Fig. 30-8a carries a current i and consists of a circular arc of radius R and central angle $\pi/2$ rad, and two straight sections whose extensions intersect the center C of the arc. What magnetic field \vec{B} does the current produce at C ?

FIGURE 30-8 (a) A wire consists of two straight sections (1 and 2) and a circular arc (3), and carries current i . (b) For a current-length element in section 1, the angle between $d\vec{s}$ and \vec{r} is zero. (c) Determining the direction of magnetic field \vec{B}_3 at C due to the current in the circular arc; the field is into the page there.

SOLUTION ■ One **Key Idea** here is that we can find the magnetic field \vec{B} at point C by applying the Biot–Savart law of Eq. 30-3 to the wire. A second **Key Idea** is that the application of Eq. 30-3 can be simplified by evaluating \vec{B} separately for the three distinguishable sections of the wire—namely, (1) the straight section at the left, (2) the straight section at the right, and (3) the circular arc.

Straight sections. For any current-length element in section 1, the angle ϕ between $d\vec{s}$ and \vec{r} is zero (Fig. 30-8b), so Eq. 30-1 gives us

$$|d\vec{B}_1| = \frac{\mu_0}{4\pi} \frac{|i d\vec{s}| \sin \phi}{r^2} = \frac{\mu_0}{4\pi} \frac{|i d\vec{s}| \sin 0}{r^2} = 0 \text{ T}.$$

Thus, the current along the entire length of wire in straight section 1 contributes no magnetic field at C :

$$\vec{B}_1 = 0 \text{ T}.$$

The same situation prevails in straight section 2, where the angle ϕ between $d\vec{s}$ and \vec{r} for any current-length element is 180° . Thus,

$$\vec{B}_2 = 0 \text{ T}.$$

Circular arc. The **Key Idea** here is that application of the Biot–Savart law to evaluate the magnetic field at the center of a circular arc leads to Eq. 30-11 ($|B| = \mu_0 |i| \phi / 4\pi R$). Here the central angle ϕ of the arc is $\pi/2$ rad. Thus from Eq. 30-11, the magnitude of the magnetic field \vec{B}_3 at the arc's center C is

$$|\vec{B}_3| = \frac{\mu_0 |i| (\pi/2)}{4\pi R} = \frac{\mu_0 |i|}{8R}.$$

To find the direction of \vec{B}_3 , we apply the right-hand rule displayed in Fig. 30-4. Mentally grasp the circular arc with your right hand as suggested in Fig. 30-8c, with your thumb in the direction of the current. The direction in which your fingers curl around the wire indicates the direction of the magnetic field lines around the wire. In the region of point C (inside the circular arc), your fingertips point *into the plane* of the page. Thus, \vec{B}_3 is directed into that plane.

Net field. Generally, when we must combine two or more magnetic fields to find the net magnetic field, we must combine the

fields as vectors and not simply add their magnitudes. Here, however, only the circular arc produces a magnetic field at point C . Thus, we can write the magnitude of the net field \vec{B} as

$$|\vec{B}| = |\vec{B}_1 + \vec{B}_2 + \vec{B}_3| = 0 + 0 + \left| \frac{\mu_0 i}{8R} \right| = \left| \frac{\mu_0 i}{8R} \right|. \quad (\text{Answer})$$

The direction of \vec{B} is the direction of \vec{B}_3 —namely, into the plane of Fig. 30-8.

TOUCHSTONE EXAMPLE 30-2: Two Long Parallel Wires

Figure 30-9a shows two long parallel wires carrying currents i_1 and i_2 in opposite directions. What are the magnitude and direction of the net magnetic field at point P ? Assume the following values: $i_1 = 15$ A, $i_2 = 32$ A, and $d = 5.3$ cm.

FIGURE 30-9 (a) Two wires carry currents i_1 and i_2 in opposite directions (out of and into the page). Note the right angle at P . (b) The separate fields \vec{B}_1 and \vec{B}_2 are combined vectorially to yield the net field \vec{B}^{net} .

SOLUTION ■ One **Key Idea** here is that the net magnetic field \vec{B} at point P is the vector sum of the magnetic fields due to the currents in the two wires. A second **Key Idea** is that we can find the magnetic field due to any current by applying the Biot–Savart law to the current. For points near the current in a long straight wire, that law leads to Eq. 30-6.

In Fig. 30-9a, point P is distance R from both currents i_1 and i_2 . Thus, Eq. 30-6 tells us that at point P those currents produce magnetic fields \vec{B}_1 and \vec{B}_2 with magnitudes

$$B_1 = \frac{\mu_0 |i_1|}{2\pi R} \quad \text{and} \quad B_2 = \frac{\mu_0 |i_2|}{2\pi R}.$$

In the right triangle of Fig. 30-9a, note that the base angles (between sides R and d) are both 45° . Thus, we may write $\cos 45^\circ = R/d$ and replace R with $d \cos 45^\circ$. Then the field magnitudes B_1 and B_2 become

$$B_1 = \frac{\mu_0 |i_1|}{2\pi d \cos 45^\circ} \quad \text{and} \quad B_2 = \frac{\mu_0 |i_2|}{2\pi d \cos 45^\circ}.$$

We want to combine \vec{B}_1 and \vec{B}_2 to find their vector sum, which is the net field \vec{B}^{net} at P . To find the directions of \vec{B}_1 and \vec{B}_2 , we apply the right-hand rule of Fig. 30-4 to each current in Fig. 30-9a. For wire 1, with current out of the page, we mentally grasp the wire with the right hand, with the thumb pointing out of the page. Then the curled fingers indicate that the field lines run counterclockwise. In particular, in the region of point P , they are directed upward to the left. Recall that the magnetic field at a point near a long, straight current-carrying wire must be directed perpendicular to a radial line between the point and the current. Thus, \vec{B}_1 must be directed upward to the left as drawn in Fig. 30-9b. (Note carefully the perpendicular symbol between vector \vec{B}_1 and the line connecting point P and wire 1.)

Repeating this analysis for the current in wire 2, we find that \vec{B}_2 is directed upward to the right as drawn in Fig. 30-9b. (Note the perpendicular symbol between vector \vec{B}_2 and the line connecting point P and wire 2.)

We can now vectorially add \vec{B}_1 and \vec{B}_2 to find the net magnetic field \vec{B}^{net} at point P , either by using a vector-capable calculator or by resolving the vectors into components and then combining the components of \vec{B}^{net} . However, in Fig. 30-9b, there is a third method: Because \vec{B}_1 and \vec{B}_2 are perpendicular to each other, they form the legs of a right triangle, with \vec{B}^{net} as the hypotenuse. The Pythagorean theorem then gives us

$$\begin{aligned} B^{\text{net}} &= \sqrt{B_1^2 + B_2^2} = \frac{\mu_0}{2\pi d (\cos 45^\circ)} \sqrt{i_1^2 + i_2^2} \\ &= \frac{(4\pi \times 10^{-7} \text{ T} \cdot \text{m/A}) \sqrt{(15 \text{ A})^2 + (32 \text{ A})^2}}{(2\pi)(5.3 \times 10^{-2} \text{ m})(\cos 45^\circ)} \\ &= 1.89 \times 10^{-4} \text{ T} \approx 190 \mu\text{T}. \end{aligned} \quad (\text{Answer})$$

The angle ϕ between the directions of \vec{B}^{net} and \vec{B}_2 in Fig. 30-9b follows from

$$\phi = \tan^{-1} \frac{B_1}{B_2},$$

which, with B_1 and B_2 as given above, yields

$$\phi = \tan^{-1} \frac{i_1}{i_2} = \tan^{-1} \frac{15 \text{ A}}{32 \text{ A}} = 25^\circ.$$

The angle between the direction of \vec{B}^{net} and the x axis shown in Fig. 30-9b is then

$$\phi + 45^\circ = 25^\circ + 45^\circ = 70^\circ. \quad (\text{Answer})$$

FIGURE 30-10 ■ Two parallel wires carrying currents in the same direction attract each other. $\vec{B}_{a \rightarrow b}$ is the magnetic field at wire b produced by the current in wire a . $\vec{F}_{a \rightarrow b}$ is the resulting force acting on wire b because it carries current in field $\vec{B}_{a \rightarrow b}$.

30-4 Force Between Parallel Currents

Back in 1820, when Ampère was first replicating Oersted's observations, he predicted that two current-carrying wires in parallel would exert forces on each other. This is a logical consequence of the Biot–Savart law, which quantifies the magnetic field surrounding a current-carrying wire, and the magnetic force law, which describes the force on a current in the presence of a magnetic field. Indeed, Ampère observed that there is a mutual interaction between the two wires. In other words, each wire exerts a force on the other. As shown in Fig. 30-10, the application of the right-hand rules that accompany the Biot–Savart law (Eq. 30-3) and the expression for the magnetic force on a current (Eq. 29-22) lead us to predict that wires that carry currents in the same direction will attract, whereas wires that carry currents in opposite directions will repel. It is interesting that the attractions and repulsions are opposite to the electrostatic and magnetic relationships, where unlike charges or poles attract and like charges or poles repel.

We can use the two equations just mentioned to derive a third equation that describes the forces between two parallel current-carrying wires. Why do we want to determine these interaction forces? Three reasons come to mind. First, we can compare the measurement of these forces to the forces predicted by our third equation to verify the Biot–Savart law. Second, these mutual interaction forces enable us to define the ampere as the SI unit of current. Finally, by understanding the nature of these forces we can design an electromagnetic launcher (like that mentioned in the “puzler” on the first page of this chapter).

Figure 30-10 shows two parallel wires, separated by a distance d and carrying currents i_a and i_b . The first step in analyzing the forces between these wires is to find an expression for the force on wire b due to the current in wire a . The current in wire a produces a magnetic field $\vec{B}_{a \rightarrow b}$ at the location of wire b , and it is this magnetic field produced by wire a that actually causes wire b to experience a force denoted as $\vec{F}_{a \rightarrow b}$. According to Eq. 30-6, the magnitude of $B_{a \rightarrow b}$ at every point along wire b is

$$B_{a \rightarrow b} = \frac{\mu_0 |i_a|}{2\pi d}. \quad (30-13)$$

The right-hand rule tells us that the direction of $\vec{B}_{a \rightarrow b}$ at wire b is down, as shown in Fig. 30-10.

Now that we have determined the magnetic field vector, we can find the force that wire a produces on wire b . The expression for the force on a length of current-carrying wire (Eq. 29-22) tells us that the force on wire b is

$$\vec{F}_{a \rightarrow b} = i_b \vec{L} \times \vec{B}_{a \rightarrow b}, \quad (30-14)$$

where \vec{L} is the length vector (direction given by the direction of current i) of the wire. In Fig. 30-10 the vectors \vec{L} and $\vec{B}_{a \rightarrow b}$ are perpendicular, so using Eqs. 30-13 and 30-14, we can express the magnitude of the force on wire b due to the current in wire a as

$$F_{a \rightarrow b} = |i_b| L B_{a \rightarrow b} \sin 90^\circ = \frac{\mu_0 L |i_a i_b|}{2\pi d}. \quad (30-15)$$

The direction of $\vec{F}_{a \rightarrow b}$ is the direction of the cross product $\vec{L} \times \vec{B}_{a \rightarrow b}$. Applying the right-hand rule for cross products to \vec{L} and $\vec{B}_{a \rightarrow b}$ in Fig. 30-10, we find that $\vec{F}_{a \rightarrow b}$ points directly toward wire a , as shown.

The general procedure for finding the force on a current-carrying wire is this:

To find the force on a current-carrying wire due to a second current-carrying wire, first find the field due to the second wire at the site of the first wire. Then find the force on the first wire due to that field.

We could now use this procedure to compute the force on wire a due to the current in wire b . We would find that the force has the same magnitude but is in the opposite direction. This is true regardless of whether the currents are the same or in opposite directions. Once again, Newton's Third Law holds:

Parallel currents attract, and antiparallel currents repel.

The forces acting between currents in parallel wires provide us with the basis for defining the ampere, which is one of the seven SI base units. It is appropriately named after André Marie Ampère, who was the first to demonstrate the forces acting between parallel currents. The official SI definition, adopted in 1946, is:

The **ampere** is that constant current which, if maintained in two straight, parallel conductors of infinite length, of negligible circular cross section, and placed 1 m apart in a vacuum, would produce between each of these conductors a force equal to 2×10^{-7} newton per meter of length.

Rail Gun

A rail gun is a device in which a magnetic force can accelerate a projectile to a high speed in a short time. The basics of a rail gun are shown in Fig. 30-11*a*. A large current flows in a circuit consisting of two conducting rails joined by a conducting “fuse” (such as a narrow piece of copper) between the rails, and then back to the current source along the second rail. The projectile to be fired lies on the far side of the fuse and fits loosely between the rails. Immediately after the current is established, the fuse element melts and vaporizes, creating a conducting gas between the rails where the fuse had been.

The right-hand rule of Fig. 30-4 shows that the current in the rails of Fig. 30-11*a* produces a magnetic field that is directed downward between the rails. The net magnetic field \vec{B} exerts a force \vec{F} on the gas due to the current i through the gas (Fig. 30-11*b*). Using Eq. 30-14 and the right-hand rule for cross products, we find that \vec{F} points outward along the rails. As the gas is forced outward along the rails, it pushes the projectile, accelerating it by as much as $5 \times 10^7 \text{ m/s}^2$ or $(5 \times 10^6 g)$, and then launches it with a speed of 10 km/s, all within less than one millisecond.

READING EXERCISE 30-3: The figure shows three long, straight, parallel, equally spaced wires with identical amounts of current either into or out of the page. Rank the wires according to the magnitude of the force on each due to the currents in the other two wires, greatest first. ■

FIGURE 30-11 (a) A rail gun, as a current i is set up in it. The current rapidly causes the conducting fuse to vaporize. (b) The current produces a magnetic field \vec{B} between the rails, and the field causes a force \vec{F} to act on the conducting gas, which is part of the current path. The gas propels the projectile along the rails, launching it.

30-5 Ampère's Law

We can find the net electric field due to *any* distribution of charges with the inverse-square law for the differential field $d\vec{E}$ (Eq. 30-5), but if the distribution is complicated, we may have to use a computer. Recall, however, that if the distribution has planar, cylindrical, or spherical symmetry, we can apply Gauss' law to find the net electric field with considerably less effort.

Similarly, we can find the net magnetic field due to any distribution of currents with the inverse-square law for the differential field $d\vec{B}$ (Eq. 30-3), but again we may have to use a computer for a complicated distribution. However, if the distribution has enough symmetry, we can apply *Ampère's law* to find the magnetic field with

considerably less effort. This law, which can be derived from the Biot–Savart law, has traditionally been credited to André Marie Ampère (1775–1836), for whom the SI unit of current is named. However, the law actually was advanced by English physicist James Clerk Maxwell.

Ampère's law is

$$\oint \vec{B} \cdot d\vec{s} = \mu_0 i^{\text{enc}} \quad (\text{Ampère's law}). \quad (30-16)$$

FIGURE 30-12 ■ Ampère's law applied to an arbitrary Ampèrian loop that encircles two long straight wires but excludes a third wire. Note the directions of the currents.

The circle on the integral sign means that the scalar (or dot) product $\vec{B} \cdot d\vec{s}$ is to be integrated around an imaginary *closed* loop, called an *Ampèrian loop*. The current i^{enc} on the right is the *net* current encircled by that loop.

In Gauss' law we choose a closed surface on which to evaluate the integral. The integral flux is proportional to the net charge enclosed by the surface. In Ampère's law, we choose a closed loop on which to evaluate the integral. The integral is proportional to the net current passing through the loop.

To see the meaning of the scalar product $\vec{B} \cdot d\vec{s}$ and its integral, let us first apply Ampère's law to the general situation shown in Fig. 30-12. This figure depicts the cross sections of three long straight wires that carry currents i_1 , i_2 , and i_3 either directly into or directly out of the page. An arbitrary Ampèrian loop lying in the plane of the page encircles two of the currents but not the third. The counterclockwise direction marked on the loop indicates the arbitrarily chosen direction of integration for Eq. 30-16.

To apply Ampère's law, we mentally divide our imaginary loop into short, nearly straight, directed pieces, $d\vec{s}$. The direction of each of these pieces is tangent to the loop along the direction of integration. Assume that at the location of the element $d\vec{s}$ shown in Fig. 30-12, the net magnetic field due to the three currents is \vec{B} . Because the wires are perpendicular to the page, we know that the magnetic field at $d\vec{s}$ due to each current is in the plane of Fig. 30-12; thus, the net magnetic field \vec{B} at $d\vec{s}$ must also be in that plane. However, we do not know the orientation of \vec{B} within the plane. In Fig. 30-12, \vec{B} is arbitrarily drawn at an angle ϕ to the direction of $d\vec{s}$.

The scalar product $\vec{B} \cdot d\vec{s}$ on the left side of Eq. 30-16 is then equal to $(B \cos \phi) ds$. Thus, Ampère's law can be written as

$$\oint \vec{B} \cdot d\vec{s} = \oint (B \cos \phi) ds = \mu_0 i^{\text{enc}}. \quad (30-17)$$

We can now interpret the scalar product $\vec{B} \cdot d\vec{s}$ as being the product of a length ds of the Ampèrian loop and the field component $B \cos \phi$ that is tangent to the loop. Then we can interpret the integration as being the summation of all such products around the entire loop.

When we can actually perform this integration, we do not need to know the direction of \vec{B} before integrating. Instead, we arbitrarily assume \vec{B} to be generally in the direction of integration (as in Fig. 30-12). Then we use the following curled fingers–straight thumb right-hand rule to assign a plus sign or a minus sign to each of the currents that make up the net encircled current i^{enc} :

CURLED-STRAIGHT RIGHT-HAND RULE FOR AMPÈRE'S LAW: Curl your right hand around the Ampèrian loop, with the fingers pointing in the direction of integration. A current through the loop in the general direction of your outstretched thumb is assigned a plus sign, and a current generally in the opposite direction is assigned a minus sign.

Finally, we solve Eq. 30-17 for the magnitude of \vec{B} . Once we have chosen a coordinate system to describe the system, we can use Ampère's law right-hand rule to decide whether \vec{B} is positive or negative.

In Fig. 30-13 we apply the curled-straight rule for Ampère's law to the situation of Fig. 30-12. With the indicated counterclockwise direction of integration, the net current encircled by the loop is

$$i^{\text{enc}} = i_1 - i_2.$$

(Current i_3 is not encircled by the loop.) We can then rewrite Eq. 30-17 as

$$\oint (B \cos \phi) ds = \mu_0 |i_2 - i_1|. \quad (30-18)$$

You might wonder why, since current i_3 contributes to the magnetic-field magnitude B on the left side of Eq. 30-18, it is not needed on the right side. The answer is that the contributions of current i_3 to the magnetic field cancel out because the integration in Eq. 30-18 is made around the full loop. In contrast, the contributions of an encircled current to the magnetic field do not cancel out.

We cannot solve Eq. 30-18 for the magnitude B of the magnetic field, because for the situation of Fig. 30-12 we do not have enough information to solve the integral. However, we do know the magnitude of the integral; it must be equal to the value of $\mu_0 |i_1 - i_2|$, which is set by the net current passing through the loop. Next we apply Ampère's law to two situations in which symmetry does allow us to solve the integrals and determine the magnetic fields.

The Magnetic Field Outside a Long Straight Wire with Current

Figure 30-14 shows a long straight wire that carries current i (assumed to be uniformly distributed) that points directly out of the page. The equation for the magnetic field magnitude, B , produced by a long straight wire (Eq. 30-6) tells us that B depends only on the radial distance from the wire. That is, the field \vec{B} has cylindrical symmetry about the wire. We can take advantage of that symmetry to simplify the integral in Ampère's law (Eqs. 30-16 and 30-17) if we encircle the wire with a concentric circular Ampèrian loop of radius r , as in Fig. 30-14. The magnetic field \vec{B} then has the same magnitude B at every point on the loop. We shall integrate counterclockwise, so that $d\vec{s}$ has the direction shown in Fig. 30-14.

We can further simplify the quantity $B \cos \phi$ in Eq. 30-17 by noting that \vec{B} is tangent to the loop at every point along the loop, as is $d\vec{s}$. Thus, \vec{B} and $d\vec{s}$ are parallel at each point on the loop. Then at every point the angle ϕ between $d\vec{s}$ and \vec{B} is 0° (so $\cos \phi = +1$). The magnitude of the integral in Eq. 30-17 then becomes

$$\left| \oint \vec{B} \cdot d\vec{s} \right| = \oint (B \cos \phi) ds = B \left| \oint ds \right| = B(2\pi r).$$

Note that $\oint ds$ above is the summation of all the line segment lengths ds around the circular loop; that is, it simply gives the circumference $2\pi r$ of the loop.

The right side of Ampère's law becomes $+\mu_0 |i|$ and we then have

$$B(2\pi r) = \mu_0 i$$

or

$$B = \frac{\mu_0 |i|}{2\pi r}. \quad (30-19)$$

With a slight change in notation, this is Eq. 30-6, which we derived earlier—with considerably more effort—using the Biot-Savart law. We know that the correct direction of \vec{B} must be the counterclockwise one shown in Fig. 30-14 when i is positive. When i is negative, the correct direction for \vec{B} is clockwise.

FIGURE 30-13 ■ A right-hand rule for Ampère's law, to determine the signs for currents encircled by an Ampèrian loop. The situation is that of Fig. 30-12.

FIGURE 30-14 ■ Using Ampère's law to find the magnetic field produced by a current i in a long straight wire. The Ampèrian loop is a concentric circle that lies outside the wire.

FIGURE 30-15 ■ Using Ampère’s law to find the magnetic field that a current i produces inside a long straight wire of circular cross section. The current is uniformly distributed over the cross section of the wire and emerges from the page. An Amperian loop is drawn inside the wire.

The Magnetic Field Inside a Long Straight Wire with Current

Figure 30-15 shows the cross section of a long straight wire of radius R that carries a uniformly distributed current i either directly out of the page or directly into the page. Because the current is uniformly distributed over a cross section of the wire, the magnetic field \vec{B} that it produces must have cylindrical symmetry. Thus, to find the magnetic field at points inside the wire, we can again use an Amperian loop of radius r , as shown in Fig. 30-15, where now $r < R$. Symmetry again requires that \vec{B} is tangent to the loop, as shown, so the left side of Ampère’s law again yields

$$\oint \vec{B} \cdot d\vec{s} = B \left| \oint d\vec{s} \right| = B(2\pi r). \quad (30-20)$$

To find the right side of Ampère’s law, we note that because the current is uniformly distributed, the current i^{enc} encircled by the loop is proportional to the area encircled by the loop; that is,

$$i^{\text{enc}} = i \frac{\pi r^2}{\pi R^2} = i \frac{r^2}{R^2}. \quad (30-21)$$

Then Ampère’s law gives us

$$B(2\pi r)\mu_0 |i^{\text{enc}}| = \mu_0 |i| \frac{r^2}{R^2}$$

or

$$B = \left(\frac{\mu_0 |i|}{2\pi R^2} \right) r. \quad (30-22)$$

Thus, inside the wire, the magnitude B of the magnetic field is proportional to r ; that magnitude is zero at the center and a maximum at the surface, where $r = R$. Note that Eqs. 30-19 and 30-22 give the same value for B at $r = R$; that is, the expressions for the magnetic field outside the wire and inside the wire yield the same result at the surface of the wire.

READING EXERCISE 30-4: The figure shows three equal currents i (two parallel and one antiparallel) and four Amperian loops. Rank the loops according to the magnitude of $\oint \vec{B} \cdot d\vec{s}$ along each, greatest first. ■

TOUCHSTONE EXAMPLE 30-3: Hollow Conducting Cylinder

Figure 30-16a shows the cross section of a long hollow conducting cylinder with inner radius $a = 2.0$ cm and outer radius $b = 4.0$ cm. The cylinder carries a current out of the page, and the current density in the cross section is given by $|\vec{J}| = cr^2$, with $c = 3.0 \times 10^6$ A/m⁴ and r in meters. What is the magnitude of the magnetic field \vec{B} at a point that is 3.0 cm from the central axis of the cylinder?

SOLUTION ■ The point at which we want to evaluate \vec{B} is inside the material of the conducting cylinder, between its inner and outer radii. We note that the current distribution has cylindrical symmetry (it is the same all around the cross section for any given radius). Thus, the **Key Idea** here is that the symmetry allows us to use Ampère’s law to find \vec{B} at the point. We first draw the Amperian loop shown in Fig. 30-16b. The loop is concentric with the cylinder and has radius $R = 3.0$ cm, because we want to evaluate \vec{B} at that distance from the cylinder’s central axis.

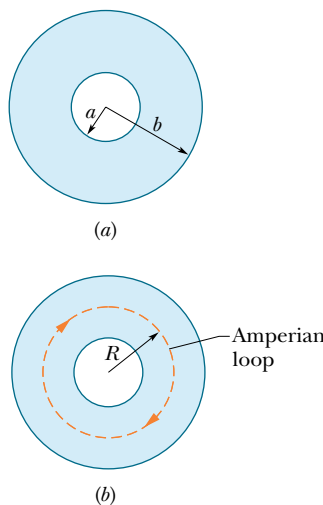

FIGURE 30-16 ■ (a) Cross section of a conducting cylinder of inner radius a and outer radius b . (b) An Amperian loop of radius R is added to compute the magnetic field at points that are a distance R from the central axis.

Next, we must compute the current i^{enc} that is encircled by the Ampèrian loop. However, a second **Key Idea** is that we *cannot* set up a proportionality as in Eq. 30-21, because here the current is not uniformly distributed. Instead, we must integrate the current density from the cylinder's inner radius a to the loop radius r . Since \vec{J} and $d\vec{A}$ are parallel, $\vec{J} \cdot d\vec{A} = JdA$, so

$$\begin{aligned} |i^{\text{enc}}| &= \left| \int \vec{J} \cdot d\vec{A} \right| = \left| \int_a^R cr^2 (2\pi r dr) \right| \\ &= \left| 2\pi c \int_a^R r^3 dr \right| = \left| 2\pi c \left[\frac{r^4}{4} \right]_a^R \right| \end{aligned}$$

since $|i^{\text{enc}}| = \frac{\pi c(R^4 - a^4)}{2}$, since $R > a$.

The direction of integration indicated in Fig. 30-16b is (arbitrarily) clockwise. Applying the right-hand rule for Ampère's law to that loop, we find that we should take i^{enc} as negative because the current is directed out of the page but our thumb is directed into the page.

We next evaluate the left side of Ampère's law exactly as we did in Fig. 30-15, and we again obtain Eq. 30-20. Then Ampère's law,

$$\oint \vec{B} \cdot d\vec{s} = \mu_0 i^{\text{enc}},$$

gives us

$$(B \cos \phi)(2\pi R) = -\frac{\mu_0 \pi c}{2}(R^4 - a^4),$$

where $\cos \phi = \cos 0^\circ = +1$ if \vec{B} is parallel to $d\vec{s}$ and $\cos \phi = \cos 180^\circ = -1$ if \vec{B} is antiparallel to $d\vec{s}$. Solving for $(B \cos \phi)$ for $\phi = 180^\circ$ and substituting known data yield

$$\begin{aligned} (B \cos \phi) &= -\frac{\mu_0 c}{4R}(R^4 - a^4) \\ -B &= -\frac{(4\pi \times 10^{-7} \text{ T} \cdot \text{m/A})(3.0 \times 10^6 \text{ A/m}^4)}{4(0.030 \text{ m})} \\ &\quad \times [(0.030 \text{ m})^4 - (0.020 \text{ m})^4] \\ -B &= -2.0 \times 10^{-5} \text{ T}. \end{aligned}$$

Thus, the magnetic field \vec{B} at a point 3.0 cm from the central axis is

$$B = 2.0 \times 10^{-5} \text{ T} \quad (\text{Answer})$$

and forms magnetic field lines that are directed opposite our direction of integration, hence counterclockwise in Fig. 30-16b.

30-6 Solenoids and Toroids

Magnetic Field of a Solenoid

We now turn our attention to another situation in which Ampère's law proves useful. It concerns the magnetic field produced by the current in a long, tightly wound helical coil of wire. Such a coil is called a **solenoid** (Fig. 30-17). Solenoids are very common electrical devices that are important in many technological applications.

To make the calculation simpler here, we will assume that the length of the solenoid is much greater than the diameter. Figure 30-18 shows a section through a portion of a "stretched-out" solenoid. The solenoid's magnetic field is the vector sum of the fields produced by the individual turns (loops) that make up the solenoid. For points very close to each turn, the wire behaves magnetically almost like a long straight wire, and the lines of \vec{B} there are almost concentric circles. Figure 30-18 suggests that the field tends to cancel between adjacent turns. It also suggests that, at points inside the solenoid and reasonably far from the wire, \vec{B} is approximately

FIGURE 30-17 ■ A solenoid carrying current i .

FIGURE 30-18 ■ A vertical cross section through the central axis of a "stretched-out" solenoid. The back portions of five turns are shown, as are the magnetic field lines due to a current through the solenoid. Each turn produces circular magnetic field lines near it. Near the solenoid's axis, the field lines combine into a net magnetic field that is directed along the axis. The closely spaced field lines there indicate a strong magnetic field. Outside the solenoid the field lines are widely spaced; the field there is very weak.

FIGURE 30-19 ■ Magnetic field lines for a real solenoid of finite length. The field is strong and uniform at interior points such as P_1 but relatively weak at external points such as P_2 .

FIGURE 30-20 ■ Application of Ampère's law to a section of a long ideal solenoid carrying a current i . The Amperian loop is the rectangle $abcd$.

parallel to the (central) solenoid axis. In the limiting case of an *ideal solenoid*, which is infinitely long and consists of tightly packed (*close-packed*) turns of square wire, the field inside the coil is uniform and parallel to the solenoid axis.

At points above the solenoid, such as P in Fig. 30-18, the field set up by the upper parts of the solenoid turns (marked \odot) is directed to the left (as drawn near P) and tends to cancel the field set up by the lower parts of the turns (marked \otimes), which is directed to the right (not drawn). In the limiting case of an ideal solenoid, the magnetic field outside the solenoid is zero. Taking the external field to be zero is an excellent assumption for a real solenoid if its length is much greater than its diameter and if we consider external points such as point P that are not near either end of the solenoid. The direction of the magnetic field along the solenoid axis is given by a curled-straight right-hand rule: Grasp the solenoid with your right hand so that your fingers follow the direction of the current in the windings; your extended right thumb then points in the direction of the axial magnetic field.

Figure 30-19 shows the lines of \vec{B} for a real solenoid. The spacing of the lines of \vec{B} in the central region shows that the field inside the coil is fairly strong and uniform over the cross section of the coil. The external field, however, is relatively weak.

Let us now apply Ampère's law,

$$\oint \vec{B} \cdot d\vec{s} = \mu_0 i^{\text{enc}}, \quad (30-23)$$

to the ideal solenoid of Fig. 30-20, where \vec{B} is uniform within the solenoid and zero outside it, using the rectangular Amperian loop $abcd$. We write $\oint \vec{B} \cdot d\vec{s}$ as the sum of four integrals, one for each loop segment:

$$\oint \vec{B} \cdot d\vec{s} = \int_a^b \vec{B} \cdot d\vec{s} + \int_b^c \vec{B} \cdot d\vec{s} + \int_c^d \vec{B} \cdot d\vec{s} + \int_d^a \vec{B} \cdot d\vec{s}. \quad (30-24)$$

The first integral on the right of Eq. 30-24 is Bh , where B is the magnitude of the uniform field \vec{B} inside the solenoid and h is the (arbitrary) length of the segment from a to b . The second and fourth integrals are zero because for every element ds of these segments, \vec{B} either is perpendicular to ds or is zero, and thus $\vec{B} \cdot d\vec{s}$ is zero. The third integral, which is taken along a segment that lies outside the solenoid, is zero because $\vec{B} = 0$ at all external points. Thus, $\oint \vec{B} \cdot d\vec{s}$ for the entire rectangular loop has the value Bh .

The net current i^{enc} encircled by the rectangular Amperian loop in Fig. 30-20 is not the same as the current i in the solenoid windings because the windings pass more than once through this loop. Let n be the number of turns per unit length of the solenoid; then the loop encloses nh turns, so

$$i^{\text{enc}} = i(nh).$$

Ampère's law then gives us

$$Bh = \mu_0 |i| nh,$$

$$\text{or} \quad B = n\mu_0 |i| \quad (\text{inside ideal solenoid}). \quad (30-25)$$

Although we derived Eq. 30-25 for an infinitely long ideal solenoid, it holds quite well for actual solenoids if we apply it only at interior points, well away from the solenoid ends. Equation 30-25 is consistent with the experimental fact that the magnetic field magnitude $|\vec{B}| = B$ within a solenoid does not depend on the diameter or the length of the solenoid and that B is uniform over the solenoidal cross section. A solenoid thus

FIGURE 30-21 (a) A toroid carrying a current i . (b) A horizontal magnetic cross section of the toroid. The interior magnetic field (inside the doughnut-shaped tube) can be found by applying Ampère's law with the Amperian loop shown.

provides a practical way to set up a known uniform magnetic field for experimentation, just as a parallel-plate capacitor provides a practical way to set up a known uniform electric field.

Magnetic Field of a Toroid

Figure 30-21a shows a **toroid**, which may be described as a solenoid bent into the shape of a hollow doughnut. What magnetic field \vec{B} is set up at its interior points (within the hollow of the doughnut)? We can find out from Ampère's law and the symmetry of the toroid.

From the symmetry, we see that the lines of \vec{B} form concentric circles inside the toroid, directed as shown in Fig. 30-21b. Let us choose a concentric circle of radius r as an Amperian loop and traverse it in the clockwise direction. Ampère's law (Eq. 30-16) yields

$$B(2\pi r) = N\mu_0|i|,$$

where i is the current in the toroid windings (and is positive for those windings enclosed by the Amperian loop) and N is the total number of turns. This gives

$$B = \frac{N\mu_0|i|}{2\pi} \frac{1}{r} \quad (\text{toroid}). \quad (30-26)$$

In contrast to the situation for a solenoid, \vec{B} is not constant over the cross section of a toroid. With Ampère's law, it is easy to show that $\vec{B} = 0$ for points outside an ideal toroid (as if the toroid were made from an ideal solenoid).

The direction of the magnetic field within a toroid follows from our curled-straight right-hand rule: Grasp the toroid with the fingers of your right hand curled in the direction of the current in the windings; your extended right thumb points in the direction of the magnetic field.

30-7 A Current-Carrying Coil as a Magnetic Dipole

So far we have examined the magnetic fields produced by current in a long straight wire, a solenoid, and a toroid. We turn our attention here to the field produced by a coil carrying a current. You saw in Section 29-10 that such a coil behaves as a magnetic dipole in that, if we place it in an external magnetic field \vec{B} , a torque $\vec{\tau}$ given by

$$\vec{\tau} = \vec{\mu} \times \vec{B} \quad (30-27)$$

acts on it. Here $\vec{\mu}$ is the magnetic dipole moment of the coil and has the magnitude NiA , where N is the number of turns (or loops), i is the current in each turn, and A is the area enclosed by each turn.

Recall that the direction of $\vec{\mu}$ is given by a curled-straight right-hand rule: Grasp the coil so that the fingers of your right hand curl around it in the direction of the current; your extended thumb then points in the direction of the dipole moment $\vec{\mu}$.

Magnetic Field of a Coil

We turn now to the other aspect of a current-carrying coil as a magnetic dipole. What magnetic field does *it* produce at a point in the surrounding space? The problem does not have enough symmetry to make Ampère's law useful, so we must turn to the Biot–Savart law. For simplicity, we first consider only a coil with a single circular loop and only points on its central axis, which we take to be a z axis. We shall show that the magnetic field at such points only has a z -component, B_z which is given by

$$\vec{B} = B_z \hat{k} = \frac{\mu_0 i R^2}{2(R^2 + z^2)^{3/2}} \hat{k}, \quad (30-28)$$

where R is the radius of the circular loop and z is the distance of the point in question from the center of the loop. Furthermore, the direction of the magnetic field \vec{B} is the same as the direction of the magnetic dipole moment $\vec{\mu}$ of the loop.

For axial points far from the loop, we have $z \gg R$ in Eq. 30-28. With that approximation, the equation for the z -component of \vec{B} , which is a function of z only, reduces to

$$B_z \approx \frac{\mu_0 i R^2}{2z^3}.$$

Recalling that πR^2 is the area A of the loop and extending our result to include a coil of N turns, we can write this equation as

$$B_z = \frac{\mu_0}{2\pi} \frac{NiA}{z^3}.$$

Further, since \vec{B} and $\vec{\mu}$ have the same direction, we can write the equation in vector form, substituting from $\mu = NiA$ (Eq. 29-32):

$$\vec{B} = B_z \hat{k} = \frac{\mu_0}{2\pi} \frac{\vec{\mu}}{z^3} \quad (\text{current-carrying coil}). \quad (30-29)$$

FIGURE 30-22 ■ A current loop produces a magnetic field like that of a bar magnet and thus has associated north and south poles. The magnetic dipole moment $\vec{\mu}$ of the loop, given by a curled-straight right-hand rule, points from the south pole to the north pole, in the direction of the field \vec{B} within the loop.

Note that the magnetic constant μ_0 and the magnetic moment vector $\vec{\mu}$ are completely different quantities with different units. The choice of the symbol μ to represent both quantities is unfortunate.

In summary, we have two ways in which we can regard a current-carrying coil as a magnetic dipole: (1) it experiences a torque when we place it in an external magnetic field; (2) it generates its own intrinsic magnetic field, given by Eq. 30-29 for distant points along its axis. Figure 30-22 shows some magnetic field lines for a current loop; one side of the loop acts as a north pole (in the direction of $\vec{\mu}$) and the other side as a south pole, as suggested by the lightly drawn magnet in the figure.

Proof of Equation 30-28

Figure 30-23 shows the back half of a circular loop of radius R carrying a current i . Consider a point P on the axis of the loop, a distance z from its plane. Let us apply the Biot–Savart law to a differential element $d\vec{s}$ of the loop, located at the left side of the loop. The length vector $d\vec{s}$ for this element points perpendicularly out of the page. The angle θ between $d\vec{s}$ and \vec{r} in Fig. 30-23 is 90° ; the plane formed by these two vectors is perpendicular to the plane of the figure and contains both \vec{r} and $d\vec{s}$. Using the Biot–Savart law and the right-hand rule, we see that the differential field $d\vec{B}$ produced at point P by the current in this element is perpendicular to this plane. Thus $d\vec{B}$ lies in the plane of the figure, perpendicular to \vec{r} (as indicated in Fig. 30-23).

Let us resolve $d\vec{B}$ into two components: $d\vec{B}_\parallel$ along the axis of the loop and $d\vec{B}_\perp$ perpendicular to this axis. From the symmetry, the vector sum of all the perpendicular components $d\vec{B}_\perp$ due to all the loop elements ds is zero. This leaves only the axial components $d\vec{B}_\parallel$ and we have the magnitude of the axial component given by

$$B_\parallel = \int dB_\parallel.$$

For the element $d\vec{s}$ in Fig. 30-23, the Biot–Savart law (Eq. 30-1) tells us that the magnitude of the axial magnetic field component at distance r is

$$dB_\parallel = \frac{\mu_0}{4\pi} \frac{i ds \sin 90^\circ}{r^2}.$$

We also have

$$dB_\parallel = dB \cos \alpha.$$

Combining these two relations, we obtain

$$dB_\parallel = \frac{\mu_0 i \cos \alpha ds}{4\pi r^2}. \quad (30-30)$$

Figure 30-23 shows that r and α are not independent but are related to each other. Let us express each in terms of the variable z , the distance between point P and the center of the loop. The relations are

$$r = \sqrt{R^2 + z^2} \quad (30-31)$$

and

$$\cos \alpha = \frac{R}{r} = \frac{R}{\sqrt{R^2 + z^2}}. \quad (30-32)$$

Substituting Eqs. 30-31 and 30-32 into Eq. 30-30, we find

$$dB_\parallel = \frac{\mu_0 i R}{4\pi (R^2 + z^2)^{3/2}} ds.$$

Note that i , R , and z have the same values for all elements $d\vec{s}$ around the loop, so when we integrate this equation, we find that the magnitude of the axial field component is given as

$$\begin{aligned} B_\parallel &= \oint dB_\parallel \\ &= \frac{\mu_0 i R}{4\pi (R^2 + z^2)^{3/2}} \oint ds, \end{aligned}$$

FIGURE 30-23 ■ A current loop of radius R . The plane of the loop is perpendicular to the page and only the back half of the loop is shown. We use the law of Biot and Savart to find the magnetic field at point P on the central axis of the loop.

or, since $\oint ds$ is simply the circumference $2\pi R$ of the loop, the axial or z -component of the magnetic field is

$$\vec{B} = B_z \hat{k} = \frac{\mu_0 i R^2}{2(R^2 + z^2)^{3/2}} \hat{k},$$

which is Eq. 30-28, the relation we sought to prove.

READING EXERCISE 30-5: The figure here shows four arrangements of circular loops of radius r or $2r$, centered on vertical axes (perpendicular to the loops) and carrying identical currents in the directions indicated. Assume the sizes of the loops are exaggerated and that $z \gg R$. Rank the arrangements according to the magnitude of the net magnetic field at the dot, midway between the loops on the central axis, greatest first.

Problems

SEC. 30-3 ■ CALCULATING THE MAGNETIC FIELD DUE TO A CURRENT

1. Surveyor A surveyor is using a magnetic compass 6.1 m below a power line in which there is a steady current of 100 A. (a) What is the magnitude of the magnetic field at the site of the compass due to the power line? (b) Will this interfere seriously with the compass reading? The horizontal component of the Earth's magnetic field at the site is $20 \mu\text{T}$.

2. Electron Gun The electron gun in a traditional television tube fires electrons of kinetic energy 25 keV at the screen in a circular beam 0.22 mm in diameter; 5.6×10^{14} electrons arrive each second. Calculate the magnitude of the magnetic field produced by the beam at a point 1.5 mm from the beam axis.

3. Philippines At a certain position in the Philippines, the magnitude of the Earth's magnetic field of $39 \mu\text{T}$ is horizontal and directed due north. Suppose the net field is zero exactly 8.0 cm above a long, straight, horizontal wire that carries a constant current. What are (a) the size and (b) the direction of the current?

4. Locate Points A long wire carrying a current of 100 A is placed in a uniform external magnetic field of 5.0 mT. The wire is perpendicular to this magnetic field. Locate the points at which the net magnetic field is zero.

5. Particle with Positive Charge A particle with positive charge q is a distance d from a long straight wire that carries a current i ; the particle is traveling with speed $|\vec{v}|$ perpendicular to the wire. What are the direction and magnitude of the force on the particle if it is moving (a) toward and (b) away from the wire?

6. Semicircular Arcs A straight conductor carrying a current i splits into identical semicircular arcs as shown in Fig. 30-24. What is

the magnitude of the magnetic field at the center C of the resulting circular loop?

7. Two Semi-Infinite A wire carrying current i has the configuration shown in Fig. 30-25. Two semi-infinite straight sections, both tangent to the same circle, are connected by a circular arc, of central angle ϕ , along the circumference of the circle, with all sections lying in the same plane. What must ϕ be in order for $|\vec{B}|$ to be zero at the center of the circle?

8. Use Biot–Savart Use the Biot–Savart law to calculate the magnitude and direction of the magnetic field \vec{B} at C , the common center of the semicircular arcs AD and HJ in Fig. 30-26a. The two arcs, of radii R_2 and R_1 , respectively, form part of the circuit $ADJHA$ carrying current i .

FIGURE 30-24 ■ Problem 6.

FIGURE 30-25 ■ Problem 7.

FIGURE 30-26 ■ Problems 8 and 9.

9. Curved Segments In the circuit of Fig. 30-26b, the curved segments are arcs of circles of radii a and b with common center P . The straight segments are along radii. Find the magnitude and direction of the magnetic field \vec{B} at point P , assuming a current i in the circuit.

10. Magnitude and Directions The wire shown in Fig. 30-27 carries current i . What are the magnitude and direction of the magnetic field \vec{B} produced at the center C of the semicircle by (a) each straight segment of length L , (b) the semicircular segment of radius R , and (c) the entire wire?

FIGURE 30-27 ■
Problem 10.

11. Straight Wire In Fig. 30-28, a straight wire of length L carries current i . Show that the magnitude of the magnetic field \vec{B} produced by this segment at P_1 , a distance R from the segment along a perpendicular bisector, is

FIGURE 30-28 ■ Problems 11 and 13.

$$B = \frac{\mu_0 |i|}{2\pi R} \frac{L}{(L^2 + 4R^2)^{1/2}}.$$

Show that this expression for $|\vec{B}|$ reduces to an expected result as $L \rightarrow \infty$.

12. Square Loop A square loop of wire of edge length a carries current i . Using the results of Problem 11, show that, at the center of the loop, the magnitude of the magnetic field produced by the current is

$$B = \frac{2\sqrt{2}\mu_0 |i|}{\pi a}.$$

13. Length L In Fig. 30-28, a straight wire of length L carries current i . Show that

$$B = \frac{\mu_0 |i|}{4\pi R} \frac{L}{(L^2 + R^2)^{1/2}}$$

gives the magnitude of the magnetic field \vec{B} produced by the wire at P_2 , a perpendicular distance R from one end of the wire.

14. Rectangular Loop Using the results of Problem 11, show that the magnitude of the magnetic field produced at the center of a rectangular loop of wire of length L and width W , carrying a current i , is

$$B = \frac{2\mu_0 |i|}{\pi} \frac{(L^2 + W^2)^{1/2}}{LW}.$$

15. Square Loop Two A square loop of wire of edge length a carries current i . Using the results of Problem 11, show that the magnitude of the magnetic field produced at a point on the axis of the loop and a distance x from its center is

$$B(x) = |\vec{B}(x)| = \frac{4\mu_0 |i| a^2}{\pi(4x^2 + a^2)(4x^2 + 2a^2)^{1/2}}.$$

Prove that this result is consistent with the result of Problem 12.

16. Length a In Fig. 30-29, a straight wire of length a carries a current i . Show that the magnitude of the magnetic field produced by the current at point P is $B = \sqrt{2}\mu_0 |i|/8\pi a$.

FIGURE 30-29 ■
Problem 16.

17. Two Wires Two wires, both of length L , are formed into a circle and a square, and each carries current i . Show that the square produces a greater magnetic field at its center than the circle produces at its center. (See Problem 12.)

FIGURE 30-30 ■ Problem 18.

18. Magnetic Field Find the magnitude and direction of the magnetic field \vec{B} at point P in Fig. 30-30. (See Problem 16.)

19. Long Thin Ribbon Figure 30-31 shows a cross section of a long thin ribbon of width w that is carrying a uniformly distributed total current i into the page. Calculate the magnitude and direction of the magnetic field \vec{B} at a point P in the plane of the ribbon at a distance d from its edge. (*Hint:* Imagine the ribbon to be constructed from many long, thin, parallel wires.)

FIGURE 30-31 ■
Problem 19.

20. Find Magnitude and Direction Find the magnitude and direction of the magnetic field \vec{B} at point P in Fig. 30-32, for $|i| = 10$ A and $a = 8.0$ cm. (See Problems 13 and 16.)

FIGURE 30-32 ■
Problem 20.

21. Perpendicular Bisector Figure 30-33 shows two very long straight wires (in cross section) that each carry currents of 4.00 A directly out of the page. Distance $d_1 = 6.00$ m and distance $d_2 = 4.00$ m. What is the magnitude of the net magnetic field at point P , which lies on a perpendicular bisector to the wires?

FIGURE 30-33 ■
Problem 21.

22. Greatest and 10% In Fig. 30-34, point P is at perpendicular distance $R = 2.00$ cm from a very long straight wire carrying a current. The magnetic field \vec{B} set up at point P is due to contributions from all the identical current-length elements $i d\vec{s}$ along the wire. What is the distance s to the current-length element that makes (a) the greatest contribution to field \vec{B} and (b) 10% of the greatest contribution?

FIGURE 30-34 ■
Problem 22.

SEC. 30-4 ■ FORCE BETWEEN TWO PARALLEL CURRENTS

23. Two Parallel Wires Two long parallel wires are 8.0 cm apart. What equal currents must be in the wires if the magnetic field halfway between them is to have a magnitude of $300 \mu\text{T}$? Answer for both (a) parallel and (b) antiparallel currents.

24. i and $3i$ Two long parallel wires a distance d apart carry currents of i and $3i$ in the same direction. Locate the point or points at which their magnetic fields cancel.

25. Two Parallel Wires Two Two long, straight, parallel wires, separated by 0.75 cm, are perpendicular to the plane of the page as shown in Fig. 30-35. Wire 1 carries a current of 6.5 A into the page. What must be the current (magnitude and direction) in wire 2 for the resultant magnetic field at point P to be zero?

FIGURE 30-35 ■ Problem 25.

26. Five Parallel Wires Figure 30-36 shows five long parallel wires in the xy plane. Each wire carries a current $i = 3.00$ A in the positive x direction. The separation between adjacent wires is $d = 8.00$ cm. In unit-vector notation, what are the magnitude and direction of the magnetic force per meter exerted on each of these five wires by the other wires?

FIGURE 30-36 ■ Problem 26.

27. Four Long Wires Four long copper wires are parallel to each other, their cross sections forming the corners of a square with sides $a = 20$ cm. A 20 A current exists in each wire in the direction shown in Fig. 30-37. What are the magnitude and direction of \vec{B} at the center of the square?

FIGURE 30-37 ■ Problems 27, 28, and 29.

28. Four Currents Form a Square Four identical parallel currents i are arranged to form a square of edge length a as in Fig. 30-37, except that they are all out of the page. What is the force per unit length (magnitude and direction) on any one wire?

29. Force per Unit Length In Fig. 30-37, what is the force per unit length acting on the lower left wire, in magnitude and direction, with the current directions as shown? The currents are i .

30. Idealized Schematic Figure 30-38 is an idealized schematic drawing of a rail gun. Projectile P sits between two wide rails of circular cross section; a source of current sends current through the rails and through the (conducting) projectile itself (a fuse is not used). (a) Let w be the distance between the rails, R the radius of

FIGURE 30-38 ■ Problem 30.

the rails, and i the current. Show that the magnitude of the force on the projectile is directed to the right along the rails and is given approximately by

$$F = |\vec{F}| = \frac{i^2 \mu_0}{\pi} \ln \frac{w + R}{R}.$$

(b) If the projectile starts from the left end of the rails at rest, find the speed v at which it is expelled at the right. Assume that $|i| = 450$ kA, $w = 12$ mm, $R = 6.7$ cm, $L = 4.0$ m, and the mass of the projectile is $m = 10$ g.

31. Rectangular Loop Two In Fig. 30-39, the long straight wire carries a current of 30 A and the rectangular loop carries a current of 20 A. Calculate the resultant force acting on the loop. Assume that $a = 1.0$ cm, $b = 8.0$ cm, and $L = 30$ cm.

FIGURE 30-39 ■ Problem 31.

SEC. 30-5 ■ AMPÈRE'S LAW

32. Eight Wires Eight wires cut the page perpendicularly at the points shown in Fig. 30-40. A wire labeled with the integer k ($k = 1, 2, \dots, 8$) carries the current ki . For those with odd k , the current is out of the page; for those with even k , it is into the page. Evaluate $\oint \vec{B} \cdot d\vec{s}$ along the closed path in the direction shown.

FIGURE 30-40 ■ Problem 32.

33. Eight Conductors Each of the eight conductors in Fig. 30-41 carries 2.0 A of current into or out of the page. Two paths are indicated for the line integral $\oint \vec{B} \cdot d\vec{s}$. What is the value of the integral for the path (a) at the left and (b) at the right?

FIGURE 30-41 ■ Problem 33.

34. Cross Section of a Cylindrical Conductor Figure 30-42 shows a cross section of a long cylindrical conductor of radius a , carrying a uniformly distributed current i . Assume that $a = 2.0$ cm and $i = 100$ A, and plot the magnitude of the magnetic field $|\vec{B}(r)| = B(r)$ over the range $0 < r < 6.0$ cm.

FIGURE 30-42 ■ Problem 34.

to the right of point a in Fig. 30-43) as one moves perpendicular to \vec{B} , say along the horizontal arrow in the figure. (*Hint:* Apply Ampère’s law to the rectangular path shown by the dashed lines.) In actual magnets “fringing” of the magnetic field lines always occurs, which means that \vec{B} approaches zero in a gradual manner. Modify the field lines in the figure to indicate a more realistic situation.

FIGURE 30-43 ■ Problem 35.

36. Two Square Conducting Loops Two square conducting loops carry currents of 5.0 and 3.0 A as shown in Fig. 30-44. What is the value of $\oint \vec{B} \cdot d\vec{s}$ for each of the two closed paths shown?

FIGURE 30-44 ■ Problem 36.

37. Current Density The current density inside a long, solid, cylindrical wire of radius a is in the direction of the central axis and varies linearly with radial distance r from the axis according to $|\vec{J}| = |\vec{J}_0|r/a$. Find the magnitude and direction of the magnetic field inside the wire.

38. Uniformly Distributed Current A long straight wire (radius = 3.0 mm) carries a constant current distributed uniformly over a cross section perpendicular to the axis of the wire. If the magnitude of the current density is 100 A/m², what are the magnitudes of the magnetic fields (a) 2.0 mm from the axis of the wire and (b) 4.0 mm from the axis of the wire?

39. Cylindrical Hole Figure 30-45 shows a cross section of a long cylindrical conductor of radius a containing a long cylindrical hole of radius b . The axes of the cylinder and hole are parallel and are a distance d apart; a current i is uniformly distributed over the tinted area. (a) Use superposition to show that the magnitude of the magnetic field at the center of the hole is

FIGURE 30-45 ■ Problem 39.

$$B = \frac{\mu_0 i |d|}{2\pi(a^2 - b^2)}.$$

(b) Discuss the two special cases $b = 0$ and $d = 0$. (*Hint:* Regard the cylindrical hole as resulting from the superposition of a complete cylinder (no hole) carrying a current in one direction and a cylinder of radius b carrying a current in the opposite direction, both cylinders having the same current density.)

40. Circular Pipe A long circular pipe with outside radius R carries a (uniformly distributed) current i into the page as shown in Fig. 30-46. A wire runs parallel to the pipe at a distance of $3R$ from

FIGURE 30-46 ■ Problem 40.

center to center. Find the amount and direction of the current in the wire such that the net magnetic field at point P has the same magnitude as the net magnetic field at the center of the pipe but is in the opposite direction.

41. Conducting Sheet Figure 30-47 shows a cross section of an infinite conducting sheet lying in the x - y plane, carrying a current per unit x -length of λ ; the current emerges perpendicularly out of the page. (a) Use the Biot–Savart law and symmetry to show that for all points P above the sheet, and all points P' below it, the magnetic field \vec{B} is parallel to the sheet and directed as shown. (b) Use Ampère’s law to prove that $B = \frac{1}{2}\mu_0|\lambda|$ at all points P and P' .

FIGURE 30-47 ■ Problems 41 and 48.

42. Field at P is Zero Figure 30-48 shows, in cross section, two long straight wires; the 3.0 A current in the right-hand wire is out of the page. What are the size and direction of the current in the left-hand wire if the net magnetic field at point P is to be zero?

FIGURE 30-48 ■ Problem 42.

SEC. 30-6 ■ SOLENOIDS AND TOROIDS

43. Field Inside Solenoid A 200-turn solenoid having a length of 25 cm and a diameter of 10 cm carries a current of 0.30 A. Calculate the magnitude of the magnetic field \vec{B} inside the solenoid.

44. Field Inside Solenoid Two A solenoid that is 95.0 cm long has a radius of 2.00 cm and a winding of 1200 turns; it carries a current of 3.60 A. Calculate the magnitude of the magnetic field inside the solenoid.

45. Toroid A toroid having a square cross section, 5.00 cm on a side, and an inner radius of 15.0 cm has 500 turns and carries a current of magnitude 0.800 A. (It is made up of a square solenoid—instead of a round one as in Fig. 30-21—bent into a doughnut shape.) What is the magnitude of the magnetic field inside the toroid at (a) the inner radius and (b) the outer radius of the toroid?

46. Length of Wire A solenoid 1.30 m long and 2.60 cm in diameter carries a current of 18.0 A. The magnitude of the magnetic field inside the solenoid is 23.0 mT. Find the length of the wire forming the solenoid.

47. Field Inside Toroid In Section 30-6, we showed that the magnitude of the magnetic field at any radius r inside a toroid is given by

$$B = \frac{\mu_0 i |N|}{2\pi r}.$$

Show that as you move from any point just inside a toroid to a point just outside, the magnitude of the change in \vec{B} that you encounter is just $\mu_0|\lambda|$. Here $|\lambda|$ is the amount of current per unit length along a circumference of radius r within the toroid. Compare this with the similar result found in Problem 48. Isn’t the equality surprising?

48. Solenoid as Cylindrical Conductor Treat an ideal solenoid as a thin cylindrical conductor whose current per unit length, measured parallel to the cylinder axis, is λ . (a) By doing so, show that the magnitude of the magnetic field inside an ideal solenoid can be written

as $B = \mu_0 |\lambda|$. This is the value of the *change* in \vec{B} that you encounter as you move from inside the solenoid to outside, through the solenoid wall. (b) Show that the same change occurs as you move through an infinite flat current sheet such as that of Fig. 30-47 (see Problem 41). Does this equality surprise you?

49. Direction of Field A long solenoid with 10.0 turns/cm and a radius of 7.00 cm carries a current of 20.0 mA. A current of 6.00 A exists in a straight conductor located along the central axis of the solenoid. (a) At what radial distance from the axis will the direction of the resulting magnetic field be at 45.0° to the axial direction? (b) What is the magnitude of the magnetic field there?

50. Find Current in Solenoid A long solenoid has 100 turns/cm and carries current i . An electron moves within the solenoid in a circle of radius 2.30 cm perpendicular to the solenoid axis. The speed of the electron is $0.0460c$ ($c =$ speed of light). Find the amount of current $|i|$ in the solenoid.

SEC. 30-7 ■ A CURRENT-CARRYING COIL AS A MAGNETIC DIPOLE

51. Magnetic Dipole What is the magnetic dipole moment $\vec{\mu}$ of the solenoid described in Problem 43?

52. One Turn Coil Figure 30-49a shows a length of wire carrying a current i and bent into a circular coil of one turn. In Fig. 30-49b the same length of wire has been bent more sharply, to give a coil of two turns, each of half the original radius. (a) If B_a and B_b are the magnitudes of the magnetic fields at the centers of the two coils, what is the ratio B_b/B_a ? (b) What is the ratio of the magnitude of the dipole moments, μ_b/μ_a of the coils?

FIGURE 30-49 ■ Problem 52.

53. Student's Electromagnet A student makes a short electromagnet by winding 300 turns of wire around a wooden cylinder of diameter $d = 5.0$ cm. The coil is connected to a battery producing a current of 4.0 A in the wire. (a) What is the magnetic moment of this device? (b) At what axial distance $z \gg d$ will the magnetic field of this dipole have the magnitude $5.0 \mu\text{T}$ (approximately one-tenth that of the Earth's magnetic field)?

54. Helmholtz Figure 30-50 shows an arrangement known as a Helmholtz coil. It consists of two circular coaxial coils, each of N turns and radius R , separated by a distance R . The two coils carry equal currents i in the same direction. Find the magnitude of the net magnetic field at P , midway between the coils.

FIGURE 30-50 ■ Problems 54, 55, and 57.

55. Field as a Function of Distance Two 300-turn coils of radius R each

carry a current i . They are arranged a distance R apart, as in Fig. 30-50. For $R = 5.0$ cm and $i = 50$ A, plot the magnitude $|B(x)| = B(x)$ of the net magnetic field as a function of distance x along the common x axis over the range $x = -5$ cm to $x = +5$ cm, taking $x = 0$ at the midpoint P . (Such coils provide an especially uniform field \vec{B} near point P .) (Hint: See Eq. 30-28).

56. Square Current Loop The magnitude $B(x)$ of the magnetic field at points on the axis of a square current loop of side a is given in Problem 15. (a) Show that the axial magnetic field of this loop, for $x \gg a$, is that of a magnetic dipole (see Eq. 30-29). (b) What is the magnitude of the magnetic dipole moment of this loop?

57. Let the Separation Be In Problem 54 (Fig. 30-50), let the separation of the coils be a variable s (not necessarily equal to the coil radius R). (a) Show that the first derivative of the magnitude of the net magnetic field of the coils (dB/dx) vanishes at the midpoint P regardless of the value of s . Why would you expect this to be true from symmetry? (b) Show that the second derivative (d^2B/dx^2) also vanishes at P , provided $s = R$. This accounts for the uniformity of B near P for this particular coil separation.

58. abcdefgha A conductor carries a current of 6.0 A along the closed path $abcdefgha$ involving 8 of the 12 edges of a cube of side 10 cm as shown in Fig. 30-51. (a) Why can one regard this as the superposition of three square loops: $bcfgb$, $abgha$, and $cdefc$? (Hint: Draw currents around those square loops.) (b) Use this superposition to find the magnetic dipole moment $\vec{\mu}$ (magnitude and direction) of the closed path. (c)

FIGURE 30-51 ■ Problem 58.

Calculate the magnitude and direction of the magnetic field \vec{B} at the points $(x, y, z) = (0.0 \text{ m}, 5.0 \text{ m}, 0.0 \text{ m})$ and $(5.0 \text{ m}, 0.0 \text{ m}, 0.0 \text{ m})$.

59. What Torque A circular loop of radius 12 cm carries a current of 15 A. A flat coil of radius 0.82 cm, having 50 turns and a current of 1.3 A, is concentric with the loop. (a) What magnetic field \vec{B} (magnitude and direction) does the loop produce at its center? (b) What torque acts on the coil? Assume that the planes of the loop and coil are perpendicular and that the magnetic field due to the loop is essentially uniform throughout the volume occupied by the coil.

60. Two Different Arcs A length of wire is formed into a closed circuit with radii a and b , as shown in Fig. 30-52 and carries a current i . (a) What are the magnitude and direction of \vec{B} at point P ? (b) Find the magnetic dipole moment of the circuit.

FIGURE 30-52 ■ Problem 60.

Additional Problems

61. Cross Section of a Wire Figure 30-53 shows the cross section of a wire that is perpendicular to the plane of the paper. Suppose a com-

pass is placed at location A , which is a distance r from the wire. The compass points in the direction shown in the diagram. (a) Resketch

the diagram and draw arrows to show what direction you expect the compass to point if it were moved to locations *B* and *C*. *Note:* Use the symbol \odot if the flow is out of the page and the symbol \otimes if the flow is into the page. (b) Indicate in what direction *positive current* is flowing through the wire and describe the rule you are using to deduce the direction of current in the wire. (c) What is the direction of the flow of *electrons* through the wire?

FIGURE 30-53 ■ Problem 61.

62. Wires in a *B*-Field A uniform magnetic field is directed toward the right in the plane of the paper as shown in Fig. 30-54. A wire lying perpendicular to the plane of the paper at location *A* carries

FIGURE 30-54 ■ Problem 62.

a current *i*. Suppose that the resultant magnetic field at point *D* due to a superposition of the uniform magnetic field of magnitude *B* and the magnetic field of the wire of magnitude *B_w* is zero. (a) Is the direction of the current in the wire into or out of the paper? Explain how you arrived at your conclusion. (b) Assume that point *A* lies at the same distance from the center of the wire as point *D* and that the length of the vector assigned to represent the magnitude of the uniform external magnetic field is that shown on the right. Construct a vector diagram showing the net magnetic field vector *B_A^{net}* at point *A*. (c) Assume that point *C* is twice the distance from the center of the wire as point *D*. Construct a vector diagram showing the net magnetic field vector, *B_C^{net}*, at point *C*. (Adapted from A. Arons, Homework and Test Questions for Introductory Physics Teaching, John Wiley and Sons, 1994.)

63. Earth's Field The magnitude of the Earth's magnetic field, *B*, at either geomagnetic pole, is about 7×10^{-5} T. Using a model in which you assume that this field is produced by a single current loop at the equator, determine the current that would generate such a field ($R_e = 6.37 \times 10^6$ m). *Hint:* The magnitudes of the magnetic field due to a single current loop of radius *R* at a distance *R* from its center and perpendicular to the plane of the loop is given by the equation

$$B = \frac{\mu_0 |i|}{2\sqrt{8}R}$$

FIGURE 30-55 ■ Problem 63.

64. Comparing Electric and Magnetic Forces One In this problem we consider situations corresponding to three different long thin lines of matter containing charges: 1. A copper wire carrying an electric current from left to right, 2. A long amber rod that has been rubbed with fur and has a uniform excess of negative charge, and 3.

FIGURE 30-56 ■ Problem 64.

A beam of electrons passing from left to right through a vacuum inside a cathode ray tube. The direction of the electric current and of the electron flow are from left to right. Figure 30-56 shows a location marked *x* and a set of directions with labels on the right.

(a) For each of the three lines of matter, indicate in what direction the electric and magnetic fields at the location *x* would point. To indicate the direction, use one of the letters associated with a directional arrow on the “compass” in Fig. 30-56. If any of the fields are zero, write 0. (b) Now consider placing a positive charge at the location *x*. In one case it is stationary, while in a second case it is moving in the direction *C* (to the right). Indicate the direction nearest to the total force the charge would feel. (Ignore gravity and air resistance.) Do this for all three lines of matter and for both cases.

65. Comparing Electric and Magnetic Forces Two

Figure 30-57 shows a long wire carrying a current *i* to the right and a long amber rod with a charge density (charge/unit length) of λ . Assume that *i* and λ are both positive.

FIGURE 30-57 ■ Problem 65.

(a) The two are separated by a distance *d*. The point marked *x* is halfway between them. Copy this figure onto your paper and draw arrows to represent the following. (Be sure to label your arrows clearly to show which one is which.)

- the direction of the magnetic field at the point marked *x*
- the direction of the electric field at the point marked *x*
- the direction of the electric force that a positive charge *q* placed at *x* would feel
- the direction of the magnetic force that a positive charge *q* placed at *x* would feel if it were moving to the right.

(b) The current, *i*, is +10 A, the charge density, λ , is -1 nC/m ($= 10^{-9}$ C/m) (note that it is negative), and the distance between the wires is 40 cm. At the instant shown, a proton with charge $q = 1.6 \times 10^{-19}$ C is moving into the page with a speed $v = 10^6$ m/s. Ignoring gravity, what is the magnitude and direction of the net force the proton feels at that time?

66. Direction of Magnetic Forces Figure 30-58 shows a cross section of four long parallel wires (labeled *A* through *D*) taken in a plane perpendicular to the wires. One or more of the wires may be carrying a current. If a wire carries a current, *i₀*, it is in the direction indicated and has strength $|i_0|$.

FIGURE 30-58 ■ Problem 66.

For each of the four vector quantities listed in (i) through (iv) below give the direction of the quantity. To indicate the direction, use one of the directions on the “compass” in Fig. 30-58. If the magnitude of the quantity is zero, write “0.” If it is nonzero but in none of the indicated directions, write “Other.”

- Only wires B and D are carrying current. The direction of the force on wire D is _____.
- Only wires B and D are carrying current. The direction of the force felt by an electron traveling in the E direction (on the compass) is _____.
- Only wires B and D are carrying current. The direction of the force felt by an electron traveling in the N direction (on the compass) is _____.
- All four wires are carrying current. The direction of the net force felt by wire A is _____.

67. Magnetic Forces and Fields Figure 30-59 shows a cross section of three long parallel wires (labeled A through C) taken in a plane perpendicular to the wires. One or more of the wires may be carrying a current. If a wire carries a current, i_0 , it is in the direction indicated and has strength $|i_0|$. For each of the five vector quantities (1) through (5) shown, indicate the direction of the quantity on the compass in Fig. 30-59. If the magnitude of the quantity is zero, write “0.” If the result is not zero but points in a direction other than one of those indicated, write “other.”

FIGURE 30-59 ■ Problem 67.

- The magnetic field at point P if only wire A is carrying a current
- The magnetic field at wire C if only wire A is carrying a current
- The magnetic force on wire C if only wires A and C carry currents
- The magnetic force on wire C if only wire A is carrying a current
- The magnetic force on a proton at P traveling to the right (i.e., in direction E) if only wire B is carrying a current.

68. Right-Hand Rules During our discussions of magnetism and rotation we have encountered a number of different right-hand

rules for obtaining the direction or sign of various quantities. Describe three right-hand rules. In your discussion of each one, include a statement of the equation or law in which the rule is applied, and whether the rule is “fundamental” or derived from a more basic principle.

69. Magnetic Forces Figure 30-60 shows parts of two long, current-carrying wires labeled 1 and 2. The wires lie in the same plane and cross at right angles at the point indicated. When carrying a current, each wire carries the same amount of current in the direction shown. At the right is shown

FIGURE 30-60 ■ Problem 69.

a set of coordinate directions for describing the direction of vectors.

For each of the vectors discussed, indicate the direction of the vector using the coordinate system shown. For example, you might specify “the $+x$ direction” or “the $-z$ direction” or “in the x - y plane at 45° between the $+x$ and $+y$ directions.” If the magnitude of the vector requested is zero, write “0.”

- The direction of the force on a positively charged ion at the point B moving in the $+y$ direction if only wire 1 carries current
- The direction of the force on a positively charged ion at the point B moving in the $-z$ direction if both wires carry current
- The direction of the force on a positively charged ion at the point A moving in the $+x$ direction if only wire 2 carries current

For the next two parts of the problem, select which answer is correct if both wires carry current.

- The magnetic force on wire 1 will
 - push it in the $-z$ direction
 - push it in the $+z$ direction
 - tend to rotate it clockwise about the joining point
 - tend to rotate it counterclockwise about the joining point
 - none of the above
- The magnetic force on wire 2 will
 - push it in the $-z$ direction
 - push it in the $+z$ direction
 - tend to rotate it clockwise about the joining point
 - tend to rotate it counterclockwise about the joining point
 - none of the above

70. Constrained to a Circle Figure 30-61 shows, in cross section, two long straight wires held against a plastic cylinder of radius 20.0 cm. Wire 1 carries current $i_1 = 60.0$ mA out of the page and is fixed in place at the left side of the cylinder. Wire 2 carries current $i_2 = 40.0$ mA out of the page and can be moved around the cylinder. At what angle θ_2 should wire 2 be positioned such that the net magnetic field at the origin from the two currents has a magnitude of 80.0 nT?

FIGURE 30-61 ■ Problem 70.

71. Element Length Figure 30-62a shows an element of length $ds = 1.00 \mu\text{m}$ in a very long straight wire carrying current. The current in that element sets up a differential magnetic field $d\vec{B}$ at points in the surrounding space. Figure 30-62b gives the magnitude dB of the field in pico-Teslas (10^{-12}T) for points 2.5 cm from the element, as a function of angle θ between the wire and a straight line to the point. What is the magnitude of the magnetic field set up by the entire wire at perpendicular distance 2.5 cm from the wire?

FIGURE 30-62 ■ Problem 71.

72. Where Is Wire 2 Two long straight thin wires with current lie against an equally long plastic cylinder, at radius $R = 20.0 \text{ cm}$ from the cylinder's central axis. Figure 30-63a shows, in cross section, the cylinder and wire 1 but not wire 2. With wire 2 fixed in place, wire 1 is moved around the cylinder, from angle $\theta_1 = 0^\circ$ to angle $\theta_1 = 180^\circ$, through the first and second quadrants of the xy coordinate system. The net magnetic field \vec{B} at the center of the cylinder is measured as a function of θ_1 . Figure 30-63b gives the x -component B_x of that field in micro-Teslas (10^{-6}T) and Fig. 30-63c gives the y -component B_y , both as functions of θ_1 . (a) At what angle θ_2 is wire 2 located? What are the size and direction of the currents in (b) wire 1 and (c) wire 2?

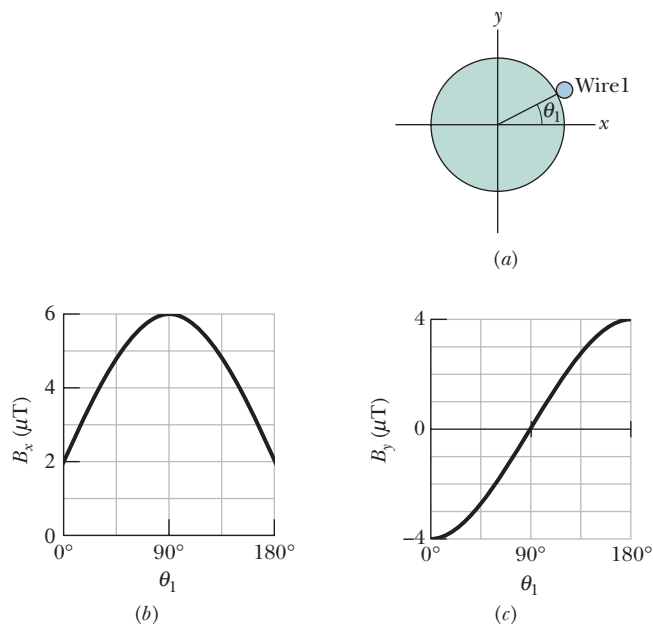

FIGURE 30-63 ■ Problem 72.

73. The Ratio of Currents Figure 30-64a shows, in cross section, two long, parallel wires carrying current and separated by distance L . The ratio $|i_1/i_2|$ of their current amounts is 4.00; the directions of the currents are not indicated. Figure 30-64b shows the y -compo-

nent B_y in nano-Teslas (10^{-9}T) of their net magnetic field along the x axis to the right of wire 2. (a) At what value of $x > 0$ is B_y maximum? (b) If $|i_2| = 3 \text{ mA}$, what is the value of the maximum? What are the directions of (c) current i_1 and (d) current i_2 ?

FIGURE 30-64 ■ Problem 73.

74. Same Radius Different Current In Fig. 30-65a two circular loops, with different currents but the same radius of 4.0 cm, are centered on a y axis. They are initially separated by distance $L = 3.0 \text{ cm}$, with loop 2 positioned at the origin of the axis. The currents in the two loops produce a net magnetic field at the origin, with y -component B_y . That component is to be measured as loop 2 is gradually moved in the positive direction of the y axis. Figure 30-65b gives B_y in micro-Teslas (10^{-6}T) as a function of the position y of loop 2. The curve approaches an asymptote of $B_y = 7.20 \mu\text{T}$ as $y \rightarrow \infty$. What are (a) current i_1 in loop 1 and (b) current i_2 in loop 2?

FIGURE 30-65 ■ Problem 74.

75. How Many Revolutions An electron is shot into one end of a solenoid, as it enters the uniform magnetic field within the solenoid, its speed is 800 m/s and its velocity vector makes an angle of 30° with the central axis of the solenoid. The solenoid carries 4.0 A and has 8000 turns along its length. How many revolutions does the electron make along its helical path within the solenoid by the time it emerges from the solenoid's opposite end? (In a real solenoid, where the field is not uniform at the two ends, the number of revolutions would be slightly less than the answer here.)

76. Force per Unit Length Two Figure 30-66 shows wire 1 in cross section; the wire is long and straight, carries a current of 4.00 mA out of the page, and is at distance $d_1 = 2.4 \text{ cm}$ from a surface. Wire 2, which is parallel to wire 1 and also long, is at horizontal distance $d_2 = 5.0 \text{ cm}$ from wire 1 and carries a current of 6.80 mA into the page. What is the x component of the magnetic force per unit length on wire 2 due to the current in wire 1?

FIGURE 30-66 ■ Problem 76.

Induction and Maxwell's Equations

The General Motors EV1 electric car was marketed in the southwest with two generations of vehicles in 1997 and 1999. Production was completed in 1999 and all leases have been assigned. The EV1 had no engine, tailpipe, valves, pistons, timing belts, or crankshaft. The EV1 came with an inductive charging system in which there was no metal-to-metal connection. The charger, which plugged into a 220-volt outlet, had a paddle which, when inserted into the charge port at the front of the car, provided the electricity to re-charge the batteries.

How can electric car batteries be charged without making electrical contact with the power source?

The answer is in this chapter.

31-1 Introduction

In the previous chapter we discovered that the moving charges that make up electric currents create magnetic fields. We also learned that both permanent magnets and moving charges can exert forces on each other. These discoveries have powerful practical consequences. They allow us to build electromagnets to create large magnetic fields. More significantly, they enable us to harness the forces these large magnetic fields can exert on moving charges to create electric motors capable of moving massive objects.

In 1820, when Oersted observed that electric currents create magnetic fields, a number of prominent scientists began to look for ways to use magnetic fields to create currents. For more than a decade, scientists searched for current induced by static magnetic fields and failed to find it. By 1831, both Michael Faraday (Fig 31-1) and an American physicist, Joseph Henry, had discovered that a *changing* magnetic field is required to induce electric current. This phenomenon is called **electromagnetic induction**.

The discovery of electromagnetic induction, usually credited to Faraday, was of tremendous technological importance. Induction made it possible to create electric power from motion. Indeed, by the end of the 19th century, systems had been developed for the generation and transmission of electric power. Applications of Faraday's and Henry's discoveries are found in the design of thousands of electrical devices including transformers, high-speed trains, inductive battery chargers, and electric guitar pickups.

Although the practical benefits of the discovery of induction are tremendous, so is its impact on science. Many scientists view Faraday's law of induction as one of the most profound laws in all of classical physics because it "closed the loop" between magnetism and electricity. By combining Faraday's law with Ampère's law, we can understand how electricity and magnetism can be treated as complimentary aspects of the same phenomenon. By the middle of the 19th century, James Clerk Maxwell incorporated the ideas of Faraday and others into a famous set of four equations describing electromagnetic phenomena. In this chapter you will learn about the characteristics of electromagnetic induction and about Maxwell's synthesis of electromagnetic interactions.

READING EXERCISE 31-1: Why did it take so long for scientists working in the early 19th century to actually observe magnetic induction? ■

31-2 Induction by Motion in a Magnetic Field

Let us start our treatment of electromagnetic induction by considering what happens if we move a coil of conducting wire at a constant velocity through a uniform magnetic field and then out of the field as shown in Fig. 31-2. This is not the observation made by Faraday. We will describe that later. Notice that the diagram shows the plane of the coil is always perpendicular to the direction of the magnetic field. Under what conditions can a current be induced? We will consider this situation from both an experimental and a theoretical perspective.

FIGURE 31-1 ■ Michael Faraday, a famous English scientist, is credited with the discovery of electromagnetic induction.

FIGURE 31-2 ■ It is not difficult to measure the current induced in a coil of wire while it is being pulled out of the gap between a pair of ferrite blocks separated by wooden spacers. The magnetic field in the central area between the magnetic blocks is essentially uniform. The ends of a multiloop coil are connected to an electronic current sensor.

FIGURE 31-3 ■ A computer data acquisition system is used to measure the induced current 200 times a second as the coil shown in Fig. 31-2 is pulled steadily out of the uniform magnetic field in the central part of the gap between the two magnetic ferrite blocks. From 0.0 s to 0.3 s the entire coil is in the uniform magnetic field. After 0.9 s the coil is entirely outside the magnetic field. Between 0.3 s and 0.9 s part of the coil is in the B -field and part is outside of it.

A Conductor Moving Through a Magnetic Field—Observation

If we connect the ends of the coil to an ammeter, we see the needle jump back and forth a bit erratically during the time that the coil is passing out of the gap between the magnets. When the whole area of the coil is still in the central part of the gap between the magnets, the ammeter needle points to zero. When the coil has completely emerged from the region of space influenced by the magnets, the ammeter needle points to zero once again. This current jump can be seen in more detail using an electronic current sensor as shown in Fig. 31-3.

Both casual observation with a sensitive ammeter and the data gathered using an electronic current sensor show that for this situation:

- When the coil is not moving, there is no induced current no matter what the steady magnetic field is like at its location.
- When the coil is moving through a region where the magnetic field is entirely uniform or zero, there is no induced current.
- When the coil is moving through a region where the steady magnetic field is not uniform, a current is induced.

We can draw the following conclusion from these observations:

OBSERVATION: When a conducting loop moves perpendicular to a magnetic field, a current will be induced whenever the coil experiences a *changing* magnetic field.

FIGURE 31-4 ■ A piece of wire is pulled through a uniform magnetic field at a constant velocity and becomes polarized.

FIGURE 31-5 ■ The right-hand rule for the magnetic force law provides an “upward” force on positive charges and a “downward” force on mobile negative charges present in the wire shown in Fig. 31-4.

A Conductor Moving Through a Magnetic Field—Theory

Although it's not obvious without reflection, you are capable of predicting that a *changing* magnetic field is required to induce an electric current in a moving coil. This induction is a natural consequence of the magnetic force laws described in Eqs. 29-2 and 29-23.

Straight Conductor Moving in a Uniform \vec{B} -Field: Let's start by using the force law to predict what happens to a straight piece of conducting wire if we pull it at a constant velocity in a direction perpendicular to a uniform magnetic field (Fig. 31-4). Each of the charges in the conductor experiences a force given by the magnetic force law, $\vec{F}^{\text{mag}} = q\vec{v} \times \vec{B}$ (Eq. 29-2). The direction of the force is given by the right-hand rule for cross products as shown in Fig. 31-5. Since there are mobile electrons in metals, these electrons will move toward the bottom of the wire, exposing fixed excess positive charge at the top of the wire. Thus, a current will flow in the wire for an instant until the electric field created by the charge separation opposes any further electron flow.

Loop Moving in a Uniform \vec{B} -Field: Perhaps we can induce a current by forming a closed loop instead of a single length of wire. This doesn't help because both the left

and right segments (a and c in Fig. 31-6) are perpendicular to the motion, so they become polarized in the same manner. This merely results in excess charge piling up on the top and bottom segments (b and d as shown in Fig. 31-6).

Loop Moving from a Uniform \vec{B} -Field to No Field: The easiest way to create a current using the polarization caused by the magnetic force law is to pull our loop in such a way that segment a is inside the magnetic field and segment c is not. Now what happens? We can see from Fig. 31-7 that the electrons in segment a , which is the trailing loop segment, continue to have magnetic forces exerted on them. But there are no forces on electrons in segment c of the loop because these electrons are not in the magnetic field. The only force that contributes to the current flow in the loop is the force on the left segment of wire, so the electrons in this segment of wire are pushed downward. The result is a net flow of electrons in a counterclockwise direction. Since “conventional current” as defined in Chapter 26 represents the flow of positive charge carriers, conventional current flow would be clockwise as shown in Fig. 31-7.

Nonuniform \vec{B} -Field: Theoretically we still expect to be able to induce a current in our loop in any nonuniform magnetic field. For example, suppose the magnetic field in Fig. 31-7 is weaker (but not necessarily zero) on the right side of the loop (near segment c) than it is at the left (near segment a). In this case, the magnetic forces on electrons in the left and right segments of the loop will no longer be equal and the forces on the charges in one of the segments will overpower those on the charges in the other segments. This will cause a net current to be induced.

Our theoretical considerations enable us to conclude that by applying the magnetic force law, we can predict the results of the observations presented in the first part of this section: When a conducting loop moves perpendicular to a magnetic field, then a current will be induced whenever the coil experiences a *changing* magnetic field through it.

READING EXERCISE 31-2: In the discussion above, we determined that the forces on the electrons in the top and bottom segments of the wire loop shown in Fig. 31-6 did not contribute to the current flow. Why is this the case? ■

READING EXERCISE 31-3: Suppose the magnetic field shown in Fig. 31-6 varies continuously in such a way that it is always stronger on the right than it is on the left. What will be the direction of the resulting (conventional) current in the loop? Explain. ■

31-3 Induction by a Changing Magnetic Field

Michael Faraday made a significant contribution to physics when he asked: What happens if instead of moving the wire loop in a magnetic field we keep the wire loop *stationary* and move a magnet toward or away from the loop to create a “moving” or changing magnetic field? One might argue that since the electrons in the wire are not moving in this case, the velocity of the loop segments used in the magnetic force law expression is zero and so there should be no force on the electrons and therefore no current. On the other hand, in many ways these two situations are the same. In order to answer his question, Faraday made observations similar to those discussed below.

Observation 1, with a magnet: Figure 31-8 shows a conducting loop connected to a sensitive ammeter. Since there is no battery or other source of emf included, there is no current in the circuit. What happens if we move a bar magnet toward the loop? We observe that a current suddenly appears in the circuit! But the current disappears as soon as the magnet stops moving. If we then move the magnet away, a current again

FIGURE 31-6 ■ A wire loop is pulled by a string through a uniform magnetic field at a constant velocity. Although excess charge accumulates on the top and bottom segments (b and d), no current is induced in the loop.

FIGURE 31-7 ■ A wire loop is pulled by a string through a region where the magnetic field is uniform on one side and zero on the other. Electrons from segment a are allowed to flow counterclockwise around the loop. The conventional current flow is clockwise.

FIGURE 31-8 ■ An idealized setup showing a current meter registering nonzero currents in a stationary wire loop when a magnet is moving near the loop. (Typically a multiturn loop is needed to generate a detectable current.)

FIGURE 31-9 ■ The current induced as a magnet is dropped through a stationary multiturn coil (like that shown in Fig. 31-8). A computer data acquisition system is used to record current data at 2000 points/second.

FIGURE 31-10 ■ An idealized setup showing an ammeter registering a current in the left-hand wire loop while switch S is being closed or opened (to turn the current in the right-hand loop on and off). No motion of the coils is involved. Faraday made essentially the same observation using multi-loop coils.

suddenly appears, but now in the opposite direction. If we experimented for a while, we would observe the following:

1. A current appears only if there is relative motion between the loop and the magnet (one must move relative to the other, but it doesn't matter which one); the current disappears when the relative motion between them ceases. See Fig. 31-9 for a graph of the current induced by a magnet dropped through a stationary coil.
2. Faster motion produces a greater current.
3. If moving the magnet's north pole toward the loop causes, say, clockwise current, then moving the north pole away causes counterclockwise current. Moving the south pole toward or away from the loop also causes current, but in the reversed direction.

We call the current produced in the loop an **induced current**; the work done per unit charge to produce that current (to move the conduction electrons that constitute the current) is called an **induced emf**, and the process of producing the current and emf is called induction. Currents that are caused by batteries in a circuit and those caused by induction in a wire loop are the same—mobile electrons are flowing through wires.

Observation 2, replacing the magnet with a current-carrying coil: Let us now perform a second observation. For this observation we use the apparatus of Fig. 31-10, with the two conducting loops close to each other but not touching. If we close switch S to turn on a current in the right-hand loop, the meter suddenly and briefly registers a current—an induced current—in the left-hand loop. If we then open the switch, another sudden and brief induced current appears in the left-hand loop, but in the opposite direction. We get an induced current (and thus an induced emf) only when the current in the right-hand loop is changing (either when turning on or off) and not when it is constant (even if the current is large). The outcome of this second observation is not surprising. We know from Ampère's law (Chapter 30) that the magnitude of the magnetic field surrounding a current-carrying wire increases as the current increases and its direction changes when the direction of current changes.

Faraday also noticed that the actual amount of magnetic field present at the area enclosed by the loop does not matter. Instead, the values of the induced emf and induced current are determined by the *rate* at which the amount changes.

When we pull all of these observations together, the way Faraday did, we conclude that

Induced emf and current are present whenever the magnetic field present in the area subtended by the conducting loop *changes* for any reason.

The amount of induced emf and current increases as a function of the rate of change of the magnetic field present at the area subtended by the loop.

Charging an Electric Car by Induction

Suppose we replace the switch in Fig. 31-10 with a source of current in the right-hand loop that varies over time sinusoidally. Then we create a magnetic field at the location of the left-hand loop that is also changing sinusoidally in time. This time-varying magnetic field then induces current in the left-hand loop that varies with time as well. By using some circuitry to filter out the negative current, we can use this induced current to charge a battery even though there is *no electrical contact* between the right- and left-hand loops. This type of noncontact charging is also used for charging familiar

devices such as electric toothbrushes. Although an actual charger for an electric toothbrush or car like that discussed in the chapter-opening puzzler has more loops of wire and electrical circuits in it, it works on the same principle of electromagnetic induction discovered by Henry and Faraday in the early 19th century.

One drawback of inductive charging is that it is slower than direct charging. This is not a problem for electric toothbrush charging, but it is for electric car charging. This is probably one reason why the inductively charged General Motors EV1 cars like the one shown in the chapter puzzler have been taken off the market. You will learn more about the practical applications of induction in Chapter 32.

READING EXERCISE 31-4: Can the magnetic force law be used to explain why a current appears in a stationary loop when a bar magnet is brought close to it? If so, use your understanding of this force law to explain how this happens. If not, justify why not. ■

READING EXERCISE 31-5: Consider the induced current data shown in Fig. 31-9. The magnet is accelerating as it falls through the stationary coil. The magnet is dropped in free fall. The extrema of currents are about +8mA and -35mA. Why is the negative extremum larger? ■

31-4 Faraday's Law

We can enhance the predictive power of Faraday's qualitative observations by developing a mathematical formulation of electromagnetic induction. The mathematical expression that describes electromagnetic induction is commonly known as **Faraday's law**. Although we derive Faraday's law for a simplified situation using concepts and laws that we have already introduced, it can be applied to virtually any situation.

Magnetic Flux

To begin we use the concept of magnetic flux to quantify the amount of magnetic field at the area enclosed by a loop. In Chapter 24, in a similar situation, we needed to calculate the amount of an electric field present on a surface. There we determined electric flux for a small element of essentially flat area in Eq. 24-2 as $\Phi^{\text{elec}} = \vec{E} \cdot \Delta\vec{A}$ (the dot product of the normal vector representing a small area and the electric field vector at the location of the area). By analogy, the *magnetic flux* at the surface of a small area element $\Delta\vec{A}$ that is located in a magnetic field \vec{B} is defined as

$$\Phi^{\text{mag}} = \vec{B} \cdot \Delta\vec{A} \quad (\text{magnetic flux at an area } \Delta\vec{A}). \quad (31-1)$$

Simply put, the flux of magnetic field Φ^{mag} at an area element A is the product of the area element and the component of the field *perpendicular* to it for a uniform magnetic field. The validity of this basic definition depends on the assumption that the magnetic field \vec{B} is uniform over the surface element $\Delta\vec{A}$. If the field varies over the area, we must break the area up into little pieces in such a way that the field will be about constant for each piece. We then calculate the flux in each little piece and perform an integration to add up all the little contributions in analogy to the more general definition of electric flux.

From Eq. 31-1, we see that the SI unit for magnetic flux is the tesla-square meter, which is called the weber (abbreviated Wb):

$$1 \text{ weber} = 1 \text{ Wb} = 1 \text{ T} \cdot \text{m}^2. \quad (31-2)$$

Using our simplified formulation of magnetic flux, we are now ready to derive Faraday's law.

FIGURE 31-11 ■ A wire loop is moving at a constant velocity through a region where the magnetic field is uniform on one side and zero on the other. While this is happening, the magnetic flux at the area subtended by the coil is decreasing at a constant rate.

A Simplified Derivation of Faraday's Law

Consider the simple situation depicted in Fig. 31-7 in which a wire loop is being pulled out of a uniform magnetic field at a constant velocity. Next we derive the relationship between the emf induced in the loop and the rate of change of the magnetic flux enclosed by the loop. To help us with the derivation we have redrawn the situation and introduced symbols for the dimensions of the loop and the axis along which it moves in Fig. 31-11.

According to the magnetic force law, each charge in the left part of the loop (segment *a*) will experience a force of magnitude $F^{\text{mag}} = qvB$. As the positive and negative charges separate, an electric field of magnitude

$$E = \frac{F^{\text{mag}}}{|q|} = vB \quad (31-3)$$

will be generated. If segment *a* has a length *L*, then the potential difference of induced emf across it is given by

$$\mathcal{E} = EL = vBL. \quad (31-4)$$

Next we need to relate the right side of Eq. 31-4 to the rate at which the magnetic flux at the area subtended by the loop is decreasing as it moves out of the uniform *B*-field. If we designate the loop as being pulled in the *x* direction, then its velocity component can be expressed as $v_x = dx/dt$. Note that the area of the moving loop is decreasing at a rate given by $dA/dt = -L dx/dt = -Lv_x$. Since the magnetic field that subtends the left part of the area enclosed by the loop is constant, the rate of change of the magnetic flux at the loop can be expressed as

$$\frac{d\Phi^{\text{mag}}}{dt} = \frac{d(BA)}{dt} = B \frac{dA}{dt} = -v_x BL. \quad (31-5)$$

Combining Eqs. 31-4 with 31-5, we get an expression for Faraday's law for a single loop or coil,

$$\mathcal{E} = -\frac{d\Phi^{\text{mag}}}{dt} \quad (\text{Faraday's law for a single-turn coil}). \quad (31-6)$$

As you will see in the next section, the induced emf \mathcal{E} tends to oppose the flux change, and the minus sign indicates that opposition. Faraday's law can also be expressed in words:

The amount of the emf \mathcal{E} induced in a conducting loop is equal to the rate at which the magnetic flux Φ^{mag} at the area enclosed by the loop changes with time.

FIGURE 31-12 ■ It is quite easy to verify Faraday's law with modern apparatus and computer data acquisition systems. Here a student holds a small multitrans pickup coil inside a larger field coil that is generating a "sawtooth" magnetic field that increases and then decreases continuously. The *B*-field is shown on the jagged dark red trace on the computer screen. The induced current in the pickup coil is shown by the squarish lighter green trace. (Photo courtesy of PASCO scientific.)

If we change the magnetic flux at a coil of *N* turns, an induced emf appears in every turn and the total emf induced in the coil is the sum of these individual induced emfs. If the coil is tightly wound (closely packed), so that the same magnetic flux Φ^{mag} is present in each turn, the total emf induced in the coil is

$$\mathcal{E} = -N \frac{d\Phi^{\text{mag}}}{dt} \quad (\text{Faraday's law for an } N\text{-turn coil}). \quad (31-7)$$

Although we have used simple geometry to derive Faraday's law (Eq. 31-7), experiments (such as the one shown in Fig. 31-12) have verified that the mathematical expression we have derived is true for any situation where the flux enclosed by a set

of conducting loops or coils is changing. In fact, there are many ways to change the magnetic flux at a coil and thus induce emfs and currents:

1. Change the magnitude B of the magnetic field within the coil.
2. Change the area of the coil, or the portion of that area that happens to lie within the magnetic field (for example, by expanding the coil or sliding it out of the field).
3. Change the angle between the direction of the magnetic field \vec{B} and the area of the coil (for example, by rotating the coil so that \vec{B} is first perpendicular to the plane of the coil and then is along that plane).

Later on in the chapter we will derive a more general form of Faraday's law that relates flux change to electric field induction even when no charges or conducting loops are present.

READING EXERCISE 31-6: The graph gives the magnitude $B(t)$ of a magnetic field that exists throughout the area subtended by a conducting loop, perpendicular to the plane of the loop. Although it changes with time, at any particular instant the magnetic field is uniform over the area of the loop. (a)

Rank the five time intervals (a , b , c , d , and e) shown on the graph according to the amount of the emf $|\mathcal{E}|$ induced in the loop, greatest first. (b) Explain your reasoning. ■

TOUCHSTONE EXAMPLE 31-1: Coil in a Long Solenoid

The long solenoid S shown (in cross section) in Fig. 31-13 has 220 turns/cm and carries a current $i = 1.5$ A; its diameter D is 3.2 cm. At its center we place a 130-turn, closely packed coil C of diameter $d = 2.1$ cm. The current in the solenoid is reduced to zero at a steady rate in 25 ms. What is the size of the emf $|\mathcal{E}|$ that is induced in coil C while the current in the solenoid is changing?

SOLUTION ■ The **Key Ideas** here are these:

1. Because coil C is located in the interior of the solenoid, it lies within the magnetic field produced by current i in the solenoid; thus, there is a magnetic flux Φ^{mag} present in coil C .
2. Because current i decreases, flux Φ^{mag} also decreases.
3. As Φ^{mag} decreases, emf \mathcal{E} is induced in coil C , according to Faraday's law.

Because coil C consists of more than one turn, we apply Faraday's law in the form of Eq. 31-7 ($\mathcal{E} = -N d\Phi^{\text{mag}}/dt$), where the number

FIGURE 31-13 ■ A coil C is located inside solenoid S , which carries current i .

of turns N is 130 and $d\Phi^{\text{mag}}/dt$ is the rate at which the flux in each turn changes.

Because the current in the solenoid decreases at a steady rate, flux Φ^{mag} also decreases at a steady rate and we can write $d\Phi^{\text{mag}}/dt$ as $\Delta\Phi^{\text{mag}}/\Delta t$. Then, to evaluate $\Delta\Phi^{\text{mag}}$, we need the final and initial flux. The final flux Φ_f^{mag} is zero because the final current in the solenoid is zero. To find the initial flux Φ_i^{mag} , we need two more **Key Ideas**:

4. The flux at the area enclosed by each turn of coil C depends on the area A and orientation of that turn in the solenoid's magnetic field \vec{B} . Because \vec{B} is uniform and directed perpendicular to area A , the flux is given by Eq. 31-1 ($\Phi^{\text{mag}} = BA$).
5. The magnitude B of the magnetic field in the interior of a solenoid depends on the solenoid's current i and its number n of turns per unit length, according to Eq. 30-25 ($B = n\mu_0|i|$).

For the situation of Fig. 31-13, A is $\frac{1}{4}\pi d^2 (=3.46 \times 10^{-4} \text{ m}^2)$ and n is 220 turns/cm, or 22 000 turns/m. Substituting Eq. 30-25 into Eq. 31-1 then leads to

$$\begin{aligned}\Phi_i^{\text{mag}} &= BA = (n\mu_0|i|)A \\ &= (22\,000 \text{ turns/m})(4\pi \times 10^{-7} \text{ T}\cdot\text{m/A})(1.5 \text{ A})(3.46 \times 10^{-4} \text{ m}^2) \\ &= 1.44 \times 10^{-5} \text{ Wb}.\end{aligned}$$

Now we can write

$$\begin{aligned}\frac{d\Phi_{\text{mag}}}{dt} &= \frac{\Delta\Phi_{\text{mag}}}{\Delta t} = \frac{\Phi_f^{\text{mag}} - \Phi_i^{\text{mag}}}{\Delta t} \\ &= \frac{(0 - 1.44 \times 10^{-5} \text{ Wb})}{25 \times 10^{-3} \text{ s}} \\ &= -5.76 \times 10^{-4} \text{ Wb/s} = -5.76 \times 10^{-4} \text{ V}.\end{aligned}$$

We are interested only in the size of the emf, so we ignore the minus signs here and in Eq. 31-7, writing

$$\begin{aligned}|\mathcal{E}| &= \left| N \frac{d\Phi_{\text{mag}}}{dt} \right| = (130 \text{ turns})(5.76 \times 10^{-4} \text{ V}) \\ &= 7.5 \times 10^{-2} \text{ V} = 75 \text{ mV}.\end{aligned}\quad (\text{Answer})$$

FIGURE 31-14 ■ Lenz's law at work. As the magnet is moved toward the loop, a current is induced in the loop. The current produces its own magnetic field, with magnetic dipole moment $\vec{\mu}$ oriented so as to oppose the motion of the magnet. Thus, the induced current must be counterclockwise as shown.

31-5 Lenz's Law

Soon after Faraday proposed his law of induction, Heinrich Friedrich Lenz devised a rule—now known as Lenz's law—for determining the direction of an induced current in a loop:

An induced current has a direction such that the magnetic field due to the current opposes the change in the magnetic flux that has induced the current.

It is important to notice that it is the *change* in the flux that determines the direction of the induced current rather than the direction of the magnetic field or motion. Furthermore, the direction of an induced emf is that of the induced current. To get a feel for Lenz's law, let us apply it in two different but equivalent ways to Fig. 31-14, where the north pole of a magnet is being moved toward a conducting loop.

1. Opposition to Flux Change. In Fig. 31-14, with the magnet initially distant, there is no magnetic flux at the area encircled by the loop. As the north pole of the magnet then nears the loop with its magnetic field \vec{B} directed *toward the left*, the flux at the loop increases. To oppose this increase in flux, the induced current i must set up its own field \vec{B}_i directed *toward the right* inside the loop, as shown in Fig. 31-15a; then the rightward flux of field \vec{B}_i opposes the increasing leftward flux of field \vec{B} . The right-hand rule of Fig. 30-19 then tells us that i must be counterclockwise in Fig. 31-15a.

2. Opposition to Pole Movement. The approach of the magnet's north pole in Fig. 31-14 increases the magnetic flux in the loop and thereby induces a current in the loop. From Fig. 30-22, we know that the loop then acts as a magnetic dipole with a south pole and a north pole, and that its magnetic dipole moment $\vec{\mu}$ is directed from south to north. To oppose the magnetic flux increase being caused by the approaching magnet, the loop's north pole (and thus $\vec{\mu}$) must face *toward* the approaching north pole so as

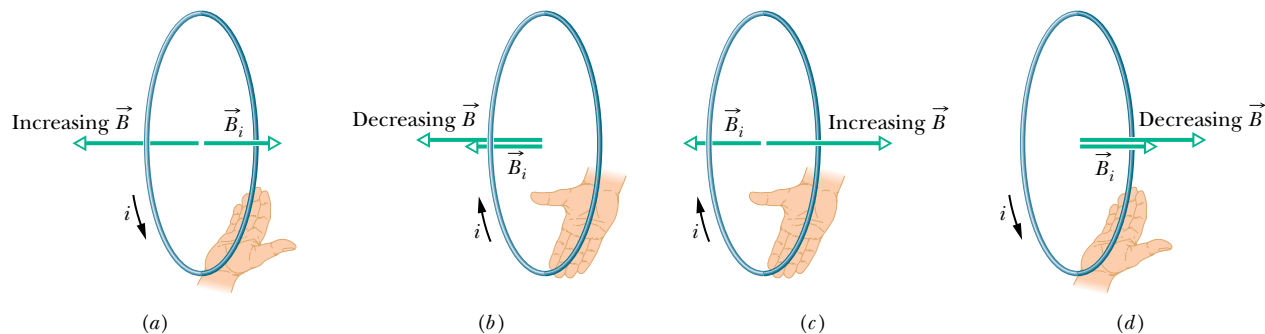

FIGURE 31-15 ■ The current i induced in a loop has the direction such that the current's magnetic field \vec{B}_i opposes the change in the magnetic field \vec{B} inducing i . The field \vec{B}_i is always directed opposite an increasing field \vec{B} shown in (a) and (c) and in the same direction as a decreasing field \vec{B} shown in (b) and (d). The curled-straight right-hand rule gives the direction of the induced current based on the direction of the induced field.

to repel it (Fig. 31-14). Then the curled-straight right-hand rule for $\vec{\mu}$ (Fig. 30-22) tells us that the current induced in the loop must be counterclockwise in Fig. 31-14.

If we next pull the magnet away from the loop, a current will again be induced. Now, however, the loop will have a south pole facing the retreating north pole of the magnet, so as to oppose the retreat. Thus, the induced current will be clockwise.

As we noted above, be careful to remember that the flux of \vec{B}_i always opposes the *change* in the flux of \vec{B} , but that does not always mean that \vec{B}_i points opposite \vec{B} . For example, if we pull the magnet away from the loop in Fig. 31-14, the flux Φ^{mag} from the magnet is still directed to the left at the area subtended by the loop, but it is now decreasing. The flux of \vec{B}_i must now be to the left inside the loop, to oppose the *decrease* in Φ^{mag} , as shown in Fig. 31-15*b*. Thus, \vec{B}_i and \vec{B} are now in the same direction.

Figures 31-15*c* and *d* show the situations in which the south pole of the magnet approaches and retreats from the loop, respectively. Figure 31-16 is a photo of a demonstration of Lenz's law in action.

Electric Guitars

Soon after rock began in the mid-1950s, guitarists switched from acoustic guitars to electric guitars—but it was Jimi Hendrix who first used the electric guitar as an electronic instrument. He was able to create new sounds that continue to influence rock music today. What is it about an electric guitar that enabled Hendrix to make different sounds?

Whereas an acoustic guitar depends for its sound on the acoustic resonance produced in the hollow body of the instrument by the oscillations of the strings, an electric guitar like that being played by Hendrix in Fig. 31-17 is a solid instrument, so there is no body resonance. Instead, the oscillations of the metal strings are sensed by electric “pickups” that send signals to an amplifier and a set of speakers.

The basic construction of a pickup is shown in Fig. 31-18. Wire connecting the instrument to the amplifier is coiled around a small magnet. The magnetic field of the magnet produces a north and south pole in the section of the metal string just above the magnet. That section of string then has its own magnetic field. When the string is plucked and thus made to oscillate, its motion relative to the coil changes the flux of its magnetic field at the area encircled by the coil, inducing a current in the coil. As the string oscillates toward and away from the coil, the induced current changes direction at the same frequency as the string's oscillations, thus relaying the frequency of oscillation to the amplifier and speaker.

On a Stratocaster[®], there are three groups of pickups, placed near the bridge at the end of the wide part of the guitar body. The group closest to the bridge better detects the high-frequency oscillations of the strings; the group farthest from the near end better detects the low-frequency oscillations. By throwing a toggle switch on the guitar, the musician can select which group or which pair of groups will send signals to the amplifier and speakers.

To gain further control over his music, Hendrix sometimes rewrapped the wire in the pickup coils of his guitar to change the number of turns. In this way, he altered the amount of emf induced in the coils and thus their relative sensitivity to string oscillations. Even without this additional measure, you can see that the electric guitar offers far more control over the sound that is produced than can be obtained with an acoustic guitar.

READING EXERCISE 31-7: Lenz's law states: “An induced current has a direction such that the magnetic field due to the current opposes the change in the magnetic flux that induces the current.” (a) Suppose there is a magnetic field directed into the plane of this page and that the strength of the field is decreasing. Would a magnetic field that opposes this change in magnetic flux be directed into the page, out of the page, or in some other direction? Explain your reasoning. (b) Suppose that there is a magnetic field directed into the plane of this page that is increasing in strength. Would a magnetic field that opposes this change in magnetic flux be directed into the page, out of the page, or in some other direction? Explain your reasoning. ■

FIGURE 31-16 ■ This demonstration of Lenz's law occurs when an electromagnet is switched on suddenly. The current induced in a metal ring opposes the electromagnet's current. The repulsive forces between the magnet and the ring cause the ring to jump more than a meter. (Photo courtesy of PASCO scientific.)

FIGURE 31-17 ■ Jimi Hendrix playing his Fender Stratocaster[®]. This guitar has three groups of six electric pickups each (within the wide part of the body). A toggle switch (at the bottom of the guitar) allows the musician to determine which group of pickups sends signals to an amplifier and thus to a speaker system.

FIGURE 31-18 ■ A side view of an electric guitar pickup. When the metal string (which acts like a magnet) oscillates, it causes a variation in magnetic flux that induces a current in the coil.

READING EXERCISE 31-8: The figure shows three situations in which identical circular conducting loops are in uniform magnetic fields that are either increasing (Inc) or decreasing (Dec) in magnitude at identical rates. In each, the dashed line coincides with a diameter. (a) Rank the situations according to the amount of the current induced in the loops, greatest first. (b) Explain your reasoning.

TOUCHSTONE EXAMPLE 31-2: Induced Emf

Figure 31-19 shows a conducting loop consisting of a half-circle of radius $r = 0.20$ m and three straight sections. The half-circle lies in a uniform magnetic field \vec{B} that is directed out of the page; the field magnitude is given by $B = (4.0 \text{ T/s}^2)t^2 + (2.0 \text{ T/s})t + 3.0 \text{ T}$. An ideal battery with $\mathcal{E}_{\text{bat}} = 2.0 \text{ V}$ is connected to the loop. The resistance of the loop is 2.0Ω .

(a) What are the amount and direction of the emf \mathcal{E}^{ind} induced around the loop by field \vec{B} at $t = 10 \text{ s}$?

SOLUTION ■ One **Key Idea** here is that, according to Faraday's law, \mathcal{E}^{ind} is equal to the negative rate $d\Phi^{\text{mag}}/dt$ at which the magnetic flux at the area encircled by the loop changes. A second **Key Idea** is that the flux at the loop depends on the loop's area A and its orientation in the magnetic field \vec{B} . Because \vec{B} is uniform and is perpendicular to the plane of the loop, the flux is given by Eq. 31-1 ($\Phi^{\text{mag}} = BA$). Using this equation and realizing that only the field magnitude B changes in time (not the area A), we rewrite Faraday's law, Eq. 31-6, as

$$|\mathcal{E}^{\text{ind}}| = \left| \frac{d\Phi^{\text{mag}}}{dt} \right| = \left| \frac{d(BA)}{dt} \right| = A \left| \frac{dB}{dt} \right|.$$

FIGURE 31-19 ■ A battery is connected to a conducting loop consisting of a half-circle of radius r that lies in a uniform magnetic field. The field is directed out of the page; its magnitude is changing.

A third **Key Idea** is that, because the flux penetrates the loop only within the half-circle, the area A in this equation is $\frac{1}{2}\pi r^2$. Substituting this and the given expression for B yields

$$\begin{aligned} |\mathcal{E}^{\text{ind}}| &= A \left| \frac{dB}{dt} \right| = \frac{\pi r^2}{2} \frac{d}{dt} [(4.0 \text{ T/s}^2)t^2 + (2.0 \text{ T/s})t + 3.0 \text{ T}] \\ &= \frac{\pi r^2}{2} [(8.0 \text{ T/s}^2)t + (2.0 \text{ T/s})]. \end{aligned}$$

At $t = 10 \text{ s}$, then,

$$\begin{aligned} |\mathcal{E}^{\text{ind}}| &= \frac{\pi(0.20 \text{ m})^2}{2} [(8.0 \text{ T/s})(10 \text{ s}) + (2.0 \text{ T/s})] \\ &= 5.152 \text{ V} \approx 5.2 \text{ V}. \end{aligned} \quad (\text{Answer})$$

To find the direction of \mathcal{E}^{ind} , we first note that in Fig. 31-19 the flux at the loop is out of the page and increasing. Then the **Key Idea** here is that the induced field B^{ind} (due to the induced current) must oppose that increase, and thus be into the page. Using the curled-straight right-hand rule (Fig. 30-8c), we find that the induced current *contribution* must be clockwise around the loop. The induced emf \mathcal{E}^{ind} must then also be clockwise.

(b) What is the current in the loop at $t = 10 \text{ s}$?

SOLUTION ■ The **Key Idea** here is that two emfs tend to move charges around the loop. The induced \mathcal{E}^{ind} tends to drive a current clockwise around the loop; the battery's \mathcal{E}_{bat} tends to drive a current counterclockwise. Because \mathcal{E}^{ind} is greater than \mathcal{E}_{bat} , the net emf \mathcal{E}^{net} is clockwise, and thus so is the current. To find the current at $t = 10 \text{ s}$, we use $i = \mathcal{E}/R$:

$$\begin{aligned} i &= \frac{\mathcal{E}^{\text{net}}}{R} = \frac{\mathcal{E}^{\text{ind}} - \mathcal{E}_{\text{bat}}}{R} \\ &= \frac{5.152 \text{ V} - 2.0 \text{ V}}{2.0 \Omega} = 1.58 \text{ A} \approx 1.6 \text{ A}. \end{aligned} \quad (\text{Answer})$$

31-6 Induction and Energy Transfers

Let us return to the simple situation we considered in Fig. 31-7. What are the consequences of the fact that a clockwise current is induced when the loop is pulled to the right and a counterclockwise current is induced when the loop is pushed to the left? If one pushes the loop back and forth (right and left), the result is an alternating current in the loop. This is current just like the current in our household electric system. It is a current that could run a motor, light a bulb, or provide heating through the resistive dissipation. If it took no effort on our part to push the loop back and forth, we could solve the energy crisis. Of course, it does take effort (work) on our part to push and pull the loop back and forth.

If you want to drag a metal loop out of a magnetic field at a constant velocity, you have to exert a force on the loop to balance the magnetic force associated with the charges moving in the magnetic field. This requires you to do work on the loop, but doing work adds energy to a system. We certainly cannot violate the principle of conservation of energy. So, where does this energy go? One place the energy could go is into an increase in the internal energy of the loop's wires. Since we observe a temperature rise in the wires, we conclude that the work done has been transformed into thermal energy—one form of internal energy. This makes sense. There is a current i in the loop that has some resistance R , and we learned in Section 26-7 that the electric power dissipation (or rate of thermal energy increase in the wires) is given by

$$P = i^2 R \quad (\text{resistive dissipation}). \quad (\text{Eq. 26-11})$$

How does this rate of energy loss compare to the rate we are doing work? Perhaps they are the same. In that case, we might conclude that the work we do in moving the loop is transformed into thermal energy in the loop. Let's work out the details.

Figure 31-11 shows a situation involving induced current. A rectangular loop of wire of width L has one end in a uniform external magnetic field that is directed perpendicularly into the plane of the loop. This field may be produced, for example, by a large electromagnet. The dashed lines in the figure show the assumed limits of the magnetic field; the fringing of the field at its edges is neglected. You are asked to pull this loop to the right at a constant velocity \vec{v} .

In the situation of Fig. 31-11, the flux of the field at the loop is changing with time. Let us now calculate the rate at which you do mechanical work as you pull steadily on the loop. The amount of work done by a force \vec{F} in moving a loop a small distance $d\vec{x}$ in a time dt is

$$dW = \vec{F} \cdot d\vec{x}.$$

For simplicity, let us consider a force \vec{F} , which is completely in the direction of the displacement $d\vec{x}$. Then

$$dW = \vec{F} \cdot d\vec{x} = F dx.$$

The rate of doing work (which is called the *power* P) is

$$P = \frac{dW}{dt} = F \frac{dx}{dt}.$$

So
$$P = Fv, \quad (31-8)$$

where v is the speed at which we move the loop.

Suppose that we wish to find an expression for the power, P , in terms of the magnitude B of the magnetic field and the characteristics of the loop—namely, its resistance

FIGURE 31-20 ■ A circuit diagram for the loop of Fig. 31-7 while it is moving.

R to current and its dimension L . As you move the loop to the right in Fig. 31-11, the portion of its area within the magnetic field decreases. Thus, the flux at the loop also decreases and, according to Lenz's law, a current is produced in the loop. It is the presence of this current that causes the force that opposes your pull.

To find the amount of the current, we first apply Faraday's law for a single loop in conjunction with Eq. 31-4. We can write the amount of this emf as

$$|\mathcal{E}| = \left| \frac{d\Phi^{\text{mag}}}{dt} \right| = BvL. \quad (31-9)$$

Figure 31-20 shows the loop depicted in Fig. 31-7, as a circuit. The induced emf, \mathcal{E} , is represented on the left, and the collective resistance R of the loop is represented on the right. The direction of the induced current i is shown as in Fig. 31-7, and we have already established that \mathcal{E} must have the same direction as the conventional current, i .

To find the amount of the induced current, we cannot apply the loop rule for potential differences in a circuit because, as you will see in Section 31-7, we cannot define a potential difference for an induced emf. However, we can apply the equation $i = \mathcal{E}/R$. With Eq. 31-9, the current amount becomes

$$|i| = \frac{BvL}{R}. \quad (31-10)$$

Because three segments of the loop in Fig. 31-7 carry this current through the magnetic field, sideways deflecting forces act on those segments. From Chapter 29, we know that the magnitude of such a deflecting force is given in general notation by

$$F_d = |i\vec{L} \times \vec{B}|. \quad (31-11)$$

The deflecting forces acting on segments a , b , and d of the loop shown in Fig. 31-7 can be denoted as \vec{F}_a , \vec{F}_b , and \vec{F}_d . Application of the right-hand rule to each of these segments shows that the forces are perpendicular to each segment and point outward from the loop. Note, however, that from the symmetry, \vec{F}_b and \vec{F}_d are oppositely directed and equal in magnitude, so they cancel. This leaves only \vec{F}_a , which is directed opposite the force \vec{F} you apply to the loop. Therefore, $\vec{F} = -\vec{F}_a$.

Using Eq. 31-11 to obtain the magnitude of \vec{F}_a and noting that the angle between \vec{B} and the length vector \vec{L} for the left segment is 90° , we can write

$$F = F_a = |i|BL \sin 90^\circ = |i|BL. \quad (31-12)$$

Substituting Eq. 31-10 for i in Eq. 31-12 then gives us

$$F = \frac{B^2vL^2}{R}. \quad (31-13)$$

Since B , L , and R are constants, the speed v at which you move the loop is constant if the magnitude F of the force you apply to the loop is also constant.

By substituting Eq. 31-13 into Eq. 31-8, we find the rate at which you do work on the loop as you pull it out of the magnetic field:

$$P = Fv = \frac{B^2v^2L^2}{R} \quad (\text{rate of doing work}). \quad (31-14)$$

To complete our analysis, let us find the rate at which internal energy appears in the loop as you pull it along at constant speed. We calculate it from Eq. 26-11,

$$P = i^2R. \quad (31-15)$$

Substituting for i from Eq. 31-10, we find

$$P = \left(\frac{BvL}{R} \right)^2 R = \frac{B^2 v^2 L^2}{R} \quad (\text{rate of internal energy gain}), \quad (31-16)$$

which is exactly equal to the rate at which you are doing work on the loop (Eq. 31-14). Thus, the work that you do in pulling the loop through the magnetic field is transferred to thermal energy in the loop, manifesting itself as a small increase in the loop's temperature.

Eddy Currents

Suppose we replace the conducting loop of Fig. 31-7 with a solid conducting plate as shown in Fig. 31-21*a*. If we then move the plate out of the magnetic field, the relative motion of the field and the conductor again induces a current in the conductor. Thus, we again encounter an opposing force and must do work because of the induced current. With the plate, however, the conduction electrons making up the induced current do not follow one path as they do with the loop. Instead, the electrons swirl about within the plate as if they were caught in an eddy (or whirlpool) of water. Such a current is called an *eddy current* and can be represented as in Fig. 31-21*a* as if it followed a single path.

Eddy currents are used to cook food on an induction stove. To do this an oscillating current is sent through a conducting coil that lies just below the cooking surface. The magnetic field produced by that current oscillates and induces an oscillating current in the conducting cooking pan. Because the pan has some resistance to that current, the electrical energy of the current is continuously transformed to the pan's energy, resulting in a temperature increase of the pan and the food in it. What's amazing is that the stove itself might not get hot at all—only the pan.

As with the conducting loop of Fig. 31-7, the current induced in the plate results in mechanical energy being dissipated as it increases the pan's thermal energy. The dissipation is more apparent in the arrangement of Fig. 31-21*b*; a conducting plate, free to rotate about a pivot, is allowed to swing down through a magnetic field like a pendulum. Each time the plate enters and leaves the field, a portion of its mechanical energy is transferred to its thermal energy. After several swings, no mechanical energy remains and the warmed-up plate just hangs from its pivot.

FIGURE 31-21 (a) As you pull a solid conducting plate out of a magnetic field, *eddy currents* are induced in the plate. A typical loop of eddy current is shown; it has the same clockwise sense of circulation as the current in the conducting loop of Fig. 31-7. (b) A conducting plate is allowed to swing like a pendulum about a pivot and into a region of magnetic field. As it enters and leaves the field, eddy currents are induced in the plate.

READING EXERCISE 31-9: The figure shows four wire loops, with edge lengths of either L or $2L$. All four loops will move through a region of uniform magnetic field \vec{B} (directed out of the page) at the same constant velocity. (a) Rank the four loops according to the maximum amount of the emf induced as they move through the field, greatest first. (b) Explain your reasoning.

31-7 Induced Electric Fields

Let us place a copper ring of radius r in a uniform external magnetic field, as in Fig. 31-22*a*. The field—neglecting fringing—fills a cylindrical volume of radius R . Suppose that we increase the strength of this field at a steady rate, perhaps by increasing—in an appropriate way—the current in the windings of the electromagnet that produces the field. The magnetic flux at the ring will then change at a steady rate and—by Faraday's law—an induced emf and thus an induced current will appear in the ring. From Lenz's law we can deduce that the direction of the induced current is counterclockwise in Fig. 31-22*a*.

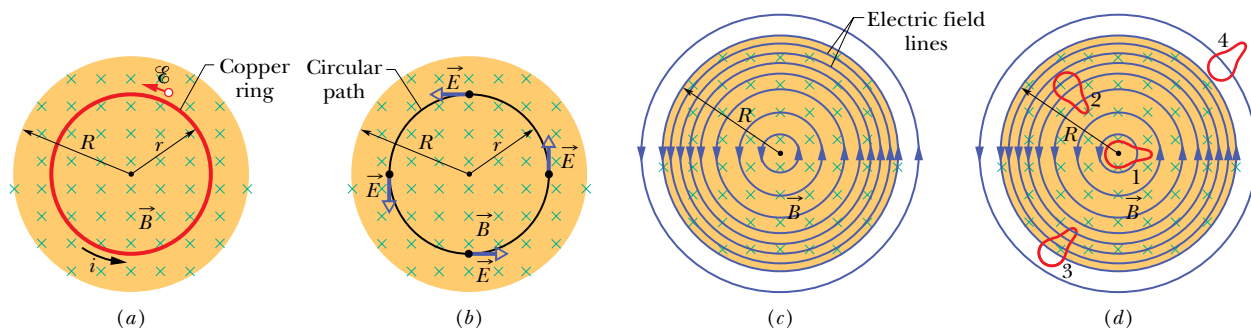

FIGURE 31-22 (a) If the magnetic field increases at a steady rate, a constant induced current appears, as shown, in the copper ring of radius r . (b) An induced electric field exists even when the ring is removed; the electric field is shown at four points. (c) The complete picture of the induced electric field, displayed as field lines. (d) Four similar closed paths that enclose identical areas. Equal emfs are induced around paths 1 and 2, which lie entirely within the region of the changing magnetic field. A smaller emf is induced around path 3, which only partially lies in that region. No emf is induced around path 4, which lies entirely outside the magnetic field.

If there is a current in the copper ring, an electric field must be present along the ring; an electric field is needed to do the work of moving the conduction electrons. Moreover, the electric field must have been produced by the changing magnetic flux. This **induced electric field** \vec{E} is just as real as an electric field produced by static charges; either field will exert a force $q\vec{E}$ on a particle of charge q .

By this line of reasoning, we are led to a more general and informative restatement of Faraday's law of induction:

A changing magnetic field produces an electric field.

The striking feature of this statement is that the electric field is induced even if there is no copper ring.

To fix these ideas, consider Fig. 31-22*b*, which is just like Fig. 31-22*a* except the copper ring has been replaced by a hypothetical circular path of radius r . We assume, as previously, that the magnetic field \vec{B} is increasing in magnitude at a constant rate dB/dt . The electric field induced at various points around the circular path must—from the symmetry—be tangent to the circle, as Fig. 31-22*b* shows.* Hence, the circular path is an electric field line. There is nothing special about the circle of radius r , so the electric field lines produced by the changing magnetic field must be a set of concentric circles, as in Fig. 31-22*c*.

As long as the magnetic field is increasing with time, the electric field represented by the circular field lines in Fig. 31-22*c* will be present. If the magnetic field remains constant with time, there will be no induced electric field and thus no electric field lines. If the magnetic field is decreasing with time (at a constant rate), the electric field lines will still be concentric circles as in Fig. 31-22*c*, but they will now have the opposite direction. All this is what we have in mind when we say: A changing magnetic field produces an electric field.

A Reformulation of Faraday's Law

Consider a particle of charge q moving around the circular path of Fig. 31-22*b*. The work W done on it in one revolution by the induced electric field is $q\mathcal{E}$, where \mathcal{E} is the

* Arguments of symmetry would also permit the lines of \vec{E} around the circular path to be radial, rather than tangential. However, such radial lines would imply that there are free charges, distributed symmetrically about the axis of symmetry, on which the electric field lines could begin or end; there are no such charges.

induced emf—that is, the work done per unit charge in moving the test charge around the path. From another point of view, the work is

$$\int \vec{F} \cdot d\vec{s} = qE(2\pi r), \quad (31-17)$$

where $|q|E$ is the magnitude of the force acting on the test charge and $2\pi r$ is the distance over which that force acts. Setting these two expressions for W equal to each other and canceling q , we find that

$$|\mathcal{E}| = 2\pi rE. \quad (31-18)$$

More generally, we can rewrite Eq. 31-17 to give the work done on a particle of charge q moving along any closed path:

$$W = \oint \vec{F} \cdot d\vec{s} = q \oint \vec{E} \cdot d\vec{s}. \quad (31-19)$$

(The circle indicates that the integral is to be taken around the closed path.) Substituting $q\mathcal{E}$ for W , we find that

$$\mathcal{E} = \oint \vec{E} \cdot d\vec{s}. \quad (31-20)$$

This integral reduces at once to Eq. 31-18 if we evaluate it for the special case of Fig. 31-22*b*.

With Eq. 31-20, we can expand the meaning of induced emf. Previously, induced emf meant the work per unit charge done in maintaining current due to a changing magnetic flux, or it meant the work done per unit charge on a charged particle that moves around a closed path in a changing magnetic flux. However, we can see in Fig. 31-22*b* and Eq. 31-20 that an induced emf can exist without the need of a current or particle: An induced emf is the sum—via integration—of quantities $\vec{E} \cdot d\vec{s}$ around a closed path, where \vec{E} is the electric field induced by a changing magnetic flux and $d\vec{s}$ is a differential length vector along the closed path.

If we combine Eq. 31-20 with Faraday's law in Eq. 31-6 ($\mathcal{E} = -d\Phi^{\text{mag}}/dt$), we can rewrite Faraday's law as

$$\oint \vec{E} \cdot d\vec{s} = -\frac{d\Phi^{\text{mag}}}{dt} \quad (\text{Faraday's law, general formula}). \quad (31-21)$$

This equation says simply that a changing magnetic field induces an electric field. The changing magnetic field appears on the right side of this equation, the electric field on the left.

Faraday's law in the form of Eq. 31-21 can be applied to *any* closed path that can be drawn in a changing magnetic field. But $\oint \vec{E} \cdot d\vec{s}$ can only be evaluated for symmetrical situations. Figure 31-22*d*, for example, shows four such paths, all having the same shape and area but located in different positions in the changing field. For paths 1 and 2, the induced emfs $\mathcal{E} (= \oint \vec{E} \cdot d\vec{s})$ are equal because these paths lie entirely in the magnetic field and thus have the same value of $d\Phi^{\text{mag}}/dt$. This is true even though the electric field vectors at points along these paths are different, as indicated by the patterns of electric field lines in the figure. For path 3 the induced emf is smaller because the enclosed flux Φ^{mag} (hence, $d\Phi^{\text{mag}}/dt$) is smaller, and for path 4 the induced emf is zero, even though the electric field is not zero at any point on the path.

A New Look at Electric Potential

Induced electric fields are produced not by static charges but by a changing magnetic flux. Although electric fields produced in either way exert forces on charged particles, there is an important difference between them. The difference is not in the way they affect charges at a given point (the electric force on a charge q in this field is still qE), but in their global properties. Their field lines behave differently and there is a problem defining the electric potential associated with induced electric fields. The simplest evidence of this difference is that the field lines of induced electric fields form closed loops, as in Fig. 31-22c. Field lines produced by static charges never do so but rather must start on positive charges and end on negative charges. Since the induced fields are not caused by charges, there is no place for the field lines to start or end. Instead, they form closed loops, similar to those of magnetic fields. (But these are still electric fields! They act on stationary charges whereas magnetic fields don't.)

So, a varying *magnetic field* is accompanied by circular *electric field lines*. An electric current is known to be accompanied by circular magnetic field lines. But is an electric *current* the only source of circular magnetic field lines? Might it be possible that a varying *electric field* is accompanied by a circulating *magnetic field*? This is a question we will consider in the next chapter.

What we are immediately concerned with is that the electric field lines make closed loops, which has a powerful implication for trying to define an electrostatic potential. Since the potential difference equals the work per unit charge, if we carry a charge around a loop of electric field line, the \vec{E} field always acts in the direction of motion, so every small step we make makes a positive contribution to the work. But since the field follows a loop, we can come back to our starting point after having only done positive work! The implication is:

Electric potential has meaning only for electric fields that are produced by static charges; it has no meaning for electric fields that are produced by induction.

You can understand this statement quantitatively by considering what happens to a charged particle that makes a single journey around the circular path in Fig. 31-22b. It starts at a certain point and, on its return to that same point, has experienced an emf \mathcal{E} of, let us say, 5 V; that is, work of 5 J/C has been done on the particle, and thus the particle should then be at a point that is 5 V greater in potential. However, that is impossible because the particle is back at the same point, which cannot have two different values of potential. We must conclude that potential has no meaning for electric fields that are set up by changing magnetic fields.

We can take a more formal look by recalling Eq. 25-16, which defines the potential difference between two points 1 and 2 in an electric field \vec{E} :

$$V_2 - V_1 = - \int_1^2 \vec{E} \cdot d\vec{s}. \quad (31-22)$$

In Chapter 25 we had not yet encountered Faraday's law of induction, so the electric fields involved in the derivation of Eq. 25-16 were those due to static charges. If 1 and 2 in Eq. 31-22 are the same point, the path connecting them is a closed loop, V_1 and V_2 are identical, and Eq. 31-22 reduces to

$$\oint \vec{E} \cdot d\vec{s} = 0 \text{ V}. \quad (31-23)$$

However, when a changing magnetic flux is present, this integral is *not* zero but is $-d\Phi^{\text{mag}}/dt$, as Eq. 31-21 asserts. Thus, assigning electric potential to an induced electric

field leads us to a contradiction. We must conclude that electric potential difference is path dependent for the electric fields associated with induction.

READING EXERCISE 31-10: The figure shows five lettered regions in which a uniform magnetic field extends either directly out of the page (as in region a) or into the page. The field is increasing in magnitude at the same steady rate in all five regions; the regions are identical in area. Also shown are four numbered paths along which $\oint \vec{E} \cdot d\vec{s}$ has the magnitudes given below in terms of a unit “mag.” Determine whether the magnetic fields in regions b through e are directed into or out of the page.

TOUCHSTONE EXAMPLE 31-3: Inducing an Electric Field

In Fig. 31-22b, take $R = 8.5$ cm and $dB/dt = 0.13$ T/s.

(a) Find an expression for the magnitude E of the induced electric field at points within the magnetic field, at radius r from the center of the magnetic field. Evaluate the expression for $r = 5.2$ cm.

SOLUTION ■ The **Key Idea** here is that an electric field is induced by the changing magnetic field, according to Faraday’s law. To calculate the field magnitude E , we apply Faraday’s law in the form of Eq. 31-21. We use a circular path of integration with radius $r \leq R$ because we want E for points within the magnetic field. We assume from the symmetry that \vec{E} in Fig. 31-22b is tangent to the circular path at all points. The path vector $d\vec{s}$ is also always tangent to the circular path, so the dot product $\vec{E} \cdot d\vec{s}$ in Eq. 31-21 must have the magnitude $E ds$ at all points on the path. We can also assume from the symmetry that E has the same value at all points along the circular path. Then the left side of Eq. 31-21 becomes

$$\oint \vec{E} \cdot d\vec{s} = \oint E ds = E \oint ds = E(2\pi r). \quad (31-24)$$

(The integral $\oint ds$ is the circumference $2\pi r$ of the circular path.)

Next, we need to evaluate the right side of Eq. 31-21. Because \vec{B} is uniform over the area A encircled by the path of integration and is directed perpendicular to that area, the magnetic flux is given by Eq. 31-1:

$$\Phi^{\text{mag}} = BA = B(\pi r^2). \quad (31-25)$$

Substituting this and Eq. 31-24 into Eq. 31-21 and dropping the minus sign, we find that the magnitude of the electric field is

$$E(2\pi r) = (\pi r^2) \frac{dB}{dt}$$

or
$$E = \frac{r}{2} \frac{dB}{dt}. \quad (\text{Answer}) (31-26)$$

Equation 31-26 gives the magnitude of the electric field at any point for which $r \leq R$ (that is, within the magnetic field). Substituting given values yields, for the magnitude of \vec{E} at $r = 5.2$ cm,

$$\begin{aligned} E &= \frac{(5.2 \times 10^{-2} \text{ m})}{2} (0.13 \text{ T/s}) \\ &= 0.0034 \text{ V/m} = 3.4 \text{ mV/m}. \end{aligned} \quad (\text{Answer})$$

(b) Find an expression for the magnitude E of the induced electric field at points that are outside the magnetic field, at radius r . Evaluate the expression for $r = 12.5$ cm.

SOLUTION ■ The **Key Idea** of part (a) applies here also, except that we use a circular path of integration with radius $r = R$, because we want to evaluate E for points outside the magnetic field. Proceeding as in (a), we again obtain Eq. 31-24. However, we do not then obtain Eq. 31-25, because the new path of integration is now outside the magnetic field, and we need this **Key Idea**: The magnetic flux encircled by the new path is only that in the area πR^2 of the magnetic field region. Therefore,

$$\Phi^{\text{mag}} = BA = B(\pi R^2). \quad (31-27)$$

Substituting this and Eq. 31-24 into Eq. 31-21 (without the minus sign) and solving for the magnitude of \vec{E} yield

$$E = \frac{R^2}{2r} \frac{dB}{dt}. \quad (\text{Answer}) (31-28)$$

Since E is not zero here, we know that an electric field is induced even at points that are outside the changing magnetic field, an

FIGURE 31-23 ■ A plot of the induced electric field $E(r)$ for the conditions given in Touchstone Example 31-3.

important result that (as you shall see in Section 32-5) makes transformers possible. With the given data, Eq. 31-28 yields the magnitude of \vec{E} at $r = 12.5$ cm:

$$E = \frac{(8.5 \times 10^{-2} \text{ m})^2}{(2)(12.5 \times 10^{-2} \text{ m})} (0.13 \text{ T/s}) \\ = 3.8 \times 10^{-3} \text{ V/m} = 3.8 \text{ mV/m.} \quad (\text{Answer})$$

Equations 31-26 and 31-28 give the same result, as they must, for $r = R$. Figure 31-23 shows a plot of $E(r)$ based on these two equations.

31-8 Induced Magnetic Fields

Let's consider a region in space where no electric currents are present. As we have seen, a changing magnetic flux induces an electric field, and we end up with Faraday's law of induction in the form

$$\oint \vec{E} \cdot d\vec{s} = -\frac{d\Phi^{\text{mag}}}{dt} \quad (\text{Faraday's law of induction}). \quad (31-29)$$

Here \vec{E} is the electric field induced along a closed loop by the changing magnetic flux Φ^{mag} encircled by that loop. Because symmetry is often so powerful in physics, we should be tempted to ask whether induction can occur in the opposite sense; that is, can a changing electric flux induce a magnetic field?

The answer is that it can; furthermore, the equation governing the induction of a magnetic field is almost symmetric with Eq. 31-21. We often call it Maxwell's law of induction after James Clerk Maxwell, and we write it as

$$\oint \vec{B} \cdot d\vec{s} = \mu_0 \epsilon_0 \frac{d\Phi^{\text{elec}}}{dt} \quad (\text{Maxwell's law of induction—no currents}). \quad (31-30)$$

Here \vec{B} is the magnetic field induced along a closed loop by the changing electric flux Φ^{elec} in the region encircled by that loop.

As an example of this sort of induction, we consider the charging of a parallel-plate capacitor with circular plates, as shown in Fig. 31-24a. (Although we shall focus on this particular arrangement, a changing electric flux will always induce a magnetic field whenever it occurs.) We assume that the charge on the capacitor is being increased at a steady rate by a constant current i in the connecting wires. Then the amount of the electric field between the plates must also be increasing at a steady rate.

Figure 31-24b is a view of the right-hand plate of Fig. 31-24a from between the plates. The electric field is directed into the page. Let us consider a circular loop through point 1 in Figs. 31-24a and b, concentric with the capacitor plates and with a radius smaller than that of the plates. Because the electric field at the area subtended by the loop is changing, the electric flux at the loop must also be changing. According to Eq. 31-22, this changing electric flux induces a magnetic field around the loop.

Experiment proves that a magnetic field \vec{B} is indeed induced around such a loop, directed as shown. This magnetic field has the same magnitude at every point around the loop and thus has circular symmetry about the central axis of the capacitor plates.

If we now consider a larger loop—say, through point 2 outside the plates in Figs. 31-24a and b—we find that a magnetic field is induced around that loop as well. Thus, while the electric field is changing, magnetic fields are induced between the plates,

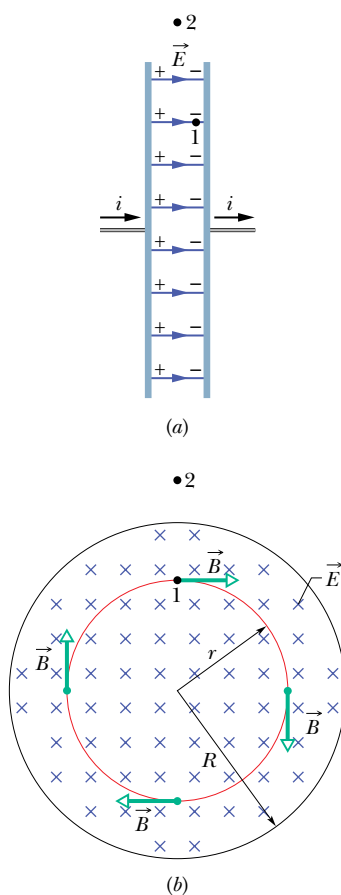

FIGURE 31-24 ■ (a) A circular parallel-plate capacitor, shown in side view, is being charged by a constant current i . (b) A view from within the capacitor, toward the plate at the right. The electric field \vec{E} is uniform, is directed into the page (toward the plate), and grows in magnitude as the charge on the capacitor increases. The magnetic field \vec{B} induced by this changing electric field is shown at four points on a circle with a radius r less than the plate radius R .

both inside and outside the gap. When the electric field stops changing, these induced magnetic fields disappear.

Although Eq. 31-30 is similar to Eq. 31-29, the equations differ in two ways. First, Eq. 31-30 has the two extra symbols, μ_0 and ϵ_0 , but they appear only because we employ SI units. Second, Eq. 31-30 lacks the minus sign of Eq. 31-29. That difference in sign means that the induced electric field \vec{E} and the induced magnetic field \vec{B} have opposite directions when they are produced in otherwise similar situations.

To see this opposition of directions, examine Fig. 31-25, in which an increasing magnetic field \vec{B} , directed into the page, induces an electric field \vec{E} . The induced field \vec{E} is counterclockwise, whereas the induced magnetic field \vec{B} in Fig. 31-24b is clockwise.

FIGURE 31-25 ■ A uniform magnetic field \vec{B} in a circular region. The field, directed into the page, is increasing in magnitude. The electric field \vec{E} induced by the changing magnetic field is shown at four points on a circle concentric with the circular region. Compare this situation with that of Fig. 31-24b.

Ampère–Maxwell Law

Now recall that the left side of Eq. 31-30, the integral of the dot product $\vec{B} \cdot d\vec{s}$ around a closed loop, appears in another equation—namely, Ampère’s law:

$$\oint \vec{B} \cdot d\vec{s} = \mu_0 i^{\text{enc}} \quad (\text{Ampère's law}), \quad (31-31)$$

where i^{enc} is the current encircled by the closed loop. Thus, our two equations that specify the magnetic field \vec{B} produced by means other than a magnetic material (that is, by a current and by a changing electric field) give the field in exactly the same form. We can combine the two equations into the single equation

$$\oint \vec{B} \cdot d\vec{s} = \mu_0 \epsilon_0 \frac{d\Phi^{\text{elec}}}{dt} + \mu_0 i^{\text{enc}} \quad (\text{Ampère–Maxwell law}). \quad (31-32)$$

When there is a current but no change in electric flux (such as with a wire carrying a constant current), the first term on the right side of Eq. 31-32 is zero, and Eq. 31-32 reduces to Eq. 31-31, Ampère’s law. When there is a change in electric flux but no current (such as inside or outside the gap of a charging capacitor), the second term on the right side of Eq. 31-32 is zero, and Eq. 31-32 reduces to Eq. 31-30, Maxwell’s law of induction.

READING EXERCISE 31-11: Referring back to Chapter 30, where we first studied Ampère’s law, describe how we found the direction of the magnetic field produced by a current. What did the magnetic field lines look like for a long, straight, current-carrying wire? Discuss any connections or similarities between the case of the current-carrying wire and the case shown in Fig. 31-24.

TOUCHSTONE EXAMPLE 31-4: Inducing a Magnetic Field

A parallel-plate capacitor with circular plates of radius R is being charged as in Fig. 31-24a.

(a) Derive an expression for the magnitude of the magnetic field at radii r for the case $r \leq R$.

SOLUTION ■ The **Key Idea** here is that a magnetic field can be set up by a current and by induction due to a changing electric flux; both effects are included in Eq. 31-32. There is no current between the capacitor plates of Fig. 31-24, but the electric flux there is

changing. Thus, Eq. 31-32 reduces to

$$\oint \vec{B} \cdot d\vec{s} = \mu_0 \epsilon_0 \frac{d\Phi^{\text{elec}}}{dt}. \quad (31-33)$$

We shall separately evaluate the left and right sides of this equation.

Left side of Eq. 31-33: We choose a circular Ampèrian loop with a radius $r \leq R$ as shown in Fig. 31-24, because we want to evaluate the magnetic field for $r \leq R$ —that is, inside the capacitor. The magnetic field \vec{B} at all points along the loop is tangent to the loop,

as is the path element $d\vec{s}$. Thus, \vec{B} and $d\vec{s}$ are either parallel or antiparallel at each point of the loop. For simplicity, assume they are parallel (the choice does not alter our outcome here). Then

$$\oint \vec{B} \cdot d\vec{s} = \oint B \cdot ds \cos 0^\circ = \oint B ds.$$

Due to the circular symmetry of the plates, we can also assume that \vec{B} has the same magnitude at every point around the loop. Thus, B can be taken outside the integral on the right side of the above equation. The integral that remains is $\oint ds$, which simply gives the circumference $2\pi r$ of the loop. The left side of Eq. 31-33 is then $(B)(2\pi r)$.

Right side of Eq. 31-33: We assume that the electric field \vec{E} is uniform between the capacitor plates and directed perpendicular to the plates. Then the electric flux Φ^{elec} encircled by the Ampèrian loop is EA , where A is the area encircled by the loop within the electric field. Thus, the right side of Eq. 31-33 is $\mu_0\epsilon_0 d(EA)/dt$.

Substituting our results for the left and right sides into Eq. 31-33, we get

$$B(2\pi r) = \mu_0\epsilon_0 \frac{d(EA)}{dt}.$$

Because A is a constant, we write $d(EA)$ as $A dE$, so we have

$$B(2\pi r) = \mu_0\epsilon_0 A \frac{dE}{dt}. \quad (31-34)$$

We next use this **Key Idea**: The area A that is encircled by the Ampèrian loop within the electric field is the full area πr^2 of the loop, because the loop's radius r is less than (or equal to) the plate radius R . Substituting πr^2 for A in Eq. 31-34 and solving the result for B give us, for $r \leq R$,

$$B = \frac{\mu_0\epsilon_0 r}{2} \frac{dE}{dt}. \quad (\text{Answer}) (31-35)$$

This equation tells us that, inside the capacitor, B increases linearly with increased radial distance r , from zero at the center of the plates to a maximum value at the plate edges (where $r = R$).

(b) Evaluate the field magnitude B for $r = R/5 = 11.0$ mm and $dE/dt = 1.50 \times 10^{12}$ V/m·s.

SOLUTION ■ From the answer to (a), we have

$$\begin{aligned} B &= \frac{1}{2}\mu_0\epsilon_0 r \frac{dE}{dt} \\ &= \frac{1}{2}(4\pi \times 10^{-7} \text{ T}\cdot\text{m/A})(8.85 \times 10^{-12} \text{ C}^2/\text{N}\cdot\text{m}^2) \\ &\quad \times (11.0 \times 10^{-3} \text{ m})(1.50 \times 10^{12} \text{ V/m}\cdot\text{s}) \\ &= 9.18 \times 10^{-8} \text{ T}. \end{aligned} \quad (\text{Answer})$$

(c) Derive an expression for the induced magnetic field for the case $r \geq R$.

SOLUTION ■ Our procedure is the same as in (a) except we now use an Ampèrian loop with a radius r that is greater than the plate radius R , to evaluate B outside the capacitor. Evaluating the left and right sides of Eq. 31-33 again leads to Eq. 31-34. However, we then need this subtle **Key Idea**: The electric field exists only between the plates, *not* outside the plates. Thus, the area A that is encircled by the Ampèrian loop in the electric field is *not* the full area πr^2 of the loop. Rather, A is only the plate area πR^2 .

Substituting πR^2 for A in Eq. 31-34 and solving the result for B give us, for $r \geq R$,

$$B = \frac{\mu_0\epsilon_0 R^2}{2r} \frac{dE}{dt}. \quad (\text{Answer}) (31-36)$$

This equation tells us that, outside the capacitor, B decreases with increased radial distance r , from a maximum value at the plate edges (where $r = R$). By substituting $r = R$ into Eqs. 31-35 and 31-36, you can show that these equations are consistent; that is, they give the same maximum value of B at the plate radius.

The magnitude of the induced magnetic field calculated in (b) is so small that it can scarcely be measured with simple apparatus. This is in sharp contrast to the magnitudes of induced electric fields (Faraday's law), which can be measured easily. This experimental difference exists partly because induced emfs can easily be multiplied by using a coil of many turns. No technique of comparable simplicity exists for multiplying induced magnetic fields. In any case, the experiment suggested by this sample problem has been done, and the presence of the induced magnetic fields has been verified quantitatively.

31-9 Displacement Current

If you compare the two terms on the right side of Eq. 31-32, you will see that the product $\epsilon_0(d\Phi^{\text{elec}}/dt)$ in the first term must have the units associated with a current. Since no charge actually flows, historically, that product has been treated as being a fictitious current called the **displacement current** i^{dis} :

$$i^{\text{dis}} = \epsilon_0 \frac{d\Phi^{\text{elec}}}{dt} \quad (\text{displacement current}). \quad (31-37)$$

“Displacement” is a poorly chosen term in that nothing is being displaced, but we are stuck with the word. Nevertheless, we can now rewrite Eq. 31-32 as

$$\oint \vec{B} \cdot d\vec{s} = \mu_0 i_{\text{dis}}^{\text{enc}} + \mu_0 i^{\text{enc}} \quad (\text{Ampère–Maxwell law}), \quad (31-38)$$

in which $i_{\text{dis}}^{\text{enc}}$ is the displacement current that is encircled by the integration loop.

Let us again focus on a charging capacitor with circular plates, as in Fig. 31-26a. The real current i that is charging the plates changes the electric field \vec{E} between the plates. The fictitious displacement current i^{dis} between the plates is associated with that changing field \vec{E} . Let us relate these two currents.

The amount of excess charge $|q|$ on each of the plates at any time is related to the magnitude $|\vec{E}| = E$ of the field between the plates at that time by Eq. 28-4:

$$|q| = \epsilon_0 A E, \quad (31-39)$$

in which A is the plate area. To get the real current i , we differentiate Eq. 31-39 with respect to time, finding

$$\frac{d|q|}{dt} = |i| = \epsilon_0 A \frac{dE}{dt}. \quad (31-40)$$

To get the displacement current i^{dis} , we can use Eq. 31-37. Assuming that the electric field \vec{E} between the two plates is uniform (we neglect any fringing), we can replace the electric flux Φ^{elec} in that equation with EA . Then Eq. 31-37 becomes

$$|i^{\text{dis}}| = \epsilon_0 \left| \frac{d\Phi^{\text{elec}}}{dt} \right| = \epsilon_0 \left| \frac{d(EA)}{dt} \right| = \epsilon_0 A \left| \frac{dE}{dt} \right|. \quad (31-41)$$

Comparing Eqs. 31-40 and 31-41, we see that the real current i charging the capacitor and the fictitious displacement current i^{dis} between the plates have the same value:

$$i^{\text{dis}} = i \quad (\text{displacement current in a capacitor}). \quad (31-42)$$

Thus, we can consider the fictitious displacement current i^{dis} to be simply a continuation of the real current i from one plate, across the capacitor gap, to the other plate. Because the electric field is uniformly spread over the plates, the same is true of this fictitious displacement current i^{dis} , as suggested by the spread of current arrows in Fig. 31-26a. Although no charge actually moves across the gap between the plates, the idea of the fictitious current i^{dis} can help us to quickly find the direction and magnitude of an induced magnetic field, as follows.

Finding the Induced Magnetic Field

In Chapter 30 we found the direction of the magnetic field produced by a real current i by using the right-hand rule of Fig. 30-4. We can apply the same rule to find the direction of an induced magnetic field produced by a fictitious displacement current i^{dis} , as shown in the center of Fig. 31-26b for a capacitor.

We can also use i^{dis} to find the magnitude of the magnetic field induced by a charging capacitor with parallel circular plates of radius R . We simply consider the space between the plates to be an imaginary circular wire of radius R carrying the imaginary current i^{dis} . Then, from Eq. 30-22, the magnitude of the magnetic field at a point inside the capacitor at radius r from the center is

$$B = \left(\frac{\mu_0 |i^{\text{dis}}|}{2\pi R^2} \right) r \quad (\text{inside a circular capacitor}). \quad (31-43)$$

FIGURE 31-26 (a) The displacement current i^{dis} between the plates of a capacitor that is being charged by a current i . (b) The right-hand rule for finding the direction of the magnetic field around a wire with a real current (as at the left) also gives the magnetic field direction around a displacement current (as in the center).

Similarly, from Eq. 30-19, the magnitude of the magnetic field at a point outside the capacitor at radius r is

$$B = \frac{\mu_0 |i^{\text{dis}}|}{2\pi r} \quad (\text{outside a circular capacitor}). \quad (31-44)$$

READING EXERCISE 31-12: Discuss the ways in which it is useful for us to think of the quantity $\epsilon_0 d\Phi^{\text{elec}}/dt$ as a current. ■

TOUCHSTONE EXAMPLE 31-5: Displacement Current

The circular parallel-plate capacitor in Touchstone Example 31-4 is being charged with a current i .

(a) Between the plates, what is the magnitude of $\oint \vec{B} \cdot d\vec{s}$, in terms of μ_0 and i , at a radius $r = R/5$ from their center?

SOLUTION ■ The first **Key Idea** of Touchstone Example 31-4a holds here too. However, now we can replace the product $\epsilon_0 d\Phi^{\text{elec}}/dt$ in Eq. 31-32 with a fictitious displacement current i^{dis} . Then integral $\oint \vec{B} \cdot d\vec{s}$ is given by Eq. 31-38, but because there is no real current i between the capacitor plates, the equation reduces to

$$\oint \vec{B} \cdot d\vec{s} = \mu_0 i_{\text{dis}}^{\text{enc}}. \quad (31-45)$$

Because we want to evaluate $\oint \vec{B} \cdot d\vec{s}$ at radius $r = R/5$ (within the capacitor), the integration loop encircles only a portion $i_{\text{dis}}^{\text{enc}}$ of the total displacement current i^{dis} . A second **Key Idea** is to assume that i^{dis} is uniformly spread over the full plate area. Then the portion of the displacement current encircled by the loop is proportional to the area encircled by the loop:

$$\frac{(\text{encircled displacement current } i_{\text{dis}}^{\text{enc}})}{(\text{total displacement current } i^{\text{dis}})} = \frac{\text{encircled area } \pi r^2}{\text{full plate area } \pi R^2}.$$

This gives us a current magnitude of

$$i_{\text{dis}}^{\text{enc}} = i^{\text{dis}} \frac{\pi r^2}{\pi R^2}.$$

Substituting this into Eq. 31-45, we obtain

$$\oint \vec{B} \cdot d\vec{s} = \mu_0 i^{\text{dis}} \frac{\pi r^2}{\pi R^2}. \quad (31-46)$$

Now substituting $i^{\text{dis}} = i$ (from Eq. 31-42) and $r = R/5$ into Eq. 31-46 leads to

$$\oint \vec{B} \cdot d\vec{s} = \mu_0 i \frac{(R/5)^2}{R^2} = \frac{\mu_0 i}{25}. \quad (\text{Answer})$$

(b) In terms of the maximum induced magnetic field, what is the magnitude of the magnetic field induced at $r = R/5$, inside the capacitor?

SOLUTION ■ The **Key Idea** here is that, because the capacitor has parallel circular plates, we can treat the space between the plates as an imaginary wire of radius R carrying the imaginary current i^{dis} . Then we can use Eq. 31-43 to find the induced magnetic field magnitude B at any point inside the capacitor. At $r = R/5$, that equation yields

$$B = \left(\frac{\mu_0 |i^{\text{dis}}|}{2\pi R^2} \right) r = \frac{\mu_0 |i^{\text{dis}}| (R/5)}{2\pi R^2} = \frac{\mu_0 |i^{\text{dis}}|}{10\pi R}. \quad (31-47)$$

The maximum field magnitude B^{max} within the capacitor occurs at $r = R$. It is

$$B^{\text{max}} = \left(\frac{\mu_0 |i^{\text{dis}}|}{2\pi R^2} \right) R = \frac{\mu_0 |i^{\text{dis}}|}{2\pi R}. \quad (31-48)$$

Dividing Eq. 31-47 by Eq. 31-48 and rearranging the result, we find

$$B = \frac{B^{\text{max}}}{5}, \quad (\text{Answer})$$

We should be able to obtain this result with a little reasoning and less work. Equation 31-43 tells us that inside the capacitor, B increases linearly with r . Therefore, a point $\frac{1}{5}$ the distance out to the full radius R of the plates, where B^{max} occurs, should have a field B that is $\frac{1}{5}B^{\text{max}}$.

31-10 Gauss' Law for Magnetic Fields

In this chapter and the two that precede it, we have investigated several fundamental aspects of electricity and magnetism. Furthermore, we have seen many ways in which magnetism and electricity are connected. When combined as a set of laws, these ideas

provide a framework from which we can understand all of the electromagnetic phenomena that fill our world, much like Newton's laws do in regard to forces and motion.

However, there remains one last idea that we must discuss before our view of electromagnetism is complete. This idea is contained in an idea known as *Gauss' law for magnetic fields*. Gauss' law for magnetic fields is a formal way of saying that magnetic monopoles do not exist. The law asserts that the net magnetic flux Φ^{mag} at any closed Gaussian surface is zero:

$$\Phi^{\text{mag}} = \oint \vec{B} \cdot d\vec{A} = 0 \quad (\text{Gauss' law for magnetic fields}). \quad (31-49)$$

Contrast this with Gauss' law for electric fields,

$$\Phi^{\text{elec}} = \oint \vec{E} \cdot d\vec{A} = \frac{q^{\text{enc}}}{\epsilon_0} \quad (\text{Gauss' law for electric fields}).$$

In both equations, the integral is taken over a *closed* Gaussian surface. Gauss' law for electric fields says that this integral (the net electric flux at the surface) is proportional to the net electric charge q^{enc} enclosed by the surface. Gauss' law for magnetic fields says that there can be no net magnetic flux at the surface because there can be no net "magnetic charge" (individual magnetic poles) enclosed by the surface. The simplest magnetic structure that can exist and thus be enclosed by a Gaussian surface is a dipole, which consists of both a source and a sink for the field lines. Thus, there must always be as much magnetic flux into the surface as out of it, and the net magnetic flux must always be zero.

Gauss' law for magnetic fields holds for more complicated structures than a magnetic dipole, and it holds even if the Gaussian surface does not enclose the entire structure. Gaussian surface II near the bar magnet of Fig. 31-27 encloses no poles, and we can easily conclude that the net magnetic flux at it is zero. Gaussian surface I is more difficult to understand. It may seem to enclose only the north pole of the magnet because it encloses the label N and not the label S. However, a south pole must be associated with the lower boundary of the surface, because magnetic field lines enter the surface there. (The enclosed section is like one piece of the broken cylindrical magnet in Fig. 31-28.) Thus, Gaussian surface I encloses a magnetic dipole and the net flux at the surface is zero.

READING EXERCISE 31-13: The figure below shows four closed surfaces with flat top and bottom faces and curved sides. The table gives the areas A of the faces and the magnitudes B of the uniform and perpendicular magnetic fields at those faces; the units of A and B are arbitrary but consistent. (a) Rank the surfaces according to the magnitudes of the magnetic flux at their curved sides, greatest first. (b) Explain your reasoning.

Surface	A_{top}	B_{top} , direction	A_{bot}	B_{bot} , direction
a	2	6, outward	4	3, inward
b	2	1, inward	4	2, inward
c	2	6, inward	2	8, outward
d	2	3, outward	3	2, outward

FIGURE 31-27 The field lines for the magnetic field \vec{B} of a short bar magnet. The red curves represent cross sections of closed, three-dimensional Gaussian surfaces.

FIGURE 31-28 If you break a magnet, each fragment becomes a separate magnet, with its own north and south poles.

31-11 Maxwell's Equations in a Vacuum

Many 18th and 19th century scientists contributed to our understanding of electricity and magnetism including Franklin, Coulomb, Gauss, Oersted, Biot, Savart, Lorentz, Ampère, Henry, Faraday, and Maxwell. But it was James Clerk Maxwell who reformulated many of the basic equations describing electric and magnetic effects we have already presented. A special case of Maxwell's equations are shown in Table 31-1 for situations in which no dielectric or magnetic materials are present.

It is amazing that these four rather compact equations can be used to *derive a complete description of all electromagnetic interactions that were understood by the end of the 19th century*. Taken together they describe a diverse range of phenomena, from how a compass needle points north to how a car starts when you turn the ignition key. They have been used to design electric motors, cyclotrons, television transmitters and receivers, telephones, fax machines, radar, and microwave ovens.

In addition, many of the equations you have seen since Chapter 22 can be derived from Maxwell's equations. Perhaps the most exciting intellectual outcome of Maxwell's equations is their prediction of electromagnetic waves and our eventual understanding of the self-propagating nature of these waves that will be introduced in Chapter 34. Maxwell's picture of electromagnetic wave propagation was not fully appreciated until scientists abandoned the idea that all waves had to propagate through an elastic medium and accepted Einstein's theory of special relativity formulated in the early part of the 20th century.

Because we now know that visible light is a form of electromagnetic radiation, these equations provide the basis for many of the equations you will see in Chapters 34 through 37, which introduce you to optics and optical devices such as telescopes and eyeglasses.

The significance of Maxwell's equations should not be underestimated. Richard Feynman, a leading famous 20th-century physicist, recognized this when he stated:

Now we realize that the phenomena of chemical interaction and ultimately of life itself are to be understood in terms of electromagnetism The electrical forces, enormous as they are, can also be very tiny, and we can control them and use them in many ways From a long view of the history of mankind—seen from, say, ten thousand years from now—there can be little doubt that the most significant event of the nineteenth century will be judged as Maxwell's discovery of the laws of electrodynamics.

TABLE 31-1
Maxwell's Equations for Vacuum^a

Name	Equation	
Gauss' law for electricity (Eq. 24-7)	$\oint \vec{E} \cdot d\vec{A} = q/\epsilon_0$	Relates net electric flux to net enclosed electric charge
Gauss' law for magnetism (Eq. 31-49)	$\oint \vec{B} \cdot d\vec{A} = 0$	Relates net magnetic flux to net enclosed magnetic charge
Faraday's law (Eq. 31-7)	$\oint \vec{E} \cdot d\vec{s} = -\frac{d\Phi^{\text{mag}}}{dt}$	Relates induced electric field to changing magnetic flux
Ampère–Maxwell law (Eq. 31-32)	$\oint \vec{B} \cdot d\vec{s} = \mu_0\epsilon_0 \frac{d\Phi^{\text{elec}}}{dt} + \mu_0 i$	Relates induced magnetic field to changing electric flux and to current

^aWritten on the assumption that no dielectric or magnetic materials are present.

READING EXERCISE 31-15: Discuss several ways in which Faraday's law and the Ampère–Maxwell law are similar. Discuss several ways in which they are different. ■

Problems

SEC. 31-4 ■ FARADAY'S LAW

1. UHF Antenna A UHF television loop antenna has a diameter of 11 cm. The magnetic field of a TV signal is normal to the plane of the loop and, at one instant of time, its magnitude is changing at the rate 0.16 T/s. The magnetic field is uniform. What emf is induced in the antenna?

2. Small Loop A small loop of area A is inside of, and has its axis in the same direction as, a long solenoid of n turns per unit length and current i . If $i = I^{\max} \sin \omega t$, find the magnitude of the emf induced in the loop.

3. Magnetic Flux The magnetic flux encircled by the loop shown in Fig. 31-29 increases according to the relation $\Phi^{\text{mag}} = (6.0 \text{ mWb/s}^2)t^2 + (3.7 \text{ mWb/s})t$. (a) What is the magnitude of the emf induced in the loop when $t = 2.0 \text{ s}$? (b) What is the direction of the current through R ?

FIGURE 31-29 ■ Problems 3 and 13.

4. Calculate emf The magnitude of the magnetic field encircled by a single loop of wire, 12 cm in radius and of 8.5Ω resistance, changes with time as shown in Fig. 31-30. Calculate the magnitude of the emf in the loop as a function of time. Consider the time intervals (a) $t_1 = 0.0 \text{ s}$ to $t_2 = 2.0 \text{ s}$, (b) $t_2 = 2.0 \text{ s}$ to $t_3 = 4.0 \text{ s}$, (c) $t_3 = 4.0 \text{ s}$ to $t_4 = 6.0 \text{ s}$. The (uniform) magnetic field is perpendicular to the plane of the loop.

FIGURE 31-30 ■ Problem 4.

5. Uniform Magnetic Field A uniform magnetic field is normal to the plane of a circular loop 10 cm in diameter and made of copper wire (of diameter 2.5 mm). (a) Calculate the resistance of the wire. (See Table 26-2.) (b) At what rate must the magnetic field change with time if an induced current of 10 A is to appear in the loop?

6. Current in Solenoid The current in the solenoid of Touchstone Example 31-1 changes, not as stated there, but according to $i = (3.0 \text{ A/s})t + (1.0 \text{ A/s}^2)t^2$. (a) Plot the induced emf in the coil from $t_1 = 0.0 \text{ s}$ to $t_2 = 4.0 \text{ s}$. (b) The resistance of the coil is 0.15Ω . What is the current in the coil at $t = 2.0 \text{ s}$?

FIGURE 31-31 ■ Problem 7.

7. Coil Outside Solenoid In Fig. 31-31 a 120-turn coil of radius 1.8 cm and resistance 5.3Ω is placed

outside a solenoid like that of Touchstone Example 31-1. If the current in the solenoid is changed as in that sample problem, what current appears in the coil while the solenoid current is being changed?

8. Elastic Conducting Material An elastic conducting material is stretched into a circular loop of 12.0 cm radius. It is placed with its plane perpendicular to a uniform 0.800 T magnetic field. When released, the radius of the loop starts to shrink at an instantaneous rate of 75.0 cm/s. What magnitude of emf is induced in the loop at that instant?

9. Square Loop A square loop of wire is held in a uniform, magnetic field 0.24 T directed perpendicularly to the plane of the loop. The length of each side of the square is decreasing at a constant rate of 5.0 cm/s. What emf is induced in the loop when the length is 12 cm?

10. Rectangular Loop A rectangular loop (area = 0.15 m^2) turns in a uniform magnetic field, $B = 0.20 \text{ T}$. When the angle between the field and the normal to the plane of the loop is $\pi/2$ rad and increasing at 0.60 rad/s, what emf is induced in the loop?

SEC. 31-5 ■ LENZ'S LAW

11. Two Parallel Loops Though not to scale, Fig. 31-32 shows two parallel loops of wire with a common axis. The smaller loop (radius r) is above the larger loop (radius R) by a distance $x \gg R$. Consequently, the magnetic field due to the current i in the larger loop is nearly constant throughout the smaller loop. Suppose that x is increasing at the constant rate of $dx/dt = v$. (a) Determine the magnetic flux at the area bounded by the smaller loop as a function of x . (*Hint:* See Eq. 30-29.) In the smaller loop, find (b) the induced emf and (c) the direction of the induced current.

FIGURE 31-32 ■ Problem 11.

12. Circular Loop In Fig. 31-33, a circular loop of wire 10 cm in diameter (seen edge-on) is placed with its normal at an angle $\theta = 30^\circ$ with the direction of a uniform magnetic field \vec{B} of magnitude 0.50 T. The loop is then rotated such that the normal rotates in a cone about the field direction at the constant rate of 100 rev/min; the angle θ remains unchanged during the process. What is the emf induced in the loop?

FIGURE 31-33 ■ Problem 12.

13. Flux At Loop In Fig. 31-29 let the flux encircled by the loop be $\Phi^{\text{mag}}(0)$ at time $t_1 = 0$. Then let the magnetic field \vec{B} vary in a continuous but unspecified way, in both magnitude and direction, so that at time t_2 the flux is represented by $\Phi^{\text{mag}}(t_2)$. (a) Show that the net charge $q(t_2)$ that has passed through resistor R in time t_2 is

$$q(t_2) = \frac{1}{R} [\Phi^{\text{mag}}(0) - \Phi^{\text{mag}}(t_2)]$$

and is independent of the way \vec{B} has changed. (b) If $\Phi^{\text{mag}}(t_2) = \Phi^{\text{mag}}(0)$ in a particular case, we have $q(t_2) = 0$. Is the induced current necessarily zero throughout the interval from 0 to t_2 ?

14. Big Loop, Little Loop A small circular loop of area 2.00 cm^2 is placed in the plane of, and concentric with, a large circular loop of radius 1.00 m . The current in the large loop is changed uniformly from 200 A to -200 A (a change in direction) in a time of 1.00 s , beginning at $t_1 = 0$. (a) What is the magnitude of the magnetic field at the center of the small circular loop due to the current in the large loop at $t_1 = 0 \text{ s}$, $t_2 = 0.500 \text{ s}$, and $t_3 = 1.00 \text{ s}$? (b) What is the magnitude of the emf induced in the small loop at $t_2 = 0.500 \text{ s}$? (Since the inner loop is small, assume the field \vec{B} due to the outer loop is uniform over the area of the smaller loop.)

15. Copper Wire on Wooden Core One hundred turns of insulated copper wire are wrapped around a wooden cylindrical core of cross-sectional area $1.20 \times 10^{-3} \text{ m}^2$. The two ends of the wire are connected to a resistor. The total resistance in the circuit is 13.0Ω . If an externally applied uniform longitudinal magnetic field in the core changes from 1.60 T in one direction to 1.60 T in the opposite direction, how much charge flows through the circuit? (*Hint:* See Problem 13.)

16. Earth's Field At a certain place, Earth's magnetic field has magnitude $|\vec{B}| = 0.590$ gauss and is inclined downward at an angle of 70.0° to the horizontal. A flat horizontal circular coil of wire with a radius of 10.0 cm has 1000 turns and a total resistance of 85.0Ω . It is connected to a meter with 140Ω resistance. The coil is flipped through a half-revolution about a diameter, so that it is again horizontal. How much charge flows through the meter during the flip? (*Hint:* See Problem 13.)

FIGURE 31-34 ■ Problem 17.

17. Square Loop A square wire loop with 2.00 m sides is perpendicular to a uniform magnetic field, with half the area of the loop in the field as shown in Fig. 31-34. The loop contains a 20.0 V battery with negligible internal resistance. If the magnitude of the field varies with time according to $B = (0.0420 \text{ T}) - (0.870 \text{ T/s})t$, what are (a) the magnitude of the net emf in the circuit and (b) the direction of the current through the battery?

FIGURE 31-35 ■ Problem 18.

18. Three Circular Segments A wire is bent into three circular segments, each of radius $r = 10 \text{ cm}$, as shown in Fig. 31-35. Each segment is

a quadrant of a circle, ab lying in the xy plane, bc lying in the yz plane, and ca lying in the zx plane. (a) If a uniform magnetic field \vec{B} points in the positive x direction, what is the magnitude of the emf developed in the wire when \vec{B} increases at the rate of 3.0 mT/s in the x direction? (b) What is the direction of the current in segment bc ?

19. Rectangular Coil A rectangular coil of N turns and of length a and width b is rotated at frequency f in a uniform magnetic field \vec{B} , as indicated in Fig. 31-36. The coil is connected to co-rotating cylinders, against which metal brushes slide to make contact. If we arbitrarily define emf as being positive during the first quarter-turn, (a) show that the emf induced in the coil is given (as a function of time t) by

$$\mathcal{E} = 2\pi f N a b B \sin(2\pi f t) = \mathcal{E}_0 \sin(2\pi f t).$$

This is the principle of the commercial alternating-current generator. (b) Design a loop that will produce an emf with $\mathcal{E}_0 = 150 \text{ V}$ when rotated at 60.0 rev/s in a uniform magnetic field of 0.500 T .

FIGURE 31-36 ■ Problem 19.

20. Semicircle A stiff wire bent into a semicircle of radius a is rotated with frequency f in a uniform magnetic field, as suggested in Fig. 31-37. What are (a) the frequency and (b) the amplitude of the varying emf induced in the loop?

FIGURE 31-37 ■ Problem 20.

21. Electric Generator An electric generator consists of 100 turns of wire formed into a rectangular loop 50.0 cm by 30.0 cm , placed entirely in a uniform magnetic field with magnitude $B = 3.50 \text{ T}$. What is the maximum value of the emf produced when the loop is spun at 1000 rev/min about an axis perpendicular to \vec{B} ?

22. Closed Circular Loop In Fig. 31-38, a wire forms a closed circular loop, with radius $R = 2.0 \text{ m}$ and resistance 4.0Ω . The circle is centered on a long straight wire; at time $t = 0$, the current in the long straight wire is 5.0 A rightward. Thereafter, the current changes according to $i = 5.0 \text{ A} - (2.0 \text{ A/s}^2)t^2$. (The straight wire is insulated, so there is no electrical contact between it and the wire of the loop.) What are the magnitude and direction of the current induced in the loop at times $t > 0$?

FIGURE 31-38 ■ Problem 22.

23. Square Loop Two In Fig. 31-39, the square loop of wire has sides of length 2.0 cm. A magnetic field is directed out of the page; its magnitude is given by $B = (4.0 \text{ T/m} \cdot \text{s}^2) t^2 y$, where B is in teslas, t is in seconds, and y is in meters. Determine the emf around the square at $t = 2.5 \text{ s}$ and indicate whether its direction is clockwise or counterclockwise.

FIGURE 31-39 ■ Problem 23.

24. Square Loop Three For the situation shown in Fig. 31-40, $a = 12.0 \text{ cm}$ and $b = 16.0 \text{ cm}$. The current in the long straight wire is given by $i = (4.50 \text{ A/s}^2)t^2 - (10.0 \text{ A/s})t$, where i is in amperes and t is in seconds. (a) Find the magnitude of the emf in the square loop at $t = 3.00 \text{ s}$. (b) Indicate whether the direction of the induced current in the loop is clockwise or counterclockwise at $t = 3.00 \text{ s}$.

FIGURE 31-40 ■ Problem 24.

25. Parallel Copper Wires Two long, parallel copper wires of diameter 2.5 mm carry currents of 10 A in opposite directions. (a) Assuming that their central axes are 20 mm apart, calculate the magnetic flux per meter of wire that exists in the space between those axes. (b) What fraction of this flux lies inside the wires? (c) Repeat part (a) for parallel currents.

26. Rectangular Wire Loop A rectangular loop of wire with length a , width b , and resistance R is placed near an infinitely long wire carrying current i , as shown in Fig. 31-41. The distance from the long wire to the center of the loop is r . Find (a) the magnitude of the magnetic flux encircled by the loop and (b) the amount of induced current in the loop $|i^{\text{ind}}|$ as it moves away from the long wire with velocity \vec{v} . (c) Indicate whether the induced current is clockwise or counterclockwise.

FIGURE 31-41 ■ Problem 26.

SEC 31-6 ■ INDUCTION AND ENERGY TRANSFERS

27. Internal Energy If 50.0 cm of copper wire (diameter = 1.00 mm) is formed into a circular loop and placed perpendicular to a uniform magnetic field that is increasing at the constant rate of 10.0 mT/s, at what rate does internal energy increase in the loop?

28. Loop Antenna A loop antenna of area A and resistance R is perpendicular to a uniform magnetic field \vec{B} . The field drops linearly to zero in a time interval Δt . Find an expression for the total internal energy added to the loop.

29. Rod on Rails A metal rod is forced to move with constant velocity \vec{v} along two parallel metal rails, connected with a strip of metal at one end, as shown in Fig. 31-42. A magnetic field of magnitude $|\vec{B}| = 0.350 \text{ T}$ points out of the page. (a) If

FIGURE 31-42 ■ Problem 29 and Problem 31.

the rails are separated by 25.0 cm and the speed of the rod is 55.0 cm/s, what emf is generated? (b) If the rod has a resistance of 18.0 Ω and the rails and connector have negligible resistance, what is the current in the rod? (c) At what rate is mechanical energy being transformed to thermal energy?

30. Find Terminal Speed In Fig. 31-43, a long rectangular conducting loop, of width L , resistance R , and mass m , is hung in a horizontal, uniform magnetic field \vec{B} that is directed into the page and that exists only above line aa . The loop is then dropped; during its fall, it accelerates until it reaches a certain terminal speed v_t . Ignoring air drag, find that terminal speed.

FIGURE 31-43 ■ Problem 30.

31. Rod on Rails Two The conducting rod shown in Fig. 31-42 has length L and is being pulled along horizontal, frictionless conducting rails at a constant velocity \vec{v} . The rails are connected at one end with a metal strip. A uniform magnetic field \vec{B} , directed out of the page, fills the region in which the rod moves. Assume that $L = 10 \text{ cm}$, $v = 5.0 \text{ m/s}$, and $B = 1.2 \text{ T}$. (a) What is the magnitude of the emf induced in the rod? (b) What is the magnitude and direction (clockwise or counterclockwise) of the current in the conducting loop? Assume that the resistance of the rod is 0.40Ω and that the resistance of the rails and metal strip is negligibly small. (c) At what rate is thermal energy added to the rod? (d) What magnitude of force must be applied to the rod by an external agent to maintain its motion? (e) At what rate does this external agent do work on the rod? Compare this answer with the answer to (c).

32. Rods Bent into V Two straight conducting rails form a right angle where their ends are joined. A conducting bar in contact with the rails starts at the vertex at time $t = 0$ and moves with a constant velocity of magnitude 5.20 m/s along them, as shown in Fig. 31-44. A magnetic field of magnitude $B = 0.350 \text{ T}$ is directed out of the page. Calculate (a) the flux through the triangle formed by the rails and bar at $t = 3.00 \text{ s}$ and (b) the magnitude of emf around the triangle at that time. (c) If we write the emf as $\mathcal{E} = at^n$, where a and n are constants, what is the value of n ?

FIGURE 31-44 ■ Problem 32.

33. Rod on Conducting Rails Two Figure 31-45 shows a rod of length L caused to move at constant speed v along horizontal conducting rails. The magnetic field in which the rod moves is *not uniform* but is provided by a current i in a long wire parallel to the rails. Assume that $v = 5.00 \text{ m/s}$, $a = 10.0 \text{ mm}$, $L = 10.0 \text{ cm}$, and $i = 100 \text{ A}$. (a) Calculate the magnitude of the emf induced in the rod. (b) What is the magnitude of the current in the conducting loop?

FIGURE 31-45 ■ Problem 33.

Assume that the resistance of the rod is $0.400\ \Omega$ and that the resistance of the rails and the strip that connects them at the right is negligible. (c) At what rate is internal energy added to the rod? (d) What magnitude of force must be applied to the rod by an external agent to maintain its motion? (e) At what rate does this external agent do work on the rod? Compare this answer to that for (c).

SEC. 31-7 ■ INDUCED ELECTRIC FIELDS

34. Two Circular Regions Figure 31-46 shows two circular regions R_1 and R_2 with radii $r_1 = 20.0\ \text{cm}$ and $r_2 = 30.0\ \text{cm}$. In R_1 there is a uniform magnetic field of magnitude $B_1 = 50.0\ \text{mT}$ into the page, and in R_2 there is a uniform magnetic field of magnitude $B_2 = 75.0\ \text{mT}$ out of the page (ignore any fringing of these fields). Both fields are decreasing at the rate of $8.50\ \text{mT/s}$. Calculate the integral $\oint \vec{E} \cdot d\vec{s}$ for each of the three dashed paths.

FIGURE 31-46 ■ Problem 34.

35. Long Solenoid A long solenoid has a diameter of $12.0\ \text{cm}$. When a current i exists in its windings, a uniform magnetic field of magnitude $B = 30.0\ \text{mT}$ is produced in its interior. By decreasing i , the field is caused to decrease at the rate of $6.50\ \text{mT/s}$. Calculate the magnitude of the induced electric field (a) $2.20\ \text{cm}$ and (b) $8.20\ \text{cm}$ from the axis of the solenoid.

36. Magnet Lab Early in 1981 the Francis Bitter National Magnet Laboratory at M.I.T. commenced operation of a 3.3-cm -diameter cylindrical magnet that produces a $30\ \text{T}$ field, then the world's largest steady-state field. The field magnitude can be varied sinusoidally between the limits of 29.6 and $30.9\ \text{T}$ at a frequency of $15\ \text{Hz}$. When this is done, what is the maximum value of the magnitude of the induced electric field at a radial distance of $1.6\ \text{cm}$ from the axis? (*Hint:* See Touchstone Example 31-3.)

37. Drop to Zero Prove that the electric field \vec{E} in a charged parallel-plate capacitor cannot drop abruptly to zero (as is suggested at point a in Fig. 31-47), as one moves perpendicular to the field, say, along the horizontal arrow in the figure. Fringing of the field lines always occurs in actual capacitors, which means that \vec{E} approaches zero in a continuous and gradual way (see Problem 35 in Chapter 30). (*Hint:* Apply Faraday's law to the rectangular path shown by the dashed lines).

FIGURE 31-47 ■ Problem 37.

SEC 31-8 ■ INDUCED MAGNETIC FIELDS

38. Charging Capacitor Touchstone Example 31-4 describes the charging of a parallel-plate capacitor with circular plates of radius $55.0\ \text{mm}$. At what two radii r from the central axis of the capacitor is the magnitude of the induced magnetic field equal to 50% of its maximum value?

39. Induced Magnetic Field The induced magnetic field $6.0\ \text{mm}$ from the central axis of a circular parallel-plate capacitor and

between the plates has magnitude of $2.0 \times 10^{-7}\ \text{T}$. The plates have radius $3.0\ \text{mm}$. At what rate $|d\vec{E}/dt|$ is the electric field magnitude between the plates changing?

40. Parallel-Plate Capacitor Suppose that a parallel-plate capacitor has circular plates with radius $R = 30\ \text{mm}$ and a plate separation of $5.0\ \text{mm}$. Suppose also that a sinusoidal potential difference with a maximum value of $150\ \text{V}$ and a frequency of $60\ \text{Hz}$ is applied across the plates. That is,

$$\Delta V = (150\ \text{V}) \sin[2\pi(60\ \text{Hz})t].$$

(a) Find $B^{\max}(R)$, the maximum value of the magnitude of the induced magnetic field that occurs at $r = R$. (b) Plot $B^{\max}(r)$ for $0 < r < 10\ \text{cm}$.

41. Uniform Electric Flux Figure 31-48 shows a circular region of radius $R = 3.00\ \text{cm}$ in which a uniform electric flux is directed out of the page. The total electric flux enclosed by the region is given by $\Phi^{\text{elec}} = (3.00\ \text{mV} \cdot \text{m/s})t$, where t is time. What is the magnitude of the magnetic field that is induced at radial distances (a) $2.00\ \text{cm}$ and (b) $5.00\ \text{cm}$?

FIGURE 31-48 ■ Problems 41 through 44, and 57, 59, and 60.

42. Nonuniform Electric Flux Figure 31-48 shows a circular region of radius $R = 3.00\ \text{cm}$ in which an electric flux is directed out of the page. The flux encircled by a concentric circle of radius r is given by $\Phi^{\text{elec}} = (0.600\ \text{V} \cdot \text{m/s})(r/R)t$, where $r \leq R$ and t is time. What is the magnitude of the induced magnetic field at radial distances (a) $2.00\ \text{cm}$ and (b) $5.00\ \text{cm}$?

43. Uniform Electric Field In Fig. 31-48, a uniform electric field is directed out of the page within a circular region of radius $R = 3.00\ \text{cm}$. The magnitude of the electric field is given by $E = (4.5 \times 10^{-3}\ \text{V/m} \cdot \text{s})t$, where t is time. What is the magnitude of the induced magnetic field at radial distances (a) $2.00\ \text{cm}$ and (b) $5.00\ \text{cm}$?

44. Nonuniform Electric Field In Fig. 31-48, an electric field is directed out of the page within a circular region of radius $R = 3.00\ \text{cm}$. The magnitude of the electric field is given by $E = (0.500\ \text{V/m} \cdot \text{s})(1 - r/R)t$, where t is the time and r is the radial distance ($r \leq R$). What is the magnitude of the induced magnetic field at radial distances (a) $2.00\ \text{cm}$ and (b) $5.00\ \text{cm}$?

45. Discharging Capacitor A capacitor with square plates of edge length L is being discharged by a current of $0.75\ \text{A}$. Figure 31-49 is a head-on view of one of the plates from inside the capacitor. A dashed rectangular path is shown. If $L = 12\ \text{cm}$, $W = 4.0\ \text{cm}$, and $H = 2.0\ \text{cm}$, what is the value of $\oint \vec{B} \cdot d\vec{s}$ around the dashed path?

FIGURE 31-49 ■ Problem 45.

46. Charging Capacitor The circuit in Fig. 31-50 consists of switch S , a $12.0\ \text{V}$ ideal battery, a $20.0\ \text{M}\Omega$ resistor, and an air-filled capacitor. The capacitor has parallel circular plates of radius $5.00\ \text{cm}$,

FIGURE 31-50 ■ Problem 46.

separated by 3.00 mm. At time $t = 0$ s, switch S is closed to begin charging the capacitor. The electric field between the plates is uniform. At $t = 250 \mu\text{s}$, what is the magnitude of the magnetic field within the capacitor, at radial distance 3.00 cm?

SEC. 31-9 ■ DISPLACEMENT CURRENT

47. Prove That Displacement Prove that the displacement current in a parallel-plate capacitor of capacitance C can be written as $i^{\text{dis}} = C(d\Delta V/dt)$, where ΔV is the potential difference between the plates.

48. At What Rate At what rate must the potential difference between the plates of a parallel-plate capacitor with a $2.0 \mu\text{F}$ capacitance be changed to produce a displacement current of 1.5 A?

49. Current Density For the situation of Touchstone Example 31-4, show that the magnitude of the current density of the displacement current is $J^{\text{dis}} = \epsilon_0(dE/dt)$ for $r \leq R$.

50. Being Discharged A parallel-plate capacitor with circular plates of radius 0.10 m is being discharged. A circular loop of radius 0.20 m is concentric with the capacitor and halfway between the plates. The displacement current through the loop is 2.0 A. At what rate is the magnitude of the electric field between the plates changing?

51. Displacement Current As a parallel-plate capacitor with circular plates 20 cm in diameter is being charged, the current density of the displacement current in the region between the plates is uniform and has a magnitude of 20 A/m^2 . (a) Calculate the magnitude B of the magnetic field at a distance $r = 50$ mm from the axis of symmetry of this region. (b) Calculate dE/dt in this region.

52. Electric Field The magnitude of the electric field between the two circular parallel plates in Fig. 31-51 is $E = (4.0 \times 10^5 \text{ V} \cdot \text{m}) - (6.0 \times 10^4 \text{ V} \cdot \text{m/s})t$, with E in volts per meter and t in seconds. At $t = 0$ s, the field is upward as shown. The plate area is $4.0 \times 10^{-2} \text{ m}^2$. For $t \geq 0$ s, (a) what are the magnitude and direction of the displacement current between the plates and (b) is the direction of the induced magnetic field clockwise or counterclockwise around the plates?

FIGURE 31-51 ■ Problem 52.

53. Magnitude of Electric Field The magnitude of a uniform electric field collapses to zero from an initial strength of $6.0 \times 10^5 \text{ N/C}$ in a time of $15 \mu\text{s}$ in the manner shown in Fig. 31-52. Calculate the amount of displacement current, $|i|$, through a 1.6 m^2 area perpendicular to the field, during each of the time intervals, a , b , and c shown on the graph. (Ignore the behavior at the ends of the intervals.)

FIGURE 31-52 ■ Problem 53.

54. Displacement Current Two A parallel-plate capacitor with circular plates is being charged. Consider a circular loop centered on the central axis between the plates. The loop radius is 0.20 m, the plate radius is 0.10 m, and the displacement current through the loop is 2.0 A. What is the rate at which the magnitude of the electric field between the plates is changing?

55. Square Plates A parallel-plate capacitor has square plates 1.0 m on a side as shown in Fig. 31-53. A current of 2.0 A charges the capacitor, producing a uniform electric field \vec{E} between the plates, with \vec{E} perpendicular to the plates. (a) What is the displacement current i^{dis} through the region between the plates? (b) What is dE/dt in this region? (c) What is the displacement current through the square dashed path between the plates? (d) What is $\oint \vec{B} \cdot d\vec{s}$ around this square dashed path?

FIGURE 31-53 ■ Problem 55.

56. Consider a Loop A capacitor with parallel circular plates of radius R is discharging via a current of 12.0 A. Consider a loop of radius $R/3$ that is centered on the central axis between the plates. (a) How much displacement current is encircled by the loop? The maximum induced magnetic field has a magnitude of 12.0 mT. (b) At what radial distance from the central axis of the plate is the magnitude of the induced magnetic field 3.00 mT?

57. Uniform Displacement-Current Density. Figure 31-48 shows a circular region of radius $R = 3.00$ cm in which a displacement current is directed out of the page. The magnitude of the displacement current has a uniform density $J^{\text{dis}} = 6.00 \text{ A/m}^2$. What is the magnitude of the magnetic field due to the displacement current at radial distances (a) 2.00 cm and (b) 5.00 cm?

58. Actual and Displacement Figure 31-54a shows current i that is produced in a wire of resistivity $1.62 \times 10^{-8} \Omega \cdot \text{m}$ in the direction indicated. The magnitude of the current versus time t is shown in Fig. 31-54b. Point P is at radius 9.00 mm from the wire's center. Determine the magnitude of the magnetic field at point P due to the real current i in the wire at (a) $t_1 = 20$ ms, (b) $t_2 = 40$ ms, (c) $t_3 = 60$ ms, and (d) $t_4 = 70$ ms. Next, assume that the electric field driving the current is confined to the wire.

FIGURE 31-54 ■ Problem 58.

Then determine the magnitude of the magnetic field at point P due to the displacement current i^{dis} in the wire at (e) $t_1 = 20$ ms, (f) $t_2 = 40$ ms, (g) $t_3 = 60$ ms, and (h) $t_4 = 70$ ms. (i) When both magnetic fields are present at point P , what are their directions in Fig. 31-54a?

59. Nonuniform Displacement-Current Density. Figure 31-48 shows a circular region of radius $R = 3.00$ cm in which a displacement current is directed out of the page. The displacement current has a density of magnitude $J^{\text{dis}} = (4.00 \text{ A/m}^2)(1 - r/R)$, where r is the radial distance $r \leq R$. What is the magnitude of the magnetic field due to the displacement current at radial distances (a) 2.00 cm and (b) 5.00 cm?

60. Uniform Displacement Current. Figure 35-48 shows a circular region of radius $R = 3.00$ cm in which a uniform displacement current $i^{\text{dis}} = 0.500$ A is directed out of the page. What is the magnitude of the magnetic field due to the displacement current at radial distances (a) 2.00 cm and (b) 5.00 cm?

SEC. 31-10 ■ GAUSS' LAW FOR MAGNETIC FIELDS

61. Rolling a Sheet of Paper Imagine rolling a sheet of paper into a cylinder and placing a bar magnet near its end as shown in Fig. 31-55. (a) Sketch the magnetic field lines that pass through the surface of the cylinder. (b) What can you say about the sign of $\vec{B} \cdot d\vec{A}$ for every area $d\vec{A}$ on the surface? (c) Does this result contradict Gauss' law for magnetism? Explain.

FIGURE 31-55 ■ Problem 61.

62. Die Suppose the magnetic flux at each of five faces of a die (singular of "dice") is given by $\Phi^{\text{mag}} = \pm N$ Wb, where $N (= 1 \text{ to } 5)$

is the number of spots on the face. The flux is positive (outward) for N even and negative (inward) for N odd. What is the flux at the sixth face of the die? Is it directed in or out?

63. Right Circular Cylinder A Gaussian surface in the shape of a right circular cylinder with end caps has a radius of 12.0 cm and a length of 80.0 cm. One end encircles an inward magnetic flux of $25.0 \mu\text{Wb}$. At the other end there is a uniform magnetic field of 1.60 mT, normal to the surface and directed outward. What is the net magnetic flux at the curved surface?

FIGURE 31-56 ■ Problem 64.

64. Weird Shape Figure 31-56 shows a closed surface. Along the flat top face, which has a radius of 2.0 cm, a magnetic field \vec{B} of magnitude 0.30 T is directed outward. Along the flat bottom face, a magnetic flux of 0.70 mWb is directed outward. What are (a) the magnitude and (b) the net magnetic flux at the curved part of the surface?

Additional Problems

65. Power from a Tether A few years ago, the space shuttle *Columbia* tried an experiment with a tethered satellite. The satellite was released from the shuttle and slowly reeled out on a long conducting cable as shown in Fig. 31-57 (not to scale). For this problem we will make the following approximations:

The shuttle is moving at a constant velocity.

The Earth's magnetic field is constant and uniform.

The line of the tether, the velocity of the system, and the magnetic field are all perpendicular to each other.

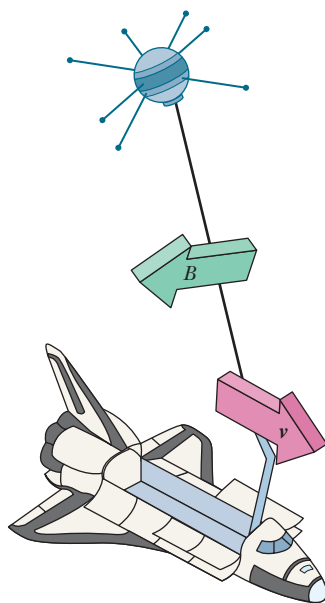

FIGURE 31-57 ■ Problem 65.

The Earth's field produces an emf from one end of the cable to the other. The idea is to use a system like this to generate electric power in space more efficiently than with solar panels.

- Explain why a voltage difference is produced.
- If the Earth's magnetic field is given by a magnitude \vec{B} , the shuttle-satellite system is moving with a velocity \vec{v} , and the tether has a length L , calculate the magnitude of the emf \mathcal{E} from one end of the tether to the other.
- At the shuttle's altitude, the Earth's field is about 0.3 gauss and the shuttle's speed is about 7.5 km/s. The tether is 20 km long (!). What is the expected potential difference in volts?
- At the altitude of the shuttle, the thin atmosphere is lightly ionized, allowing a current of about 0.5 amps to flow from the satellite

back to the shuttle through the thin air. What is the resistance of the 20 km of ionized air?

66. Building a Generator The apparatus shown in Fig. 31-58 can be used to build a motor. This device can also be used to build a generator that will produce a voltage. (a) Explain the setup that one would use to make a motor and explain how it works. Do the same for the generator. (b) Estimate the maximum voltage that would be produced if you cranked the generator by hand. (*Hint:* As a comparison for estimating the strength of the bar magnet, the Earth's magnetic field at our location is about 0.4 gauss.)

FIGURE 31-58 ■ Problem 66.

67. Faraday's Law Faraday's law describes the emf produced by magnetic fields in a variety of circumstances. State and discuss Faraday's law, being careful to include a discussion of different physical situations that may be described by the statement of the law.

68. Magnetic Field, Force, and Torque Figure 31-59 shows two long, current-carrying wires and a bar magnet. At the right is shown a compass specifying set of direction labels. For each of the vectors (a)–(e) below, select the direction label that best gives the direction of the item. If the magnitude of the item is zero, write 0. If none of the directions are correct, write N.

FIGURE 31-59 ■ Problem 68.

- (a) The magnetic field due to the lower wire at the center of the upper wire
 (b) The force on the lower wire due to the magnetic field from the upper wire
 (c) The net torque acting on the upper wire
 (d) The magnetic field due to the currents at the center of the magnet
 (e) The net force acting on the lower wire due to the bar magnet

69. B Increases in Time In Fig. 31-60a, a uniform magnetic field \vec{B} increases in magnitude with time t as given by Fig. 31-60b. A circular conducting loop of area $8.0 \times 10^{-4} \text{ m}^2$ lies in the field, in the plane of the page. The amount of charge q that has passed point A on the loop is given in Fig. 31-60c as a function of t . What is the loop's resistance?

FIGURE 31-60 ■ Problem 69.

70. Circular Loop Around a Solenoid In Fig. 31-61a, a circular loop of wire is concentric with a solenoid and lies in a plane that is perpendicular to the solenoid's central axis. The loop has radius 6.00 cm. The solenoid has radius 2.00 cm, consists of 8000 turns per meter, and has a current i_{sol} that varies with time t as given in Fig. 31-61b. Figure 31-61c shows, as a function of time, the energy E^{thermal} that is transformed to thermal energy in the loop. What is the loop's resistance?

FIGURE 31-61 ■ Problem 70.

71. Magnitudes and Direction Figure 31-62a shows a wire that forms a rectangle and has a resistance of $5.0 \text{ m}\Omega$. Its interior is split into three equal areas with different magnetic fields \vec{B}_1 , \vec{B}_2 , and \vec{B}_3 that are either directly out of or into the page, as indicated. The fields are uniform within each region. Figure 31-62b gives the change in the z components B_z of the three fields with time t . What are the magnitude and direction of the current induced in the wire?

FIGURE 31-62 ■ Problem 71.

72. Two Concentric Regions Figure 31-63a shows two concentric circular regions in which uniform magnetic fields can change. Region 1, with radius $r_1 = 1.0 \text{ cm}$, has an outward magnetic field \vec{B}_1 that is increasing in magnitude. Region 2, with radius $r_2 = 2.0 \text{ cm}$, has an outward magnetic field \vec{B}_2 that may also be changing. Imagine that a conducting ring of radius R is centered on the two regions and then the emf \mathcal{E} around the ring is determined. Figure 31-63b gives emf \mathcal{E} as a function of the square of the ring's radius, R^2 , to the outer edge of region 2. What are the rates of B -field magnitude change (a) dB_1/dt and (b) dB_2/dt ? (c) Is the magnitude of \vec{B}_2 increasing, decreasing, or remaining constant?

FIGURE 31-63 ■ Problem 72.

73. Pulled at Constant Speed Figure 31-64a shows a rectangular conducting loop of resistance $R = 0.020 \Omega$, height $H = 1.5 \text{ cm}$, and length $D = 2.5 \text{ cm}$ being pulled at constant speed $v = 40 \text{ cm/s}$ through two regions of uniform magnetic field. Figure 31-64b gives the current i induced in the loop as a function of the position x of the right side of the loop. For example, a current of $3.0 \mu\text{A}$ is induced clockwise as the loop enters region 1. What are the magnitudes and directions of the magnetic field in (a) region 1 and (b) region 2?

FIGURE 31-64 ■ Problem 73.

74. Plane Loop A plane loop of wire consisting of a single turn of area 8.0 cm^2 is perpendicular to a magnetic field that increases uniformly in magnitude from 0.50 T to 2.5 T in a time of 1.0 s . What is the resulting induced current if the coil has a total resistance of 2.0Ω ?

75. At What Rate Must B Change The plane of a rectangular coil of dimensions 5.0 cm by 8.0 cm is perpendicular to the direction of magnetic field B . If the coil has 75 turns and a total resistance of 8.0Ω , at what rate must the magnitude of B change in order to induce a current of 0.10 A in the windings of the coil?

76. Rod on Rails 3 In the arrangement shown in Fig. 31-65, a conducting rod rolls to the right along parallel conducting rails connected on one end by a 6.0Ω resistor. A 2.5 T magnetic field is directed *into* the paper. Let $L = 1.2 \text{ m}$. Neglect the mass of the bar and friction. (a) Calculate the applied force required to move the bar to the right at a *constant* speed of 2.0 m/s . (b) At what rate is energy dissipated in the resistor?

FIGURE 31-65 ■ Problem 76.

77. An Engineer An engineer has designed a setup with a small pickup coil placed in the center of a large field coil as shown in Fig. 31-66. Both coils have many turns of conducting wire. The field coil produces a magnetic field that is proportional in magnitude to the amount of current flowing through its wires. The pickup coil is smaller and its many turns can sense or “pick up” the changing magnetic field in the field coil. The pickup coil produces an emf that is proportional in magnitude to the rate of change of the magnetic field and the angle ϕ . Here ϕ is the angle between the normal to the field coil and the normal to the pickup coil. You have been hired as a consultant to check on the reliability of the engineer’s work. You figure out how to use Faraday’s law along with proportional reason-

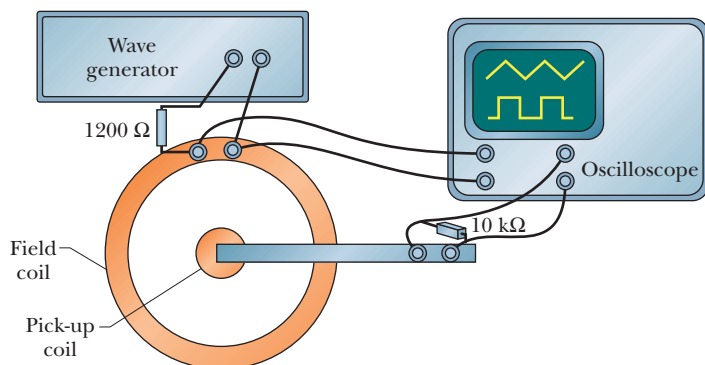

FIGURE 31-66a ■ Problem 77.

ing to check on the validity of the results that have been reported without doing any formal calculations or measurements. Sketches from the engineer’s notebook are shown in Fig. 31-66b. (a) Look at the graph pair in Fig. 31-66b. Sketch the measured emf induced in the pickup coil if the engineer has adjusted the scope so the maximum emf is the first positive grid line and the minimum emf is on the first negative grid line. Assume that the normal to each of the coils is pointing in the same direction. (b) According to the engineer’s notebook, she fed exactly the same pattern of current to the field coil but she turned the pickup coil so its normal makes an angle of $+45^\circ$ with respect to the normal to the plane of the field coil. Carefully sketch the pattern of emf observed in the pickup coil. What is the maximum and minimum amplitude of the emf in “grid” units? (c) What happens when she flips the pickup coil over around so its normal is 180° from the normal to the field coil? Sketch the emf and use the correct signs for the values of the induced emf for this situation. Explain the reasons for the shape and magnitude of your sketch in each case.

FIGURE 31-66b ■ Problem 77.

78. Engineer Task 2 You are still double-checking the work of the engineer from Problem 77. Consider the graph shown in Fig. 31-67. (a) What should our honest and competent engineer have reported for the pattern of emf values as a function of time? Assume that

FIGURE 31-67 ■ Problem 78.

once again the normal to the pickup coil is in the same direction as the normal to the field coil. Please take care to sketch not only the shape of the emf graph but also its proper magnitude using the same gain setting on the oscilloscope as you did in Problem 77. Use a solid line for your sketch. (b) Suppose the engineer reduced the number of turns in the pickup coil by a factor of 2 and redid the measurements. Sketch a new graph showing the shape and proper magnitudes for the expected pickup coil emf using a dashed line. Explain the reasons for the shape and magnitude of your sketch in each case.

79. Engineer Task 3 You are still double-checking the work of the engineer from Problem 31-77. Assume that the number of turns in both the field and pickup coils is the same as in that problem, as is the oscilloscope setting. Consider the graph shown in Fig. 31-68. (a) What should our honest and competent engineer have reported for the pattern of current fed into the field coil as a function of time? Assume that once again the normal to the pickup coil is in the same

FIGURE 31-68 ■ Problem 79.

direction as the normal to the field coil. Please take care to sketch not only the shape of the emf graph but also its proper magnitude using the same gain setting on the oscilloscope as you did in Problem 31-77. Use a solid line for your sketch. (b) Suppose the engineer reduced the number of turns in the pickup coil by a factor of 2 and redid the measurements. Sketch a new graph showing the shape and proper magnitudes for emf in the field coil using a dashed line. Explain the reasons for the shape and magnitude of your sketch in each case.

80. Engineer Task 4 You are still double-checking the work of the engineer from Problem 31-77. Assume that the number of turns in both the field and pickup coils is the same as in that problem. Consider the graph shown in Fig. 31-69. What should our honest and competent engineer have reported for the pattern of emf induced in the pickup coil if the oscilloscope gain is adjusted to give a maximum value of emf of +2 oscilloscope grid units and a minimum value of -2 oscilloscope units? (*Hint*: What is the derivative of the sine function?) Explain the reason for the shape and magnitude of your sketch in each case.

FIGURE 31-69 ■ Problem 80.

81. Ring of Copper

Figure 31-70 shows a ring of copper with its plane perpendicular to the axis of the nearby rod-shaped magnet. In which of the following situations will a current be induced in the ring? Choose all correct answers.

FIGURE 31-70 ■ Problem 81.

- (a) The magnet is moved horizontally toward the left.
- (b) The ring is moved away from the magnet.
- (c) The ring is rotated around any of its diameters.
- (d) The magnet is moved up or down.
- (e) The ring is rotated around its center in the plane in which it lies.

32

Inductors and Magnetic Materials

This is a microscopic view of a bacterium found in Australia that will swim to the muddy bottom of a pond to escape oxygen in its environment and find the nutrients it needs to survive. But if this bacterium were transported to a pond in the United States, it would swim to the top of the pond and die.

How does this bacterium know how to swim down in Australia but not in the U.S.?

The answer is in this chapter.

32-1 Introduction

In the previous chapter we described how an electric car or toothbrush could be charged without electrical contacts. Likewise the guitar pickup described in Section 31-5 amplifies sound. These devices make practical use of inductance. In this chapter we consider some additional practical uses of inductance phenomena in common electric circuit elements known as inductors and transformers. You will consider the basic behaviors of these elements in circuits where the voltage changes in time. Then you will move on to what appears to be an unrelated topic—the behavior of magnetic materials.

The simplest magnetic structure contained in magnetic materials is a magnetic dipole. We will trace the origin of magnetic dipoles, and the associated magnetic properties of materials back to atoms and electrons. You will then reconsider inductors and transformers and learn how magnetic materials can be used to enhance their performance. Some of the first inductors are pictured in Fig. 32-1.

Finally, we will discuss recent theories that enable us explain why the Earth behaves like a huge magnetic dipole, and we will consider the possible role induction plays in explaining the characteristics and changing nature of the Earth's magnetic field.

32-2 Self-Inductance

Let's explore how the phenomenon of inductance introduced in the previous chapter can be useful in the design of electric circuits with changing currents. In Section 31-3 we saw that when two coils are near each other, a changing current in one of the coils can induce an emf in the other according to Faraday's law ($\mathcal{E} = -Nd \Phi^{\text{mag}}/dt$). But if the second coil is part of an electric circuit, the current induced in it can also induce an emf in the first coil. This phenomenon, known as **mutual induction**, is used in the design of *inductive chargers*—noncontact charging systems like those used for electric toothbrushes and other devices. In multiple-loop coils the emfs produced by mutual induction are proportional to the number of loops in the coil. For this reason mutual induction is also used in the design of **transformers**—devices that can transform time-varying voltages to larger or smaller time-varying voltages.

In addition, when current in a single coil with one or more loops changes, this induces an emf in the *same* coil. This emf is produced as the result to the changing flux the coil produces in the area it encloses. This process is known as **self induction**. In general,

A self-induced emf \mathcal{E}_L appears in any coil whenever its current is changing.

According to Lenz's law the self-induced emf acts to oppose the change of current in the coil. For this reason, coils of wire called **inductors** (sometimes called "chokes") are useful in circuits whenever it is desirable to stabilize currents. In a circuit diagram, an inductor is denoted by a symbol that looks like helical loops of wire () . See Figs. 32-2 and 32-3. In addition, inductors can be combined with resistors and capacitors to modify the characteristics in circuits driven by oscillating voltage sources. In this chapter we consider the role of inductors in stabilizing currents. In the next chapter we will study the behavior of inductors in circuits with oscillating voltages.

A typical **inductor** consists of a wire that is coiled into a very large number of loops wrapped around a piece of hollow cardboard or perhaps a magnetic rod. Inductors come in many shapes. A common shape is a **solenoid**, which consists of a tightly

FIGURE 32-1 ■ The crude inductors with which Michael Faraday discovered the law of induction. In those days amenities such as insulated wire were not commercially available. It is said that Faraday insulated his wires by wrapping them with strips cut from one of his wife's petticoats.

FIGURE 32-2 ■ If the current in a coil is changed by varying the contact position on a variable resistor, a self-induced emf \mathcal{E}_L will appear in the coil while the current is changing.

FIGURE 32-3 ■ The arrow and the + and – signs on either side of the inductor indicate the direction the emf \mathcal{E}_L acts in relative to the direction of the current in the circuit alongside the coil. (a) The current i is increasing and the self-induced emf \mathcal{E}_L appears along the coil in a direction such that it opposes the increase. (b) The current i is decreasing and the self-induced emf appears in a direction such that it opposes the decrease.

wound helical coil of wire—like the one Faraday wound shown in the lower part of Fig. 32-1. Because the magnetic field inside a solenoid is very uniform, it is not difficult to calculate the emfs created by current changes in solenoids. For this reason, we shall consider a solenoid as our basic type of inductor. Also, at first we assume that all inductors are air-core inductors that have no magnetic materials such as iron in their vicinity to distort their magnetic fields.

The Mathematics of Self-Inductance

We start our mathematical treatment of self-inductance with a solenoid-shaped inductor of length l and total number of loops N . When a charge flows through an inductor, the coil produces a magnetic field inside its coils whose strength is *directly proportional* to the current. For an ideal solenoid, the magnitude of the magnetic field is given by Eq. 30-25,

$$B = \mu_0 n |i| \quad (\text{inside an ideal solenoid}), \quad (\text{Eq. 30-25})$$

where μ_0 is the magnetic constant and n the number of turns per unit length.

This magnetic field yields an amount of flux over the area A enclosed by the coil of $|\Phi^{\text{mag}}| = BA = n(\mu_0 A |i|)$. Now, if we try to change the current by changing the resistance in the circuit shown in Fig. 32-2, then the magnetic field and hence the flux at the center of the coil changes. According to Faraday’s law this change in flux will produce an emf in the coil given by Eq. 31-7 ($\mathcal{E} = -Nd \Phi^{\text{mag}}/dt$). According to Lenz’s law this emf will act to oppose the change in the current. Thus, if you close a switch that connects a voltage source to an inductor, the induced “back” emf will retard the rise in current through the circuit. An emf that acts to oppose a change in current is known as a **back emf**. Alternately, if a current already exists in a circuit then opening a switch will slow the rate of reduction of the current (Fig. 32-3). Applying Faraday’s law and noting that the total number of turns N is the product of the turns per unit length, n , and the length, l , of the solenoid gives us

$$\mathcal{E}_L = -N \frac{d\Phi^{\text{mag}}}{dt} = -nl \frac{d\Phi^{\text{mag}}}{dt} = -\mu_0 An^2 l \frac{di}{dt} \quad (\text{solenoidal air-core inductor}), \quad (32-1)$$

where \mathcal{E}_L is the self-induced emf in the solenoid.

If the solenoid is very much longer than its radius, then Eq. 32-1 expresses its inductance to a good approximation. However, we have neglected the spreading of the magnetic field lines near the ends of the solenoid, just as the parallel-plate capacitor formula $C = \epsilon_0 A/d$ neglects the fringing of the electric field lines near the edges of the capacitor plates.

Equation 32-1 tells us that the amount of self-induced back emf is directly proportional to the rate of change of the current through the coil. The minus sign tells us that \mathcal{E}_L is a back emf. It is customary to combine the product of constants (which for a solenoid is $\mu_0 An^2 l$) and write this proportionality between the self-induced emf and the rate of current change as

$$\mathcal{E}_L = -L \frac{di}{dt}, \quad (32-2)$$

where L is known as the self-inductance of the coil. As we learned in Chapter 31, the minus sign in the equation indicates that the emf acts to oppose the change in current. From Eq. 32-2 we see that when the inductance L is large, a large emf will be produced for a given rate of current change.

This combination of terms (such as area, length, and so on) that makes up the constant of proportionality, L , is only valid for a long solenoid. The terms will be different if

the coil has a flat shape or if the inductor wire is wrapped around an iron core. In addition, since any electric circuit is basically a loop of some sort, all circuits have a certain amount of self-inductance even when no inductor is present. Self-inductance is usually negligible, but it can be significant when high-voltage circuits are switched on or off or when the circuit current oscillates at high frequencies. If we have a complicated geometry and cannot calculate inductance simply, the inductance L can be determined experimentally by measuring both the emf and the rate of change of current and taking the ratio of these quantities. Thus, for any geometry the **self-inductance** of an inductor or a circuit can be defined as the ratio of the induced emf to the rate of current change or

$$L \equiv -\frac{\mathcal{E}_L}{di/dt} \quad (\text{self-inductance defined}). \quad (32-3)$$

For any inductor having a self-inductance L , Eqs. 32-1 and 32-2 tell us that $N(d\Phi^{\text{mag}}/dt) = L di/dt$. Thus we conclude that $\mathcal{E}_L = -Nd \Phi^{\text{mag}}/dt = -L di/dt$, so $Li = N\Phi^{\text{mag}}$, where N is the number of turns in the coil producing flux and i is the current in the coil producing the flux. The windings of the inductor are said to be *linked* by the shared flux, and the product $N\Phi^{\text{mag}}$ is called the *magnetic flux linkage*. This leads us to an alternate definition of inductance (which is equivalent to that given in Eq. 32-3):

$$L \equiv \frac{N\Phi^{\text{mag}}}{i} \quad (\text{alternative definition of self-inductance}). \quad (32-4)$$

The inductance L is thus a measure of the flux linkage produced by the inductor per unit of current.

Because the SI unit of magnetic flux is the tesla-square meter, the SI unit of inductance is the tesla square-meter per ampere ($\text{T} \cdot \text{m}^2/\text{A}$). We call this the **henry** (H), after American physicist Joseph Henry, the co-discoverer, with Faraday, of the law of induction. Thus,

$$1 \text{ henry} = 1 \text{ H} = 1 \text{ T} \cdot \text{m}^2/\text{A}. \quad (32-5)$$

In any inductor (such as a flat coil, a solenoid, or a toroid) a self-induced emf appears whenever the current changes with time. The amount of the current has no influence on the amount of induced emf. Only the rate of change of the current matters.

You can find the *direction* of a self-induced emf from Lenz's law. The minus signs in Eqs. 32-2 and 32-3 indicate that—as the law states and Fig. 32-2 shows—the self-induced emf \mathcal{E}_L has an orientation such that it opposes the change in current i .

Ideal Inductors

In Section 31-7 we saw that we cannot define an electric potential for an emf that is induced by a changing magnetic flux. This means that when a self-induced emf is produced, we cannot define an electric potential within the inductor itself. However, electric potentials can still be defined at points in a circuit that are not within the inductor—points where the electric fields are due to charge distributions.

Moreover, we can define a self-induced potential difference ΔV_L across an inductor (between its terminals, which we assume to be outside the region of changing flux). If the inductor is ideal so that its wire has negligible resistance, the amount of the measured voltage change ΔV_L is equal to the amount of the self-induced emf \mathcal{E}_L .

If, instead, the wire in the inductor has resistance R_L , we mentally separate the inductor into a resistance R_L (which we take to be outside the region of changing flux) and an ideal inductor of self-induced emf \mathcal{E}_L . As with a real battery of emf \mathcal{E} and

internal resistance R , the potential difference across the terminals of a real inductor then differs from the emf. Unless otherwise indicated, we assume here that inductors are ideal.

READING EXERCISE 32-2: The figure shows an emf \mathcal{E}_L induced in a coil. Which of the following can describe the current through the coil: (a) constant and rightward, (b) constant and leftward, (c) increasing and rightward, (d) decreasing and rightward, (e) increasing and leftward, (f) decreasing and leftward? ■

32-3 Mutual Induction

In this section we return to the case of two interacting coils, which we started discussing in the previous section. We saw earlier that if two coils are close together as in Fig. 32-4 (or Fig. 31-10), a steady current i in one coil will set up a magnetic flux Φ^{mag} at the other coil (*linking* the other coil). If we change the current, i , in the first coil with time, an emf \mathcal{E} given by Faraday's law ($\mathcal{E} = -Nd \Phi^{\text{mag}}/dt$) will be induced in the second coil. We called this process **mutual induction**, to suggest the mutual interaction of the two coils and to distinguish it from *self-induction*, in which only one coil is involved.

Let us look at mutual induction quantitatively. For any inductor having a self-inductance L , Eq. 32-3 tells us that

$$L \equiv -\frac{\mathcal{E}_L}{di/dt}$$

where i is the current in the coil producing the flux. Figure 32-4a shows two circular coils near each other that share a common central axis. Assume there is a steady current i_1 in coil 1, produced by the battery in the external circuit. This current creates a magnetic field represented by the lines of \vec{B}_1 in the figure. Coil 2 is connected to a

FIGURE 32-4 ■ Mutual induction. (a) If the current in coil 1 changes, an emf will be induced in coil 2. (b) If the current in coil 2 changes, an emf will be induced in coil 1.

sensitive meter but contains no battery. A magnetic flux $\Phi_{1\rightarrow 2}$ (the flux associated with the current in coil 1 that passes through coil 2) links the N_2 turns of coil 2.

Suppose that by external means we cause i_1 to vary with time. Then by analogy to the definition of self-inductance, we can write a mutual induction equation that is analogous to Eq. 32-2,

$$\mathcal{E}_2 = -M_{1\rightarrow 2} \frac{di_1}{dt}.$$

This leads us to define the mutual inductance $M_{1\rightarrow 2}$ of coil 2 due to coil 1 as

$$M_{1\rightarrow 2} \equiv -\frac{\mathcal{E}_2}{di_1/dt} \quad (\text{mutual inductance defined}). \quad (32-6)$$

Once again we can formulate an alternate definition of mutual induction using the relationship between flux linkage in coil 2 and the current in coil 1, which is $M_{1\rightarrow 2}i_1 = N_2\Phi_{1\rightarrow 2}$. The factor N_2 is the number of turns in coil 2 and the factor $\Phi_{1\rightarrow 2}$ is the magnetic flux present inside coil 2 due to coil 1. This allows us to define mutual inductance as

$$M_{1\rightarrow 2} \equiv \frac{N_2\Phi_{1\rightarrow 2}}{i_1} \quad (\text{alternate definition of mutual inductance}). \quad (32-7)$$

If we take the time derivative of all terms in the expression $M_{1\rightarrow 2}i_1 = N_2\Phi_{1\rightarrow 2}$ we can write

$$\mathcal{E}_2 = -M_{1\rightarrow 2} \frac{di_1}{dt} = -N_2 \frac{d\Phi_{1\rightarrow 2}}{dt}. \quad (32-8)$$

According to Faraday's law, the right side of this equation is just the amount of the emf \mathcal{E}_2 appearing in coil 2 due to the changing current in coil 1. As usual, the minus sign reminds us that induced emf acts to oppose the change in current.

Let us now interchange the roles of coils 1 and 2, as in Fig. 32-4b; that is, we set up a current i_2 in coil 2 by means of a battery, and this produces a magnetic flux $\Phi_{2\rightarrow 1}$ that links coil 1. If we change i_2 with time, we have, by the arguments given above,

$$\mathcal{E}_1 = -M_{2\rightarrow 1} \frac{di_2}{dt} = -N_1 \frac{d\Phi_{2\rightarrow 1}}{dt}. \quad (32-9)$$

Thus, we see that the emf induced in either coil is proportional to the rate of change of current in the other coil. The proportionality constants $M_{1\rightarrow 2}$ and $M_{2\rightarrow 1}$ seem to be different. We assert, without proof, that they are in fact the same so that no subscripts are needed. (This conclusion is true but is not obvious.) Thus, we have

$$M_{1\rightarrow 2} = M_{2\rightarrow 1} = M, \quad (32-10)$$

and we can rewrite Eqs. 32-9 and 32-10 as

$$\mathcal{E}_2 = -M \frac{di_1}{dt} \quad (32-11)$$

and

$$\mathcal{E}_1 = -M \frac{di_2}{dt}. \quad (32-12)$$

The induction is indeed mutual. The SI unit for M (as for L) is the henry.

TOUCHSTONE EXAMPLE 32-1: Two Coupled Coils

Figure 32-5 shows two circular close-packed coils, the smaller (radius R_2 , with N_2 turns) being coaxial with the larger (radius R_1 , with N_1 turns) and in the same plane.

(a) Derive an expression for the mutual inductance M for this arrangement of these two coils, assuming that $R_1 \gg R_2$.

FIGURE 32-5 ■ A small coil is located at the center of a large coil. The mutual inductance of the coils can be determined by sending current i_1 through the large coil.

SOLUTION ■ The **Key Idea** here is that the mutual inductance M for these coils is the ratio of the flux linkage ($N\Phi$) through one coil to the current i in the other coil, which produces that flux linkage. Thus, we need to assume that currents exist in the coils; then we need to calculate the flux linkage in one of the coils.

The magnetic field through the larger coil due to the smaller coil is nonuniform in both magnitude and direction, so the flux in the larger coil due to the smaller coil is nonuniform and difficult to calculate. However, the smaller coil is small enough for us to assume that the magnetic field through it due to the larger coil is approximately uniform. Thus, the flux in it due to the larger coil is also approximately uniform. Hence, to find M we shall assume a current i_1 in the larger coil and calculate the flux linkage $N_2\Phi_{1\rightarrow 2}$ in the smaller coil:

$$M_{1\rightarrow 2} = \frac{N_2\Phi_{1\rightarrow 2}}{i_1}. \quad (32-13)$$

A second **Key Idea** is that the flux $\Phi_{1\rightarrow 2}$ through each turn of the smaller coil is, from Eq. 31-1,

$$\Phi_{1\rightarrow 2} = B_1 A_2,$$

where B_1 is the magnitude of the magnetic field at points within the small coil due to the larger coil, and $A_2 (= \pi R_2^2)$ is the area enclosed by the coil. Thus, the flux linkage in the smaller coil (with its N_2 turns) is

$$N_2\Phi_{1\rightarrow 2} = N_2 B_1 A_2. \quad (32-14)$$

A third **Key Idea** is that to find B_1 at points within the smaller coil, we can use Eq. 30-28, with z set to 0 because the smaller coil is in the plane of the larger coil. That equation tells us that each turn of the larger coil produces a magnetic field of magnitude $\mu_0 i_1 / 2R_1$ at points within the smaller coil. Thus, the larger coil (with its N_1 turns) produces a total magnetic field of magnitude

$$B_1 = N_1 \frac{\mu_0 i_1}{2R_1} \quad (32-15)$$

at points within the smaller coil.

Substituting Eq. 32-15 for B_1 and πR_2^2 for A_2 in Eq. 32-14 yields

$$N_2\Phi_{1\rightarrow 2} = \frac{\pi\mu_0 N_1 N_2 R_2^2 i_1}{2R_1}.$$

Substituting this result into Eq. 32-7, and using Eq. 32-10, we find

$$M = M_{1\rightarrow 2} = \frac{N_2\Phi_{1\rightarrow 2}}{i_1} = \frac{\pi\mu_0 N_1 N_2 R_2^2}{2R_1}. \quad (\text{Answer}) \quad (32-16)$$

Just as capacitance does not depend on the amount of charge on capacitor plates, mutual inductance, M , does not depend on the current in the coils.

(b) What is the value of M for $N_1 = N_2 = 1200$ turns, $R_2 = 1.1$ cm, and $R_1 = 15$ cm?

SOLUTION ■ Equation 32-16 yields

$$\begin{aligned} M &= \frac{(\pi)(4\pi \times 10^{-7} \text{ H/m})(1200)(1200)(0.011 \text{ m})^2}{(2)(0.15 \text{ m})} \\ &= 2.29 \times 10^{-3} \text{ H} \approx 2.3 \text{ mH}. \end{aligned} \quad (\text{Answer})$$

Consider the situation if we reverse the roles of the two coils—that is, if we produce a current i_2 in the smaller coil and try to calculate M from Eq. 32-7 in the form

$$M_{2\rightarrow 1} = \frac{N_2\Phi_{2\rightarrow 1}}{i_2}.$$

The calculation of $\Phi_{2\rightarrow 1}$ (the nonuniform flux of the smaller coil's magnetic field encompassed by the larger coil) is not simple. If we were to do the calculation numerically using a computer, we would find M to be 2.3 mH, as above! This emphasizes that Eq. 32-10 ($M_{1\rightarrow 2} = M_{2\rightarrow 1} = M$) is not obvious.

32-4 RL Circuits (With Ideal Inductors)

In Section 28-9 we saw that if we suddenly switch an emf \mathcal{E} on in a series circuit containing a resistor R and a capacitor C , the charge on the capacitor q does not build up immediately to its final equilibrium value $C\mathcal{E}$ but approaches it in an exponential fashion:

$$q = C\mathcal{E}(1 - e^{-t/\tau_C}). \quad (32-17)$$

The rate at which the charge builds up is determined by the capacitive time constant τ_C , defined in Eq. 28-42 as

$$\tau_C = RC. \quad (32-18)$$

If we suddenly remove the emf from this same circuit, the charge does not immediately fall to zero but approaches zero in an exponential fashion:

$$q = q_0 e^{-t/\tau_C}. \quad (32-19)$$

The time constant τ_C describes the fall of the charge as well as its rise and q_0 is the initial charge on the capacitor.

An analogous slowing of the rise (or fall) of the current occurs if we introduce an emf \mathcal{E} into (or remove it from) a single-loop circuit containing a resistor R and an inductor L . We assume the inductor is ideal and has a resistance R_L that is much less than R . When the switch S in Fig. 32-6 is closed on a , for example, the current in the resistor starts to rise. If the inductor were not present, the current would rise rapidly to a steady value \mathcal{E}/R . Because of the inductor, however, a self-induced emf \mathcal{E}_L appears in the circuit. As predicted from Lenz's law, this emf opposes the rise of the current. This means that it opposes the battery emf \mathcal{E} in polarity. Thus the current in the resistor responds to the *difference* between two emfs, a constant one \mathcal{E} due to the battery, and a variable one $\mathcal{E}_L (= -L di/dt)$ due to self-induction. As long as \mathcal{E}_L is present, the current in the resistor will be less than \mathcal{E}/R . As time goes on, the rate at which the current increases becomes less rapid and the amount of the self-induced emf, which is proportional to di/dt , becomes smaller. Thus, the current in the circuit approaches \mathcal{E}/R asymptotically.

We can generalize these results as follows: When a switch is opened or closed in a dc circuit, an inductor initially acts to oppose changes in the current through it. A long time later, it acts like ordinary connecting wire that has some resistance R_L .

Now let us analyze the situation quantitatively. With the switch S in Fig. 32-6 thrown to a , the circuit is equivalent to that of Fig. 32-7. Let us apply the loop rule, starting at point x in this figure and moving clockwise around the loop along with current i .

1. *Resistor.* Because we move through the resistor in the direction of current i , the electric potential decreases by iR . Thus, as we move from point x to point y where these points lie *outside* the inductor, we encounter a potential change of $-iR$.
2. *Inductor.* Because current i is changing, there is a self-induced emf \mathcal{E}_L in the inductor. The amount of \mathcal{E}_L is given by Eq. 32-2 as $L di/dt$. The direction of \mathcal{E}_L is upward in Fig. 32-7 because current i is downward through the inductor and increasing. Thus, as we move from point y to point z , opposite the direction of \mathcal{E}_L , we encounter a potential change of $-L di/dt$.
3. *Battery.* As we move from point z back to starting point x , we encounter a potential change of $+\mathcal{E}$ due to the battery's emf.

FIGURE 32-6 ■ An RL circuit. When switch S is closed on a , the current rises and approaches a limiting value of \mathcal{E}/R .

FIGURE 32-7 ■ The circuit of Fig. 32-6 with the switch closed on a . We apply the loop rule for circuits clockwise, starting at x .

Thus, the loop rule gives us

$$-iR - L \frac{di}{dt} + \mathcal{E} = 0$$

$$\text{or} \quad L \frac{di}{dt} + Ri = \mathcal{E} \quad (RL \text{ circuit}). \quad (32-20)$$

Equation 32-20 is a differential equation involving the variable i and its first derivative di/dt . To solve it, we seek the function $i(t)$ such that when $i(t)$ and its first derivative are substituted in Eq. 32-20, the equation is satisfied and the initial condition $i(0) = 0$ A is satisfied.

Equation 32-20 and its initial condition are of exactly the form of Eq. 28-38 for an RC circuit, with i replacing q , L replacing R , and R replacing $1/C$. The solution of Eq. 32-20 must then be of exactly the form of Eq. 28-39 with the same replacements. That solution is

$$i = \frac{\mathcal{E}}{R} (1 - e^{-(R/L)t}), \quad (32-21)$$

which we can rewrite as

$$i = \frac{\mathcal{E}}{R} (1 - e^{-t/\tau_L}) \quad (\text{rise of current}). \quad (32-22)$$

Here τ_L , the inductive time constant, is given by

$$\tau_L = \frac{L}{R} \quad (\text{time constant}). \quad (32-23)$$

What happens to the current described in Eq. 32-22 between the time the switch is closed (at time $t = 0$ s) and a later time ($t \rightarrow \infty$)? If we substitute $t = 0$ s into Eq. 32-22, the exponential becomes $e^{-0} = 1$. Thus, Eq. 32-22 tells us that the current is initially $i = 0$ A, as expected. Next, if we let t go to infinity, then the exponential goes to $e^{-\infty} = 0$. Thus, Eq. 32-22 tells us that the current goes to its equilibrium value of \mathcal{E}/R .

We can also examine the potential differences in the circuit. The graphs of Fig. 32-8 show experimental data describing how the potential differences $|\Delta V_R| = iR$ across a resistor and $|\Delta V_L| = L di/dt$ across an inductor vary with time for particular

FIGURE 32-8 ■ A computer data acquisition system is used to record the time variation of potential differences (a) ΔV_R across the resistor in Fig. 32-7 and (b) ΔV_L across the inductor in that circuit. The data were obtained at 10 000 samples per second for $R = 9830 \Omega$, $L \approx 20$ H, and $\mathcal{E} = 5.88$ V. The inductor has a direct current resistance of 167Ω , so it is not ideal. The data show some different characteristics than those predicted by Eqs. 32-22 and 32-23.

values of \mathcal{E} , L , and R . Compare this figure carefully with the corresponding figure for an RC circuit (Fig. 28-23).

To show that the quantity $\tau_L (=L/R)$ has the dimension of time, we convert from henries per ohm as follows:

$$1 \frac{\text{H}}{\Omega} = 1 \frac{\text{H}}{\Omega} \left(\frac{1 \text{ V} \cdot \text{s}}{1 \text{ H} \cdot \text{A}} \right) \left(\frac{1 \Omega \cdot \text{A}}{1 \text{ V}} \right) = 1 \text{ s}.$$

The first quantity in parentheses is a conversion factor based on Eq. 32-20, and the second one is a conversion factor based on the relation $\Delta V = iR$.

The physical significance of the time constant follows from Eq. 32-21. If we put $t = \tau_L = L/R$ in this equation, it reduces to

$$i = \frac{\mathcal{E}}{R} (1 - e^{-1}) = 0.63 \frac{\mathcal{E}}{R}. \quad (32-24)$$

Thus, the time constant τ_L is the time it takes the current in the circuit to reach about 63% of its final equilibrium value \mathcal{E}/R . Since the potential difference ΔV_R across the resistor is proportional to the current i , a graph of the increasing current versus time has the same shape as that of ΔV_R in Fig. 32-8a.

If the switch S in Fig. 32-6 is closed on a long enough for the equilibrium current \mathcal{E}/R to be established and then is thrown to b , the effect will be to remove the battery from the circuit. (The connection to b must actually be made an instant before the connection to a is broken. A switch that does this is called a *make-before-break* switch.)

With the battery gone, the current through the resistor will decrease. However, because of the inductor it cannot drop immediately to zero but must decay to zero over time. The differential equation that governs the decay can be found by putting $\mathcal{E} = 0$ in the RL circuit voltage loop equation (Eq. 32-20):

$$L \frac{di}{dt} + iR = 0. \quad (32-25)$$

By analogy with Eqs. 28-44 and 28-45, the solution of this differential equation that satisfies the initial condition $i(0) = i_0 = \mathcal{E}/R$ is

$$i = \frac{\mathcal{E}}{R} e^{-t/\tau_L} = i_0 e^{-t/\tau_L} \quad (\text{decay of current}). \quad (32-26)$$

We see that both current rise (Eq. 32-21) and current decay (Eq. 32-26) in an RL circuit are governed by the same inductive time constant, τ_L .

We have used i_0 in Eq. 32-26 to represent the current at time $t = 0$. In our case that happened to be \mathcal{E}/R , but it could be any other initial value.

TOUCHSTONE EXAMPLE 32-2: Two Inductors and Three Resistors

Figure 32-9a shows a circuit that contains three identical resistors with resistance $R = 9.0 \Omega$, two identical ideal inductors with inductance $L = 2.0 \text{ mH}$, and an ideal battery with emf $\mathcal{E} = 18 \text{ V}$.

(a) What is the current i through the battery just after the switch is closed?

SOLUTION ■ The **Key Idea** here is that just after the switch is closed, the inductor acts to oppose a change in the current through it. Because the current through each inductor is zero before the switch is closed, it will also be zero just afterward. Thus, immediately after the switch is closed, the inductors act as broken wires, as indicated in Fig. 32-9b. We then have a single-loop circuit

FIGURE 32-9 (a) A multiloop RL circuit with an open switch. (b) The equivalent circuit just after the switch has been closed. (c) The equivalent circuit a long time later. (d) The single-loop circuit that is equivalent to circuit (c).

for which the loop rule gives us

$$\mathcal{E} - iR = 0.$$

Substituting given data, we find that

$$i = \frac{\mathcal{E}}{R} = \frac{18 \text{ V}}{9.0 \Omega} = 2.0 \text{ A.} \quad (\text{Answer})$$

(b) What is the current i through the battery long after the switch has been closed?

SOLUTION ■ The **Key Idea** here is that long after the switch has been closed, the currents in the circuit have reached their equilibrium values, and the inductors act as simple connecting wires, as indicated in Fig. 32-9c. We then have a circuit with three identical resistors in parallel; from Eq. 27-12, their equivalent resistance is $R^{\text{eq}} = R/3 = (9.0 \Omega)/3 = 3.0 \Omega$. The equivalent circuit shown in Fig. 32-9d then yields the loop equation $\mathcal{E} - iR^{\text{eq}} = 0.0 \text{ V}$, or

$$i = \frac{\mathcal{E}}{R^{\text{eq}}} = \frac{18 \text{ V}}{3.0 \Omega} = 6.0 \text{ A.} \quad (\text{Answer})$$

32-5 Inductors, Transformers, and Electric Power

In most countries the electrical power used in homes and industries involves voltages and currents that change over time periodically, often sinusoidally. Such power is usually referred to as alternating current or ac electricity. Alternating electrical power is usually generated using induction. An **ac generator** simply consists of a magnet or electromagnet rotating inside an inductor coil or, alternatively, an inductor coil rotating in a magnetic field like that shown in Fig. 32-10.

FIGURE 32-11 ■ A periodic emf is induced in a coil that is being turned by a hand crank in the presence of a magnet. The generator is similar to that shown in Fig. 32-10. If the coil were less bulky and the \vec{B} -field were more uniform, the emf would vary sinusoidally when the crank is turned steadily.

FIGURE 32-10 ■ A simplified diagram of an electric generator showing how a crank can be used to rotate a pickup coil in a magnetic field such that the flux through the coil is changing periodically. Most large generators have a geometry in which the coil rotates outside of an electromagnet.

Generators don't care what form of energy is used to cause the rotation (Fig. 32-11). The shaft can turn when steam produced by a coal-fired or nuclear power plant pushes on propeller-like blades. In hydroelectric plants, falling water can provide the rotational energy. Since the potential difference and current in a generator vary sinusoidally, the voltages and currents are reported as root mean square (or rms) values. The use of rms values is explained in the next chapter, where we deal with alternating-current circuits in more detail.

The Role of Transformers

Generators typically produce power at low voltage, but it is important to transmit this power from generation stations to consumers with minimum energy loss. It turns out

that the losses are minimized when ac power is transmitted at high voltages. The reason has to do with how power loss is related to current and voltage. The total power generated is given by Eq. 26-10 as $P^{\text{gen}} = i^{\text{gen}}\Delta V^{\text{gen}}$. If this power is transmitted to consumers with an rms current i^{gen} flowing over long distances, then the power lost in heating transmission lines is given by

$$P^{\text{lost}} = (i^{\text{gen}})^2 R \quad (\text{power lost in transmission}), \quad (32-27)$$

where R is the total resistance of the wires that make up the transmission lines. The power available to consumers is then $P^{\text{gen}} - P^{\text{lost}}$. Although we can't get something for nothing, it is obvious from Eq. 32-27 that reorganizing the generated power so that it is transmitted at high voltage and low current would greatly reduce the transmission losses. In other words, we would like to achieve

$$P^{\text{gen}} = i^{\text{gen}}\Delta V^{\text{gen}} = i^{\text{trans}}\Delta V^{\text{trans}}, \quad (32-28)$$

where $\Delta V^{\text{trans}} \gg \Delta V^{\text{gen}}$ so that $i^{\text{trans}} \ll i^{\text{gen}}$.

As an example, consider the 735 kV line used to transmit electric energy from the La Grande 2 hydroelectric plant in Quebec to Montreal, 1000 km away. Suppose that the current is 500 A. Then from Eq. 32-28, energy is supplied at the average rate

$$P^{\text{gen}} = i^{\text{gen}}\Delta V^{\text{gen}} = (7.35 \times 10^5 \text{ V})(500 \text{ A}) = 368 \text{ MW}.$$

The resistance of the transmission line is about $0.220 \Omega/\text{km}$. Thus, there is a total resistance of about 220Ω for the 1000 km stretch. Energy is dissipated due to that resistance at a rate of about

$$P^{\text{lost}} = (i^{\text{gen}})^2 R = (500 \text{ A})^2(220 \Omega) = 55.0 \text{ MW},$$

which is nearly 15% of the supply rate.

Imagine what would happen if we could halve the current and double the voltage. Energy would be supplied by the plant at the same average rate of 368 MW as before, but now energy would be dissipated at the much lower rate of about

$$P^{\text{lost}} = (i^{\text{gen}})^2 R = (250 \text{ A})^2(220 \Omega) = 13.8 \text{ MW},$$

This rate of energy loss is *only 4% of the supply rate*. Hence the general energy transmission rule: Transmit at the highest possible voltage and the lowest possible current. There is an upper limit to the voltage that can be used. If the voltage gets too high, the power line insulation and the surrounding air will not be able to prevent the current from passing through them and leaking to the ground.

The Ideal Transformer

The *ideal transformer* in Fig. 32-12 consists of two coils, a *primary* and a *secondary*. These coils have different numbers of turns and are wound around the same iron core. The coils experience mutual induction. The iron core concentrates the flux so that it is the same in both coils. (We will discuss the role iron plays in Section 32-7 on ferromagnetism.) In use, the **primary coil**, of N_p turns, is connected to an alternating-current generator whose emf \mathcal{E} at any time t is given by

$$\mathcal{E} = \mathcal{E}^{\text{max}} \sin \omega t. \quad (32-29)$$

The **secondary coil**, of N_s turns, is connected to load resistance R , but its circuit is an open circuit as long as switch S is open (which we assume for the present). Thus, there

FIGURE 32-12 ■ An ideal transformer (two coils wound on an iron core) in a basic transformer circuit. An ac generator produces current in the coil at the left (the *primary*). The coil at the right (the *secondary*) is connected to the resistive load R when switch S is closed.

can be no current through the secondary coil. We assume further for this ideal transformer that the resistances of the primary and secondary coils (or **windings**) are negligible as are energy losses in the iron core. Well-designed, high-capacity transformers can have energy losses as low as 1%, so our assumptions are reasonable.

For the assumed conditions, the primary winding (or *primary*) is a pure inductance that carries a small alternating primary current i_p . This current induces an alternating magnetic flux Φ^{mag} in the iron core. Because the core extends through the secondary winding (or *secondary*), this induced flux also extends through the turns of the secondary. At any given time the flux in the primary and secondary coils are the same. Therefore, Faraday's law of induction (Eq. 31-7) tells us that the amount of the induced emf per turn, denoted as $\mathcal{E}_{\text{turn}}$ is the same for both the primary and the secondary coils. Also, the voltage ΔV_p across the primary is equal to the emf induced in the primary, and the voltage ΔV_s across the secondary is equal to the emf induced in the secondary. Thus, we can write

$$\mathcal{E}_{\text{turn}} = \frac{d\Phi^{\text{mag}}}{dt} = \frac{\Delta V_p}{N_p} = \frac{\Delta V_s}{N_s},$$

and thus,

$$\Delta V_s = \Delta V_p \frac{N_s}{N_p} \quad (\text{transformation of voltage}). \quad (32-30)$$

If $N_s > N_p$, the transformer is called a **step-up transformer** because it steps the primary's voltage ΔV_p up to a higher voltage ΔV_s . Alternatively, if $N_s < N_p$, the device is a **step-down transformer**.

So far, with switch S open, no energy is transferred from the generator to the rest of the circuit. Now let us close S to connect the secondary to the resistive load R . (In general, the load would also contain inductive and capacitive elements, but here we neglect the capacitance.) We find that now energy is transferred from the generator. To see why, let's explore what happens when we close switch S.

1. An alternating current i_s appears in the secondary circuit, with corresponding energy dissipation rate $i_s^2 R = (\Delta V_s^2)/R$ in the resistive load. Since the emf produced in the secondary coil is a back emf that opposes the direction of the change in current in the primary, the secondary current is out of phase with the primary current.
2. This current produces its own alternating magnetic flux in the iron core, and this flux induces (from Faraday's law and Lenz's law) an opposing emf in the primary windings.
3. The voltage ΔV_p of the primary, however, cannot change in response to this opposing emf because it must always be equal to the emf \mathcal{E} that is provided by the generator; closing switch S cannot change this fact.

In order to relate i_s to i_p , we can apply the principle of conservation of energy. For the ideal transformer without losses in the magnetic core, the power drawn from the primary is equal to the power transferred to the secondary (via the alternating magnetic field linking the two coils). Conservation of energy requires that

$$i_p \Delta V_p = i_s \Delta V_s. \quad (32-31)$$

Substituting for ΔV_s from Eq. 32-30, we find that

$$i_s = i_p \frac{N_p}{N_s} \quad (\text{transformation of currents}). \quad (32-32)$$

This equation tells us that the amount of the current i_s in the secondary can be greater than, less than, or the same as the amount of current i_p in the primary, depending on the *ratio of turns (or loops) in the coils given by N_p/N_s* .

Current i_p appears in the primary circuit because of the resistive load R in the secondary circuit. To find i_p , we substitute $i_s = \Delta V_s/R$ into Eq. 32-32 and then we substitute for ΔV_s from Eq. 32-30. We find

$$i_p = \frac{1}{R} \left(\frac{N_s}{N_p} \right)^2 \Delta V_p. \quad (32-33)$$

This equation has the form $i_p = \Delta V_p/R_{\text{eq}}$, where equivalent resistance R_{eq} is

$$R_{\text{eq}} = \left(\frac{N_p}{N_s} \right)^2 R. \quad (32-34)$$

Here R is the actual resistance in the secondary circuit and R_{eq} is the value of the load resistance as “seen” by the generator. The generator produces the current i_p and voltage ΔV_p as if it were connected to a resistance R_{eq} .

Impedance Matching

Equation 32-34 suggests still another function for the transformer. For maximum transfer of energy from an emf device to a resistive load, the resistance of the emf device and the resistance of the load must be equal. The same relation holds for ac circuits (discussed in Chapter 33) except that the *impedance* (rather than just the resistance) of the generator must be matched to that of the load. Often this condition is not met. For example, in a music-playing system, the amplifier can have high impedance and the speaker set have low impedance. We can match the impedances of the two devices by coupling them through a transformer with a suitable turns ratio N_p/N_s .

READING EXERCISE 32-3: An alternating-current emf device has a smaller resistance than that of the resistive load; to increase the transfer of energy from the device to the load, a transformer will be connected between the two. (a) Should N_s be greater than or less than N_p ? (b) Will that make it a step-up or step-down transformer? ■

32-6 Magnetic Materials—An Introduction

Today, magnets and magnetic materials are ubiquitous. In addition to naturally magnetic lodestones, magnets are also in VCRs, audiocassettes, credit cards, electronic speakers, audio headsets, and even the inks in paper money. In fact, some breakfast cereals that are “iron fortified” contain small bits of magnetic materials (you can collect them from a slurry of cereal and water with a magnet). In this section we are interested in understanding more about why so-called bulk matter, made of billions upon billions of individual atoms, has magnetic properties.

Characteristics of Magnetic Materials

When we speak of magnetism in everyday conversation, we usually have a mental picture of a bar magnet, a disk magnet (probably clinging to a refrigerator door), or even a tiny compass needle. That is, we picture a *ferromagnetic* material made of iron having strong, permanent magnetism. Although most bulk matter does not behave like the familiar iron bar magnets, it turns out that almost all bulk materials have some

magnetic behaviors. There are three general types of magnetism: ferromagnetism, paramagnetism, and diamagnetism.

1. **Ferromagnetism** is present if a material produces a strong magnetic field of its own in the presence of an external field, and if its magnetic field partially persists after the external field is removed. We usually use the term *ferromagnetic material*, and also the common term *magnetic material*, to refer to materials that exhibit primarily ferromagnetism. Iron, nickel, and cobalt (and compounds and alloys of these elements) are ferromagnetic.
2. **Paramagnetism** is present if a material that is placed in an external magnetic field is attracted to the region of greater magnetic field and produces a magnetic field of its own—but only while it is in the presence of the external field. The term *paramagnetic material* usually refers to materials that exhibit primarily paramagnetism. This type of magnetism is exhibited by materials such as liquid oxygen and aluminum as well as transition elements, rare earth elements, and actinide elements (see Appendix G).
3. **Diamagnetism** is present if a material that is placed near a magnet is repelled from the region of greater magnetic field. This is opposite to the behavior of the other two types of magnetism. Diamagnetism is exhibited by all common materials, but it is so weak that it is masked if the material exhibits magnetism of either of the other two types. Thus, the term *diamagnetic material* refers to materials that only exhibit diamagnetism. Metals such as bismuth, copper, gold, silver, and lead, as well as many nonmetals such as water and most organic compounds, are diamagnetic. Because people and other animals are made largely of water and organic compounds, they are diamagnetic too.

FIGURE 32-13 ■ A bar magnet is a magnetic dipole. The orientations of the iron filings suggest the direction of magnetic field lines.

FIGURE 32-14 ■ If you break a bar magnet, each fragment becomes a smaller magnet, with its own north and south poles. It is impossible to break a fragment into separate north and south poles.

What causes magnetism? Why are there three types of magnetism? We now believe that magnetism is caused by tiny magnetic dipoles that are intrinsic to the atoms contained in all materials. For this reason, understanding the characteristics of magnetic dipoles is essential to understanding the behavior of magnetic materials. We will conclude this section with a discussion of magnetic dipoles, and then in the next two sections we will explore how the characteristics of atomic magnetic dipoles help us understand the three types of magnetism.

Characteristics of Magnetic Dipoles

Both the bar magnets with which we are familiar and small coils of wire carrying current are magnetic dipoles. Let's review some of the characteristics of magnetic dipoles that we have already discussed. A magnetic dipole:

- Has a magnetic field pattern associated with it similar to that of an electric dipole (like that shown in Fig. 32-13 or that described by the equations derived in Sections 23-6 and 30-7).
- *Always has two poles*, which we have chosen to call north (seeking) and south (seeking) because of the way they behave when placed in the Earth's magnetic field, as shown in Fig. 32-14 (see Section 29-3 for a review).
- Can be described by a magnetic dipole moment $\vec{\mu}$, which is a vector quantity whose *magnitude* tells us how *strong* the magnetic field associated with the dipole is and whose *direction* tells how the field pattern is oriented. The orientation is along the axis of a bar magnet pointing from its south pole and to its north pole or perpendicular to the plane of a current-carrying coil with a direction determined by the right-hand rule (Section 29-10). *Note:* Our use of conventional notation is unfortunate here. The magnetic moment $\vec{\mu}$ should not be

confused with the permeability constant μ_0 or μ that sometimes appears in the same equation.

- Will attempt to align its magnetic dipole moment with an external magnetic field, \vec{B} , because the dipole experiences a torque, $\vec{\tau}$, given by $\vec{\tau} = \vec{\mu} \times \vec{B}$ (Section 30-7).
- Has a potential energy U in an external magnetic field given by $U = -\vec{\mu} \cdot \vec{B}$, so that the dipole's potential energy is a minimum when its dipole moment is aligned with an external magnetic field.

Magnetism in Atoms

We believe that the combined effect of tiny magnetic dipole moments in atoms are responsible for all magnetic interactions in bulk matter. Before we attempt to explain why different materials exhibit certain types of magnetism, we need to discuss what is known about atomic magnetism.

The focus of this book is on classical physics. However, understanding atomic phenomena requires some familiarity with quantum physics, which is in general beyond the scope of this book. So, we will present some basic ideas of quantum physics that apply to atomic magnetism without discussing the existing body of experimental evidence.

So far in our classical treatment of magnetism we have already identified two sources of magnetic dipole fields: (1) electric charges that create a current if they move in a loop and (2) magnetic dipoles consisting of a bar or rod of magnetized iron. Also, some effects of atomic magnetism can be explained using a classical model that identifies two types of atomic magnetic dipoles—orbital and spin. First, if we think of electrons as “orbiting” around a nucleus, then an orbit is a current loop with an orbital magnetic moment. Second, we think of the electron as having an intrinsic magnetic dipole moment that we call spin. This model is quite comfortable because it is rather like the familiar picture of the Earth spinning about its own axis as it orbits the Sun. But when we try to predict the magnetic behavior of various types of materials using this classical model, its usefulness is limited and it is completely wrong in many ways.

The bad classical predictions are not surprising since quantum physics, devised to explain atomic behavior, tells us that: (1) We cannot think of electrons as having distinct orbits. Instead we visualize them as swarming about in the vicinity of a nucleus without having distinct paths. So all we can know is something about the probability of finding the electron at various locations in the vicinity of the nucleus and that these probabilities are different for each type of atom or molecule. (2) The spin magnetic moments are a fundamental property of electrons and should not be thought of as being produced by an electron spinning about an internal axis. (3) The spin and orbital magnetic moments associated with atomic electrons are quantized. This means they can only have certain values.

Next let's examine the characteristics of these two types of atomic magnetic moments in more detail.

Spin Magnetic Dipole Moment

An electron has an intrinsic **spin magnetic dipole moment** $\vec{\mu}^{\text{spin}}$. (By *intrinsic*, we mean that $\vec{\mu}^{\text{spin}}$ is a basic characteristic of an electron, like its mass and electric charge.) According to quantum theory,

1. $\vec{\mu}^{\text{spin}}$ itself cannot be measured directly. Only its component along a single axis can be well-defined (and therefore measured) at any one time.
2. A measured component of $\vec{\mu}^{\text{spin}}$ is *quantized*, which is a general term that means it is restricted to certain values.

Let us assume that the component of the spin magnetic moment $\vec{\mu}^{\text{spin}}$ is measured along the z axis of a coordinate system you have chosen. Then the measured component μ_z^{spin} can have only the two values given by

$$\mu_z^{\text{spin}} = +\frac{eh}{4\pi m} \quad \text{or} \quad \mu_z^{\text{spin}} = -\frac{eh}{4\pi m}, \quad (32-35)$$

where $h = 6.63 \times 10^{-34} \text{ J}\cdot\text{s}$ and is the well-known Planck constant used often in quantum physics. The constants e and m represent the charge and mass of the electron, respectively. The plus and minus signs given in Eq. 32-35 describe the direction of μ_z^{spin} along the chosen z axis. The plus sign indicates that μ_z^{spin} is parallel to the z axis, and the electron is said to be “spin up.” When μ_z^{spin} is antiparallel to the z axis, the minus sign is used and the electron is said to be “spin down.”

The combination of constants in Eq. 32-35 is called the *Bohr magneton* μ_B , which can be calculated from the known values of Planck’s constant and the electron charge and mass:

$$\mu_B = \frac{eh}{4\pi m} = 9.27 \times 10^{-24} \text{ J/T} \quad (\text{Bohr magneton value for an electron}). \quad (32-36)$$

Spin magnetic dipole moments of electrons and other elementary particles can be expressed in terms of μ_B . In terms of the Bohr magneton, we can substitute in to Eq. 32-35 to rewrite the expression for the two possible values of μ_z^{spin} as

$$\mu_z^{\text{spin}} = +\mu_B \quad \text{or} \quad \mu_z^{\text{spin}} = -\mu_B. \quad (32-37)$$

When an electron is placed in an external magnetic field \vec{B}^{ext} , a potential energy U can be associated with the orientation of the electron’s spin magnetic dipole moment $\vec{\mu}^{\text{spin}}$ just as a potential energy can be associated with the orientation of the magnetic dipole moment $\vec{\mu}$ of a current loop placed in an external magnetic field \vec{B}^{ext} . From Eq. 29-35, the potential energy for the electron due to its spin orientation has only two possible values

$$U^{\text{spin}} = -\vec{\mu}^{\text{spin}} \cdot \vec{B}^{\text{ext}} = -\mu_z^{\text{spin}} B^{\text{ext}} = \pm \mu_B B^{\text{ext}}, \quad (32-38)$$

where the z axis is taken to be in the direction of \vec{B}^{ext} .

Again, although we use the word “spin” here, according to quantum theory the fact that electrons have intrinsic magnetic moments does not mean that they spin like tops.

Protons and neutrons also have intrinsic magnetic dipole moments. In fact, these nuclear magnetic moments are a critical element in the development of magnetic resonance imaging—a valuable diagnostic tool in medicine. The masses of protons and neutrons are almost 2000 times that of the electron, so the magnetic moment for these particles is much smaller than that of the electron. For this reason, the contributions of nuclear dipole moments to the magnetic fields of atoms are negligible.

Orbital Magnetic Dipole Moment

An electron that is part of an atom has an additional dipole magnetic moment. This is called its **orbital magnetic moment** $\vec{\mu}^{\text{orb}}$. Again, although we use the “orbital” here, electrons do not orbit the nucleus of an atom like planets orbiting the Sun. According to quantum physics, an “orbit” roughly defines a region in space where the electron is

most likely to be found. The orientation of this region specifies the direction of the electron's orbital angular momentum. The so-called "outer electrons" in an atom with many electrons will tend to be found further from its nucleus. An outer electron has a larger orbital angular momentum and, hence, a larger magnetic moment. It turns out that in any given atom there are typically more than two possible quantized values for the z -components of orbital magnetic moments. We can express these possible components along a chosen z axis in terms of the Bohr magneton as

$$\mu_z^{\text{orb}} = -m_l^{\text{max}}\mu_B, \dots, -3\mu_B, -2\mu_B, -1\mu_B, 0\mu_B, 1\mu_B, 2\mu_B, 3\mu_B, \dots, m_l^{\text{max}}\mu_B, \quad (32-39)$$

where m_l^{max} is an integer that designates the magnitude of the orbital magnetic moment component an electron can have.

When an atom is placed in an external magnetic field \vec{B}^{ext} , an orbital potential energy U^{orb} can be associated with the orientation of the orbital magnetic dipole moment of each electron in the atom. Its value is

$$U^{\text{orb}} = -\vec{\mu}^{\text{orb}} \cdot \vec{B}^{\text{ext}} = -\mu_z^{\text{orb}} B^{\text{ext}}, \quad (32-40)$$

where the z axis is taken in the direction of \vec{B}^{ext} so that $\vec{B}^{\text{ext}} = B^{\text{ext}} \hat{k}$.

The Magnetic Dipole Moment of an Atom

Each electron in an atom has an orbital magnetic dipole moment and a spin magnetic dipole moment that combine vectorially. The resultant of these two vector quantities combines vectorially with similar resultants for all other electrons in the atom, and the resultant for each atom combines with those for all the other atoms in a bulk sample of matter. If the combination of all these magnetic dipole moments produces a magnetic field, then the material is magnetic.

We have one more step in preparing to explain the magnetic behavior of bulk material on the basis of the magnetic behavior of its atoms. We need to consider how the spin and orbital magnetic moments associated with all the electrons in a single atom of a certain element (such as iron, arsenic, and so on) could combine to determine its total magnetic moment.

If the spin and orbital magnetic moments of all the electrons in a given atom lined up with each other and then if all the individually aligned atoms lined up with each other in a solid or liquid, we would have an incredibly strong magnet. Most materials are not strongly magnetic because whenever possible it is natural for the electron magnetic moments in an atom to cancel out. Atomic electrons are located in regions around the nucleus called shells. The number of electrons in a shell is governed by a quantum mechanical rule known as the *Pauli exclusion principle*. This exclusion principle requires that no two electrons in the same shell can have both the same components of orbital magnetic moment and the same components of spin magnetic moment. When all different combinations of orbital and spin states have occurred in a shell it is full. Once a shell is full the pairing of electrons in their locations with respect to the nucleus cancel each other. Each successive shell has more possible orbital magnetic moment components than its electrons can have. In addition, the electrons in a given shell have more energy than the ones in the previous shell. If the atom is in its lowest possible energy state, the shells usually fill in order.

In an atom with many electrons, the number of electrons in a full shell is $4n + 2$, where n is 0, 1, 2, 3, and so on. So the first shell can have 2 electrons, the second 6 electrons, the third 10, the fourth 14, and so on. Typically it is unpaired outermost electrons in an atom that determine the magnetic behavior of bulk matter. Magnetism depends critically on how atoms combine with each other as a result of the sharing and interaction of the outermost electrons.

READING EXERCISE 32-4: In this section, we discuss three types of magnetism in materials. Which one is associated with a refrigerator magnet? A standard paper clip? A piece of silver wire? Explain your reasoning. ■

READING EXERCISE 32-5: The figure shows the spin orientations of two particles in an external magnetic field \vec{B}^{ext} . (a) If the particles are electrons, which spin orientation is at lower potential energy? (b) If, instead, the particles are protons, which spin orientation is at lower potential energy? Explain your reasoning.

32-7 Ferromagnetism

Iron, cobalt, nickel, gadolinium, dysprosium, and alloys of these become strongly magnetized in the presence of an external magnetic field. Because they retain this magnetism when the external field is removed, we call them ferromagnetic.

Atomic Magnetic Moments in Ferromagnetism

Although most heavy elements are not ferromagnetic, all ferromagnetic materials are relatively heavy elements with complex electronic structures. The lightest of these is iron, which has 26 electrons. The best explanation to date for iron's ferromagnetism involves the complex behavior of its electrons. The 20 innermost electrons are paired in such a way that their spin and orbital magnetic moments cancel each other. The other 6 electrons behave in a manner that is unusual for most materials. Instead of piling into the third shell that has plenty of room for them, 2 of the 6 electrons move out into the fourth shell. These 2 electrons form outer conduction electrons. The key to the ferromagnetism of iron is that the third shell is unfilled, which allows 4 of 14 electrons in that shell to have spin magnetic moments that end up being aligned. However, these aligned electrons do not participate in chemical bonding with other atoms. The detailed quantum mechanical calculations reveal that this unusual arrangement of electrons gives an individual iron *atom* both a net magnetic moment and a lower energy—a situation that is similar for cobalt and nickel.

Even though individual iron atoms have permanent magnetic dipole moments, we might assume that their orientations relative to each other are random, leaving a bulk sample of iron with no net magnetic moment. We know this is not the case. Although various explanations have been put forth to explain why individual atoms line up in ferromagnetic materials, the situation is not well understood. It is currently believed that the spin-aligned electrons in the third shell, which causes the magnetism, influence the outermost conduction electrons, which are wandering through the material. Because of the Pauli exclusion principle, the spin magnetic moment of a conduction electron will have a tendency to be aligned in a direction opposite to that of the third-shell electrons. This anti-aligned conduction electron could, in turn, influence the alignment of the third-shell spin magnetic moments in a neighboring atom. This interaction could align the third-shell spin magnetic moments in the two neighboring atoms, and so on. The jargon for this quantum physical effect, in which spins of the electrons in one atom interact with those of neighboring atoms via conduction electrons, is called **exchange coupling**. The result is an alignment of the magnetic dipole moments of the atoms, in spite of the randomizing effects of thermal energy that causes atomic collisions. We currently believe that this type of coupling is what gives ferromagnetic materials their permanent magnetism.

Magnetic Domains

Exchange coupling in which spins of the electrons in one atom interact with those of neighboring atoms via conduction electrons, produces strong alignment of adjacent atomic dipoles in a ferromagnetic *material*. So we might expect that all the atoms in a sample of iron would align themselves into a permanent magnet even in the absence of an external magnetic field. This doesn't happen. Instead, a piece of iron, nickel, or cobalt is always made up of a number of *magnetic domains*. Each domain is a region in which the alignment of the atomic dipoles is essentially perfect. The domains, however, are not all aligned. For the sample as a whole, the domains are so oriented that they largely cancel each other as far as their external magnetic effects are concerned.

Two reasons are often given for the existence of domains in ferromagnetic materials. First, calculations reveal that a pure sample with perfectly aligned atoms (known as a *single crystal*) has a lower energy state when there are distinct domains with boundaries between them. Second, most real samples have impurities that can cause even more boundaries between domains to form.

A photograph of a single crystal of nickel is shown in Fig. 32-15. A suspension of powdered iron oxide was sprinkled on the crystal surface. The domain boundaries, which are thin regions in which the alignment of the elementary dipoles changes from a certain orientation in one domain to a different orientation in the other, are the sites of intense, but highly localized and nonuniform, magnetic fields. The suspended iron oxide particles are attracted to some of the more prominent boundaries and show up as the white lines. Although the atomic dipoles in each domain are completely aligned as shown by the arrows, the crystal as a whole has a very small resultant magnetic moment.

Actually, a piece of iron as we ordinarily find it is not a single crystal but an assembly of many tiny crystals, randomly arranged; we call it a polycrystalline solid. Each tiny crystal, however, has its array of variously oriented domains, just as in Fig. 32-15. We can magnetize such a specimen by placing it in an external magnetic field B_z^{ext} of gradually increasing strength, and measuring the magnetization B_z^M of the iron. (The measurement process is explained in the next subsection on Bulk Properties.) A common way to display the results is to plot a magnetization curve. If the piece of iron had all of its magnetic dipoles aligned perfectly with the external field, its magnetization would be a maximum represented by B_{max}^M . The magnetization curve consists of a plot of the ratio B_z^M/B_{max}^M as a function of the external field (shown in Fig. 32-16). Note that B^M/B_{max}^M is always less than one, so the iron does not become perfectly magnetized.

By photographing domain patterns as in Fig. 32-15, we see two microscopic effects that serve to explain the shape of the magnetization curve: One effect is a growth in size of the domains that are oriented along the external field at the expense of those that are not. The second effect is a shift of the orientation of the dipoles within a domain, as a unit, to become closer to the field direction.

Exchange coupling and domain shifting give us the following result:

A ferromagnetic material placed in an external magnetic field \vec{B}^{ext} develops a strong magnetic dipole moment in the direction of \vec{B}^{ext} . If the field is nonuniform, the ferromagnetic material is attracted toward a region of greater magnetic field from a region of lesser field.

Bulk Properties of Ferromagnetic Materials

If the temperature of a ferromagnetic material is raised above a certain critical value, called the **Curie temperature**, the exchange coupling ceases to be effective. Most such materials then become simply paramagnetic. That is, the dipoles still tend to align with an external field but much more weakly, and thermal agitation can now more easily disrupt the alignment. The Curie temperature for iron is 1043 K (= 770°C).

FIGURE 32-15 ■ A photograph of domain patterns within a single crystal of nickel; white lines reveal the boundaries of the domains. The white arrows superimposed on the photograph show the orientations of the magnetic dipoles within the domains and thus the orientations of the net magnetic dipoles of the domains. The crystal as a whole is unmagnetized if the net magnetic field (the vector sum over all the domains) is zero.

FIGURE 32-16 ■ A magnetization curve for a ferromagnetic core material in the Rowland ring of Fig. 32-17. On the vertical axis, 1.0 corresponds to complete alignment (saturation) of the magnetic dipoles within the material.

FIGURE 32-17 ■ A toroidal Rowland ring coil in which a current i_p is sent through a primary coil P . This current is used to study the behavior of the ferromagnetic material of the iron core inside the windings. The extent of magnetization of the core determines the total magnetic field \vec{B} within coil P . Field \vec{B} can be measured by means of a secondary or “pickup” coil.

FIGURE 32-18 ■ A magnetization curve (ab) for a ferromagnetic specimen and an associated hysteresis loop ($bcdeb$).

We can express the extent to which a given paramagnetic sample is magnetized by finding the ratio of its magnetic dipole moment to its volume V . This vector quantity, the magnetic dipole moment per unit volume, is called the **magnetization** \vec{M} of the sample, and its magnitude is

$$\vec{M} = \frac{\text{measured magnetic moment}}{V}. \quad (32-41)$$

The unit of \vec{M} is the ampere-square meter per cubic meter, or ampere per meter (A/m). Complete alignment of the atomic dipole moments, called **saturation** of the sample, corresponds to the maximum magnetization of magnitude $M^{\max} = N\mu/V$ where N is the number of atoms in the volume V .

The magnetization of a ferromagnetic material such as iron can be studied using a toroidal coil called a *Rowland ring* (Fig. 32-17). A Rowland ring is basically a long solenoid with an iron cylinder at its core, except the whole thing is bent into the shape of a donut. Assume that the ring’s primary coil P has n turns per unit length and carries current i_p . If the iron core were not present, the magnitude of the magnetic field inside the coil caused by the “external” solenoid windings (as distinct from the magnetization of a core material inside the windings) would be given by Eq. 30-25,

$$B^{\text{ext}} = n\mu_0|i_p| \quad (\text{no iron core}). \quad (32-42)$$

Here μ_0 represents the magnetic constant (or permeability) of air (and is not a magnetic moment).

If an iron core is present, the magnitude of the magnetic field B inside the coil is proportional to B^{ext} but is on the order of 1000 to 10 000 times greater due to the magnetization of the iron core. This magnetization results from the alignment of the atomic dipole moments within the iron. The field \vec{B} inside the coil should be the vector sum of the field \vec{B}^{ext} contributed by the coil without the core and the field \vec{B}^{M} contributed by the magnetization of the core. Since the magnitude of \vec{B}^{ext} field is much smaller than that produced by the core magnetization

$$\vec{B} = \vec{B}^{\text{ext}} + \vec{B}^{\text{M}} \approx \vec{B}^{\text{M}}. \quad (32-43)$$

To determine \vec{B}^{M} we use a secondary coil S to measure \vec{B} and hence \vec{B}^{M} . If needed, we compute \vec{B}^{ext} using Eq. 32-42.

Figure 32-18 shows a magnetization curve for a ferromagnetic material in a Rowland ring: the ratio of magnitudes $B^{\text{M}}/B_{\text{max}}^{\text{M}}$ is plotted as a function of B^{ext} (where $B_{\text{max}}^{\text{M}}$ is the maximum possible value of B^{M} , corresponding to saturation). The curve is similar to that for the magnetization curve for a paramagnetic substance shown in Fig. 32-19. Both curves are measures of the extent to which an applied magnetic field can align the atomic dipole moments of a material.

For the ferromagnetic core described by the graph in Fig. 32-16, the alignment of the dipole moments is about 70% complete for $B^{\text{ext}} \approx 1 \times 10^{-3}$ T. If B^{ext} were increased to 1 T, the alignment would be almost complete (but $B^{\text{ext}} = 1$ T, and thus almost complete saturation, is quite difficult to achieve).

Hysteresis

Magnetization curves for ferromagnetic materials are not retraced as we increase and then decrease and then reverse the external magnetic field \vec{B}^{ext} . Let’s assume that we choose the z axis to be along the direction of the external magnetic field. Figure 32-18 is a plot of the z -component of the magnetization field B_z^{M} versus the z -component of the external field B_z^{ext} during the following operations with a Rowland ring: (1) Starting with the iron unmagnetized (point a), increase the current in the toroid until $B_z^{\text{ext}} = n\mu_0|i|$ has the value corresponding to point b ; (2) reduce the current in the toroid winding (and

thus B^{ext} back to zero (point c); (3) reverse the toroid current and increase it in amount until B^{ext} has the value corresponding to point d ; (4) reduce the current to zero again (point e); (5) reverse the current once more until point b is reached again.

The lack of retraceability shown in Fig. 32-18 is called **hysteresis**, and the curve $bcdeb$ is called a *hysteresis loop*. Note that at points c and e the iron core is magnetized, even though there is no current in the toroid windings; this is the familiar phenomenon of permanent magnetism. In fact when engineers are designing permanent magnets, they look for materials that have a high degree of hysteresis.

Hysteresis can be understood through the concept of magnetic domains. When the magnetic field in the coil due to the current in the solenoid windings, \vec{B}^{ext} , is increased and then decreased back to its initial value, the domains do not return completely to their original configuration but retain some “memory” of their alignment after the initial increase. This memory of magnetic materials is essential for the magnetic storage of information, as on cassette tapes and computer disks.

This memory of the alignment of domains can also occur naturally. When lightning sends currents along multiple tortuous paths through the ground, the currents produce intense magnetic fields that can suddenly magnetize any ferromagnetic material in nearby rock. Because of hysteresis, such rock material retains some of that magnetization after the lightning strike (after the currents disappear) then becomes lodestones.

Inductors and Transformers with Iron Cores

Based on our discussion above of the Rowland ring, it is clear that the use of iron and iron alloys in inductors and transformers can literally increase the performance of these devices by a thousandfold or more.

A great deal of engineering has gone into the design of cores for large inductors and high-performance transformers. For example, these cores should not behave like permanent magnets with large hysteresis. Instead, they should have small hysteresis so that the magnetization of the core can change rapidly in the presence of alternating currents. In addition, transformer cores are not single hunks of iron. Rather, they are built up in layers to prevent eddy currents from being induced in the cores that could reduce the efficiency of the power transfer from the primary to secondary coils in a transformer.

READING EXERCISE 32-6: Iron is a ferromagnetic material. Why then isn't every piece of iron—for example, an iron nail—a naturally strong magnet? ■

READING EXERCISE 32-7: What is hysteresis and why does it occur? ■

32-8 Other Magnetic Materials

Paramagnetism

In paramagnetic materials, the spin and orbital magnetic dipole moments of the electrons in individual atoms do not cancel but add vectorially to give each *atom* a net (and permanent) magnetic dipole moment $\vec{\mu}$. In the absence of an external magnetic field, these atomic dipole moments are randomly oriented, and the net magnetic dipole moment of the *material* is zero. However, if a sample of the material is placed in an external magnetic field \vec{B}^{ext} , the magnetic dipole moments tend to line up with the field, which gives the sample a net magnetic dipole moment not unlike that found in a ferromagnetic sample. However, paramagnetic materials lack the exchange coupling needed to set up permanent magnetic domains. Paramagnetism is fairly weak compared to ferromagnetism because the forces of alignment from external magnetic

Liquid oxygen is suspended between the two pole faces of a magnet because the liquid is paramagnetic and is magnetically attracted to the magnet.

fields are smaller than the randomizing forces due to thermal motions. Also, paramagnetic materials do not retain their magnetism once an external magnetic field is turned off.

A paramagnetic material placed in an external magnetic field \vec{B}^{ext} develops a magnetic dipole moment in the direction of \vec{B}^{ext} . If the field is not uniform, the paramagnetic material is attracted toward a region of greater magnetic field from a region of lesser field.

As is the case for ferromagnetism, we can express the extent to which a given paramagnetic sample is magnetized by measuring the magnetization \vec{M} (defined in Eq. 32-41). In 1895, Pierre Curie discovered that the magnitude of the magnetization of a paramagnetic sample is directly proportional to the external magnetic field magnitude B^{ext} and inversely proportional to the temperature T in kelvins; that is,

$$M = C \frac{B^{\text{ext}}}{T}. \quad (32-44)$$

Equation 32-44 is known as **Curie's law**, and C is called the **Curie constant**. Curie's law is reasonable in that increasing \vec{B}^{ext} tends to align the atomic dipole moments in a sample and thus to increase \vec{M} , whereas increasing T tends to disrupt the alignment via thermal agitation and thus to decrease \vec{M} . However, the law is actually an approximation that is valid only when the ratio B^{ext}/T is not too large.

Figure 32-19 shows the ratio M/M^{max} as a function of B^{ext}/T for a sample of the salt potassium chromium sulfate, in which chromium ions are the paramagnetic substance. The plot is called a **magnetization curve**. The straight line for Curie's law fits the experimental data at the left, for B^{ext}/T below about 0.5 T/K. The curve that fits all the data points is based on quantum physics. The data on the right side, near saturation, are very difficult to obtain because they require very strong magnetic fields (about 100 000 times Earth's field), even at the very low temperatures noted in Fig. 32-19.

Diamagnetism

The *atoms* in diamagnetic materials have no net magnetic dipole moments. However, diamagnetic *materials* do undergo a very weak nonpermanent alignment in the presence of an external magnetic field. The strength of the alignments is still proportional to the strength of the external magnetic field (as is the case for both ferro- and paramagnetism). However, the behavior of diamagnetic materials is not very temperature dependent.

The most interesting characteristic of diamagnetism is that in the presence of an external magnetic field that is nonuniform, each atom experiences a net force that is directed *away* from the region of greater magnetic field. Thus, in diamagnetism the

FIGURE 32-19 ■ A magnetization curve for potassium chromium sulfate, a paramagnetic salt. The ratio of the magnitudes of the salt magnetization \vec{M} to the maximum possible magnetization \vec{M}^{max} is plotted versus the ratio of the magnitude of the applied magnetic field B^{ext} to the temperature T . Curie's law fits the data at the left; quantum theory fits all the data. (Based on research by Warren E. Henry, 1909–2001.)

alignment of atomic magnetic moments with an external magnetic field is opposite to that associated with ferromagnetic and paramagnetic materials. In general,

A diamagnetic material placed in an external magnetic field \vec{B}^{ext} develops a magnetic dipole moment directed opposite \vec{B}^{ext} . If the field is nonuniform, the diamagnetic material is repelled from a region of greater magnetic field toward a region of lesser field.

Animals like the frog shown in Fig. 32-20 are diamagnetic. This frog has been placed in the diverging magnetic field near the top end of a vertical current-carrying solenoid; every atom in the frog was repelled upward, away from the region of stronger magnetic field at that end of the solenoid. The frog moved upward into weaker and weaker magnetic field until the upward magnetic force balanced the gravitational force on it, and there it hung in midair. People are also diamagnetic, so if we built a large enough solenoid, we could also suspend a person in midair.

FIGURE 32-20 ■ An overhead view of a diamagnetic frog that is being levitated in a magnetic field. The \vec{B} -field is produced by current in a vertical solenoid below the frog. The solenoid's upward magnetic force on the frog balances the downward gravitational force on the frog. (The frog is not in discomfort; the sensation is like floating in water, which frogs don't seem to mind.)

READING EXERCISE 32-8: The figure here shows two paramagnetic spheres located near the south pole of a bar magnet. Are (a) the magnetic forces on the spheres and (b) the magnetic dipole moments of the spheres directed toward or away from the bar magnet? (c) Is the magnetic force on sphere 1 greater than, less than, or equal to that on sphere 2?

READING EXERCISE 32-9: The figure shows two diamagnetic spheres located near the south pole of a bar magnet. Are (a) the magnetic forces on the spheres and (b) the magnetic dipole moments of the spheres directed toward or away from the bar magnet? (c) Is the magnetic force on sphere 1 greater than, less than, or equal to that on sphere 2?

32-9 The Earth's Magnetism

The Earth has a magnetic field associated with it that behaves approximately like that of a magnetic dipole. In other words, the Earth's magnetic field can be thought of as being produced by a bar magnet that straddles the center of the planet with its axis more or less aligned with the Earth's rotation axis. Figure 32-21 is an idealized depiction of the Earth's dipole field that ignores the distortion of field lines caused by charged particles streaming out of the Sun and other factors.

Characteristics of the Earth's Magnetic Field

For the idealized magnetic field shown in Fig. 32-21, the Earth's magnetic dipole moment $\vec{\mu}$ has a magnitude of 8.0×10^{22} J/T. The point where the Earth's rotation axis intersects the surface is known as the *geographic north pole*. In 2001, the geological survey of Canada placed the direction of the Earth's dipole moment at an angle of $\theta = 8.7^\circ$ from the rotation axis (RR) of the Earth.* The *dipole axis* (MM in Fig. 32-21) lies along $\vec{\mu}$ and intersects the Earth's surface at the *geomagnetic north and south poles*. These days the magnetic north pole is estimated to be somewhere in the Arctic Ocean north of Canada and the south pole is in the Antarctic Ocean. Since the poles are currently moving at about 40 km/yr, the possibility exists that the magnetic north pole could pass north of Alaska and in about fifty years end up in Siberia, although this outcome is not certain.

FIGURE 32-21 ■ An idealized view of the Earth's magnetic field as a dipole field. At present, dipole axis MM makes an angle of 8.7° with Earth's rotational axis RR . The "south pole" of the dipole is in Earth's northern hemisphere.

*http://www.geolab.nrcan.gc.ca/geomag/northpole_e.shtml

The lines of the magnetic field \vec{B} generally emerge in the southern hemisphere and reenter Earth in the northern hemisphere. Thus, the magnetic pole that is in the Earth's northern hemisphere and known as a "north magnetic pole" is *really the south pole of the Earth's magnetic dipole*. This means that the north pole of a compass is attracted to the Earth's geographic north pole.

The direction of the magnetic field varies from location to location on the Earth. The field direction at any location on the Earth's surface is commonly specified in terms of two angles. The **field declination** is the angle (left or right) between geographic north (which is toward 90° latitude) and the horizontal component of the field. The **field inclination** is the angle (up or down) between a horizontal plane and the field's direction.

The field's inclination and declination at a given location can be measured with a *compass* and a *dip meter*. A **compass** is simply a needle-shaped magnet that is mounted so it can rotate freely about a vertical axis. When it is held in a horizontal plane, the north-pole end of the needle points, generally, toward the geomagnetic north pole (really a south magnetic pole). The angle between the compass needle and geographic north is the field declination.* A dip meter, used to measure inclination, is simply another needle-shaped magnet mounted so it can rotate freely about a *horizontal* axis. If the plane of the dip meter is aligned with the direction of the compass needle used to measure the declination, then the angle the dip meter needle makes with the horizontal is defined as the inclination angle. The magnetic north pole is defined as the location in the northern hemisphere for which the dip angle is 90° .

Causes of the Earth's Magnetism

The mechanisms that produce the Earth's magnetic field are not completely understood. However, it is helpful to begin our discussion of the latest models with a consideration of what is known about the Earth's formation and structure.

The Earth's Structure: Measurements of the spread of seismic waves tell us that the structure of the Earth is rather like that of a chocolate-covered cherry with gooey liquid between the cherry and the chocolate. This structure makes sense when we consider the currently accepted theory that the Earth was formed five billion years ago as a conglomeration of colliding meteorites and comets. Iron and other dense elements from meteorites were pulled by gravitational forces toward the center of the Earth. Compounds made of lighter elements, as well as the water contained in comets, migrated toward the surface. In between the solid core at the center of the Earth and the solid crust at the Earth's surface there is the gooey liquid consisting of molten lava (Fig. 32-22).

FIGURE 32-22 ■ Seismic data reveal that the Earth has an **inner core** (white) of solid iron with a radius of about 1200 km, an **outer core** (yellow) of iron rich molten lava about 2200 km thick, a more or less solid **mantle** (orange and red—not to scale) of less dense matter about 2600 km thick, and a very thin **crust** of rocks and soils at the surface with an average thickness of 20 km.

Continuous Molten Lava Currents: Many scientists believe that most of the Earth's magnetic field is produced by electromagnetic interactions that depend on the molten lava acting like a moving electrical conductor. We know from our study of Faraday's law that if even a small magnetic field is present in a region of the core, the electrical currents can be induced in the conducting fluid that travels through it. These induced currents can, in turn, produce magnetic fields that can act on other parts of the liquid core that are also moving. Thus a continuous cycle of induction and magnetic field production can take place as long as the material in the liquid core keeps flowing. In principle, this process is rather like that described for the generator shown in Fig. 32-10.

Two mechanisms have been proposed that explain the flow of molten lava in the liquid core. One possible mechanism is thermal convection produced by the temperature

*Inclination is the angle that a magnetic needle makes with the plane of the horizon. It is also called the angle of dip. Declination is the angle between magnetic north and geographic north.

difference between the hot solid inner core and the much cooler mantle. A second proposed mechanism for the flow of lava involves condensation of the heavier elements onto a growing inner core. This causes lighter, less dense, elements to flow toward the Earth's surface. In either case liquid convection currents are produced that are not unlike those in a pot of boiling water.

The Earth's magnetic field depends critically on the existence of *continuous* convection currents that requires the solid core to remain very hot for billions of years. Some scientists believe that nuclear energy in the core is being transformed to thermal energy through the decay of heavy radioactive elements. Other scientists have suggested that thermal energy can be released if the inner core expands by condensing material from the liquid core.

Changes in the Earth's Magnetic Field Over Time: Some mysterious characteristics of the Earth's magnetic field have been gleaned from fossil records and other geomagnetic measurements. The strength of the field and the location of the magnetic poles are constantly changing. For example, in recent years the geographic location of the magnetic poles has changed by an average of about 100 meters a day. These relatively small day-to-day changes are not obvious to someone a long distance from a magnetic pole who uses a compass and dip meter to measure a local field direction. It's another story when longer time scales are involved. We can use simple instruments to detect changes over a time period of a year or more. When even longer time periods are considered, the changes have been dramatic. In fact, the orientations of magnetized minerals imbedded in ancient rocks indicate that the Earth's magnetic field has completely reversed itself many times in the Earth's five billion year history, though reversals seem to take 1000 years or more.

The Glatzmaier/Roberts Model: A few years ago, two scientists, Gary Glatzmaier and Paul Roberts, developed a comprehensive numerical model of the electromagnetic and fluid dynamic processes in the Earth's interior. When this model was run on a CRAY supercomputer for thousands of hours these investigators were able to simulate over 300,000 years of magnetic field conditions. Their results showed many of the key features revealed by geological data, including the existence of a dipole field outside the Earth, a preference for approximate alignment between the Earth's dipole moment and its rotation axis, field strength variations, migration of the magnetic poles over the Earth's surface, and several field reversals. One such configuration of magnetic field lines is seen in Fig. 32-23.

There is still a great deal to be learned about the actual mechanisms responsible for the continual changes in the Earth's magnetic field, but scientists expect to resolve many of their uncertainties within the next few decades.

Magnetic Bacteria

The survival of many organisms depends on their ability to sense the Earth's magnetic field. For example, it is believed that the Earth's dipole field is critical to the navigation of migrating birds and fish as well as certain types of bacteria.

Magnetotactic bacteria are one-celled organisms that can be found almost anywhere in the world where there are ponds, marshes, or muddy lake bottoms. Many species of these bacteria are anaerobic or microanaerobic and must burrow in mud both to get away from oxygen and to feed on nutrients. Notice that on the lower left side of the bacterium shown in the photo at the beginning of this chapter there is a string of tiny 100-nanometer-long particles. These particles, known as magnetosomes, are oriented along the bacterium's long axis. An enlarged view of a set of magnetosomes is shown in Fig. 32-24.

Magnetotactic bacteria synthesize these magnetic particles out of iron-oxygen or iron sulfur compounds. Each magnetosome is just big enough to have a permanent

FIGURE 32-23 ■ This image shows one of many configurations of the Earth's magnetic field lines created by the model developed by Glatzmaier and Roberts.

FIGURE 32-24 ■ The type of bacterium shown in the puzzler at the beginning of the chapter is magnetotactic because it contains a chain of dense iron-rich magnetosomes each having a length of about 100 nm. The chain shown in this transmission electron micrograph has a net magnetic moment and tends to align itself with the Earth's magnetic field.

magnetic dipole moment and just small enough to be a single ferromagnetic domain. When strung together like a set of microscopic refrigerator magnets, the array has a net dipole moment. So instead of bumbling around randomly, these bacteria align with the Earth's magnetic field. This allows them to swim naturally along field lines.

Through natural selection, the bacteria that have their magnetosome strings oriented so they swim down along magnetic field lines to the mud at the bottom of a pond or lake will survive and multiply. Those that don't will swim up and die. An examination of the pattern of the Earth's magnetic field lines shown in Fig. 32-21 reveals that "down" is opposite to the direction of the field lines in the southern hemisphere and in the same direction as the field lines in the northern hemisphere. Thus, an Australian bacterium evolved to swim down in its normal habitat would swim up if transported to the United States. Alternatively, a healthy bacterium that evolves in the United States would be preset by evolutionary processes to have its magnetosomes oriented in the opposite direction, so it will swim down.

It is interesting to note that the orientations of bacterial magnetosome strings in fossils have helped scientists piece together evidence for past changes in the Earth's magnetic field.

READING EXERCISE 32-10: Describe the ways in which the Earth's magnetic field varies over its surface. Does the Earth's magnetic field vary in time as well? ■

Problems

SEC. 32-2 ■ SELF-INDUCTANCE

1. Close-Packed Coil The inductance of a close-packed coil of 400 turns is 8.0 mH. Calculate the magnetic flux through the coil when the current is 5.0 mA.

2. Circular Coils and Flux A circular coil has a 10.0 cm radius and consists of 30.0 closely wound turns of wire. An externally produced magnetic field of magnitude 2.60 mT is perpendicular to the coil. (a) If no current is in the coil, what is the magnitude of the magnetic flux that links its turns? (b) When the current in the coil is 3.80 A in a certain direction, the net flux through the coil is found to vanish. What is the inductance of the coil?

3. Equal Currents, Opposite Directions Two long parallel wires, both of radius a and whose centers are a distance d apart, carry equal currents in opposite directions. Show that, neglecting the flux within the wires, the inductance of a length l of such a pair of wires is given by

$$L = \frac{\mu_0 l}{\pi} \ln \frac{d - a}{a}$$

(Hint: Calculate the flux through a rectangle of which the wires form two opposite sides.)

4. Wide Copper Strip A wide copper strip of width W is bent to form a tube of radius R with two parallel planar extensions, as shown in Fig. 32-25. There is a current i through the strip, distributed uniformly over its width. In this way a "one-turn solenoid" is formed. (a) Derive an expression for the magnitude of the magnetic field \vec{B} in the

FIGURE 32-25 ■ Problem 4.

tubular part (far away from the edges). (Hint: Assume that the magnetic field outside this one-turn solenoid is negligibly small.) (b) Find the inductance of this one-turn solenoid, neglecting the two planar extensions.

5. Inductor Carries Steady Current A 12 H inductor carries a steady current of 2.0 A. How can a 60 V self-induced emf be made to appear in the inductor?

6. At a Given Instant At a given instant the current and self-induced emf in an inductor are directed as indicated in Fig. 32-26. (a) Is the current increasing or decreasing? (b) The induced emf is 17 V and the rate of change of the current is 25 kA/s; find the inductance.

FIGURE 32-26 ■ Problem 6.

7. Inductors in Series Two inductors L_1 and L_2 are connected in series and are separated by a large distance. (a) Show that the equivalent inductance is given by

$$L_{\text{eq}} = L_1 + L_2.$$

(Hint: Review the derivations for resistors in series and capacitors in series. Which is similar here?) (b) Why must their separation be large for this relationship to hold? (c) What is the generalization of (a) for N inductors in series?

8. Current Varies with Time The current i through a 4.6 H inductor varies with time t as shown by the graph of Fig. 32-27. The inductor has a resistance of 12 Ω . Find the magnitude of the induced emf \mathcal{E} during the time intervals (a) $t_1 = 0$ to $t_2 = 2$ ms, (b) $t_2 = 2$ ms to $t_3 = 5$ ms, (c) $t_3 = 5$ ms to $t_4 = 6$ ms. (Ignore the behavior at the ends of the intervals.)

FIGURE 32-27 ■ Problem 8.

9. At What Rate At time $t = 0$ ms, a 45 V potential difference is suddenly applied to the leads of a coil with inductance $L = 50$ mH and resistance $R = 180 \Omega$. At what rate is the current through the coil increasing at $t = 1.2$ ms?

10. Inductors in Parallel Two inductors L_1 and L_2 are connected in parallel and separated by a large distance. (a) Show that the equivalent inductance is given by

$$\frac{1}{L_{\text{eq}}} = \frac{1}{L_1} + \frac{1}{L_2}.$$

(Hint: Review the derivations for resistors in parallel and capacitors in parallel. Which is similar here?) (b) Why must their separation be large for this relationship to hold? (c) What is the generalization of (a) for N inductors in parallel?

11. What Is L The inductance of a closely wound coil is such that an emf of 3.0 mV is induced when the current changes at the rate of 5.0 A/s. A steady current of 8.0 A produces a magnetic flux of $40 \mu\text{Wb}$ through each turn. (a) Calculate the inductance of the coil. (b) How many turns does the coil have?

SEC. 32-3 ■ MUTUAL INDUCTION

12. Coil 1, Coil 2 Coil 1 in Fig. 32-4 has $L_1 = 25$ mH and $N_1 = 100$ turns. Coil 2 has $L_2 = 40$ mH and $N_2 = 200$ turns. The coils are rigidly positioned with respect to each other; their mutual inductance M is 3.0 mH. A 6.0 mA current in coil 1 is changing at the rate of 4.0 A/s. (a) What magnetic flux $\Phi_{1 \rightarrow 2}$ links coil 2, and what self-induced emf appears there? (b) What magnetic flux $\Phi_{2 \rightarrow 1}$ links coil 1, and what mutually induced emf appears there?

13. Two Coils at Fixed Locations Two coils are at fixed locations. When coil 1 has no current and the current in coil 2 increases at the rate 15.0 A/s, the emf in coil 1 is 25.0 mV. (a) What is their mutual inductance? (b) When coil 2 has no current and coil 1 has a current of 3.60 A, what is the flux linkage in coil 2?

14. Two Solenoids Two solenoids are part of the spark coil of an automobile. When the current in one solenoid falls from 6.0 A to zero in 2.5 ms, an emf of 30 kV is induced in the other solenoid. What is the mutual inductance M of the solenoids?

15. Two Connected Coils Two coils, connected as shown in Fig. 32-28, separately have inductances L_1 and L_2 . Their mutual inductance is M . (a) Show that this combination can

FIGURE 32-28 ■ Problem 15.

be replaced by a single coil of equivalent inductance given by

$$L_{\text{eq}} = L_1 + L_2 + 2M.$$

(b) How could the coils in Fig. 32-28 be reconnected to yield an equivalent inductance of

$$L_{\text{eq}} = L_1 + L_2 - 2M?$$

(This problem is an extension of Problem 7, but the requirement that the coils be far apart has been removed.)

16. Coil Around Solenoid A coil C of N turns is placed around a long solenoid S of radius R and n turns per unit length as in Fig. 32-29. Show that the mutual inductance for the coil-solenoid combination is given by $M = \mu_0 \pi R^2 n N$. Explain why M does not depend on the shape, size, or possible lack of close-packing of the coil.

FIGURE 32-29 ■ Problem 16.

17. Coaxial Solenoid Figure 32-30 shows, in cross section, two coaxial solenoids. Show that the mutual inductance M for a length l of this solenoid-solenoid combination is given by $M = \pi R_1^2 l \mu_0 n_1 n_2$, in which n_1 and n_2

FIGURE 32-30 ■ Problem 17.

18. Coils Over a Toroid Figure 32-31 shows a coil of N_2 turns wound as shown around part of a toroid of N_1 turns. The toroid's inner radius is a , its outer radius is b , and its height is h . Show that the mutual inductance M for the toroid-coil combination is

$$M = \frac{\mu_0 N_1 N_2 h}{2\pi} \ln \frac{b}{a}.$$

FIGURE 32-31 ■ Problem 18.

19. Rectangular Loop A rectangular loop of N close-packed turns is positioned near a long straight wire as shown in Fig. 32-32. (a) What is the mutual inductance M for the loop-wire combination? (b) Evaluate M for $N = 100$, $a = 1.0$ cm, $b = 8.0$ cm, and $l = 30$ cm.

SEC. 32-4 ■ RL CIRCUITS (WITH IDEAL INDUCTORS)

FIGURE 32-32 ■ Problem 19.

20. Inductive Time Constant The current in an RL circuit builds up to one third of its steady-state value in 5.00 s. Find the inductive time constant.

21. How Long Must We Wait In terms of τ_L , how long must we wait for the current in an RL circuit to build up to within 0.100% of its equilibrium value?

22. In Terms of the emf Consider the RL circuit of Fig. 32-6. In terms of the battery emf \mathcal{E} , (a) what is the self-induced emf ΔV_2 when the switch has just been closed on a , and (b) what is ΔV_2 when $t = 2.0\tau_L$? (c) In terms of τ_L , when will ΔV_2 be just one-half the battery emf \mathcal{E} ?

23. First Second The current in an RL circuit drops from 1.0 A to 10 mA in the first second following removal of the battery from the circuit. If L is 10 H, find the resistance R in the circuit.

24. emf Varies with Time Suppose the emf of the battery in the circuit of Fig. 32-7 varies with time t so that the current is given by $i(t) = 3.0 \text{ A} + (5.0 \text{ A/s})t$, where i is in amperes and t is in seconds. Take $R = 4.0 \Omega$ and $L = 6.0 \text{ H}$, and find an expression for the battery emf as function of time. (*Hint:* Apply the loop rule.)

25. Solenoid A solenoid having an inductance of $6.30 \mu\text{H}$ is connected in series with a $1.20 \text{ k}\Omega$ resistor. (a) If a 14.0 V battery is inserted into the circuit, how long will it take for the current through the resistor to reach 80.0% of its final value? (b) What is the current through the resistor at time $t = 1.0\tau_L$?

26. Wooden Toroidal Core A wooden toroidal core with a square cross section has an inner radius of 10 cm and an outer radius of 12 cm. It is wound with one layer of wire (of diameter 1.0 mm and resistance per meter $0.020 \Omega/\text{m}$). What are (a) the inductance and (b) the inductive time constant of the resulting toroid? Ignore the thickness of the insulation on the wire.

27. Suddenly Applied At time $t = 0 \text{ ms}$, a 45.0 V potential difference is suddenly applied to a coil with $L = 50.0 \text{ mH}$ and $R = 180 \Omega$. At what rate is the current increasing at $t = 1.20 \text{ ms}$?

28. In the Circuit In the circuit of Fig. 32-33, $\mathcal{E} = 10 \text{ V}$, $R_1 = 5.0 \Omega$, $R_2 = 10 \Omega$, and $L = 5.0 \text{ H}$. For the two separate conditions (I) switch S just closed and (II) switch S closed for a long time, calculate (a) the current i_1 through R_1 , (b) the current i_2 through R_2 , (c) the current i through the switch, (d) the potential difference across R_2 , (e) the potential difference across L , and (f) the rate of change di_2/dt .

FIGURE 32-33 ■ Problem 28.

29. In the Figure In Fig. 32-34, $\mathcal{E} = 100 \text{ V}$, $R_1 = 10.0 \Omega$, $R_2 = 20.0 \Omega$, $R_3 = 30.0 \Omega$, and $L = 2.00 \text{ H}$. Find the values of i_1 and i_2 (a) immediately after closing of switch S , (b) a long time later, (c) immediately after the reopening of switch S , and (d) a long time after the reopening.

FIGURE 32-34 ■ Problem 29.

30. What Is the Constant Figure 32-35a shows a circuit consisting of an ideal battery with emf $\mathcal{E} = 6.00 \mu\text{V}$, a resistance R , and a small wire loop of area 5.0 cm^2 . For the time interval $t_1 = 10$ to $t_2 = 20 \text{ s}$, an external magnetic field is set up throughout the loop. The field is uniform, its direction is into the page in Fig. 32-35a, and the field magnitude is given by $B = at$, where B is in teslas, a is a

FIGURE 32-35 ■ Problem 30.

constant with units of teslas per second, and t is in seconds. Figure 32-35b gives the current i in the circuit before, during, and after the external field is set up. Find a .

31. Once the Switch Is Closed Once the switch S is closed in Fig. 32-36 the time required for the current to reach any obtainable value depends, in part, on the value of resistance R . Suppose the emf \mathcal{E} of the ideal battery is 12 V and the inductance of the ideal (resistanceless) inductor is 18 mH . How much time is needed for the current to reach 2.00 A if R is (a) 1.00Ω , (b) 5.00Ω , and (c) 6.00Ω ? (d) Why is there a huge jump between the answers to (b) and (c)? (e) For what value of R is the time required for the current to reach 2.00 A least? (f) What is that least time? (*Hint:* Rethink Eq. 32-21.)

FIGURE 32-36 ■ Problems 31, 34, and 61.

32. Circuit Shown In the circuit shown in Fig. 32-37, switch S is closed at time $t = 0$. Thereafter, the constant current source, by varying its emf, maintains a constant current i out of its upper terminal. (a) Derive an expression for the current through the inductor as a function of time. (b) Show that the current through the resistor equals the current through the inductor at time $t = (L/R) \ln 2$.

FIGURE 32-37 ■ Problem 32.

33. When Is the Flux Equal In Fig. 32-38a, switch S has been closed on A long enough to establish a steady current in the inductor of inductance $L_1 = 5.00 \text{ mH}$ and the resistor of resistance $R_1 = 25 \Omega$. Similarly, in Fig. 32-38b, switch S has been closed on A long enough to establish a steady current in the inductor of inductance $L_2 = 3.00 \text{ mH}$ and the resistor of resistance $R_2 = 30 \Omega$. The ratio Φ_{02}/Φ_{01} of the magnetic flux through a turn in inductor 2 to that in inductor 1 is 1.5. At time $t = 0$, the two switches are closed on B . At what time t is the flux through a turn in the two inductors equal?

FIGURE 32-38 ■ Problem 33.

34. When Is emf Equal Switch S in Fig. 32-36 is closed at time $t = 0$, initiating the buildup of current in the 15.0 mH inductor and the 20.0Ω resistor. At what time is the emf across the inductor equal to the potential difference across the resistor?

SEC. 32-5 ■ INDUCTORS, TRANSFORMERS, AND ELECTRIC POWER

35. A Transformer A transformer has 500 primary turns and 10 secondary turns. (a) If ΔV_p is 120 V (rms), what is ΔV_s with an open circuit? (b) If the secondary now has a resistive load of $15\ \Omega$, what are the currents in the primary and secondary?

36. A Generator A generator supplies 100 V to the primary coil of a transformer of 50 turns. If the secondary coil has 500 turns, what is the secondary voltage?

37. Audio Amplifier In Fig. 32-39 let the rectangular box on the left represent the (high-impedance) output of an audio amplifier, with $r = 1000\ \Omega$. Let $R = 10\ \Omega$ represent the (low-impedance) coil of a loudspeaker. For maximum transfer of energy to the load R we must have $R = r$, and that is not true in this case. However, a transformer can be used to “transform” resistances, making them behave electrically as if they were larger or smaller than they actually are. Sketch the primary and secondary coils of a transformer that can be introduced between the amplifier and the speaker in Fig. 32-39 to match the impedances. What must be the turns ratio?

FIGURE 32-39 ■ Problem 37.

38. Autotransformer Figure 32-40 shows an “autotransformer.” It consists of a single coil (with an iron core). Three taps T_N are provided. Between taps T_1 and T_2 there are 200 turns, and between taps T_2 and T_3 there are 800 turns. Any two taps can be considered the “primary terminals” and any two taps can be considered the “secondary terminals.” List all the ratios by which the primary voltage may be changed to a secondary voltage.

FIGURE 32-40 ■ Problem 38.

SEC. 32-6 ■ MAGNETIC MATERIALS—AN INTRODUCTION

39. Orbital Magnetic Dipole What is the measured component of the orbital magnetic dipole moment of an electron with (a) $m_l = 1$ and (b) $m_l = -2$?

40. Energy Difference What is the energy difference between parallel and antiparallel alignment of the z -component of an electron’s spin magnetic dipole moment with an external magnetic field of magnitude $0.25\ \text{T}$, directed parallel to the z axis?

41. Electron in an Atom If an electron in an atom has an orbital angular momentum with $m_l = 0$, (a) what is the component μ_z^{orb} ? If the atom is in an external magnetic field \vec{B} of magnitude $35\ \text{mT}$ and directed along z axis, what are the potential energies associated with the orientations of (b) the electron’s orbital magnetic dipole moment and (c) the electron’s spin magnetic dipole moment? (d) Repeat (a) through (c) for $m_l = -3$.

42. Spin Magnetic Moment An electron is placed in a magnetic field \vec{B} that is directed along a z axis. The energy difference between parallel and antiparallel alignments of the z -component of the electron’s spin magnetic moment with \vec{B} is $6.00 \times 10^{-25}\ \text{J}$. What is the magnitude of \vec{B} ?

43. How Many Suppose that ± 4 are the limits to the values of m_l for an electron in an atom. (a) How many different values of the z -component μ_z^{orb} of the electron’s orbital magnetic dipole moment are possible? (b) What is the greatest magnitude of those possible values? Next, suppose that the atom is in a magnetic field of magnitude $0.250\ \text{T}$, in the positive direction of the z axis. What are (c) the maximum potential energy and (d) the minimum potential energy associated with those possible values of μ_z^{orb} ?

44. NMR and MRI Nuclear Magnetic Resonance (NMR) and Magnetic Resonance Imaging (MRI) exploit the interactions between charged particles and very strong magnetic fields in order to produce images (including images of soft tissue). The magnetic field in a certain MRI machine is $0.5\ \text{Tesla}$. What is the maximum difference in energy that one might measure for a single electron placed in this field?

SEC. 32-7 ■ FERROMAGNETISM

45. Saturation Magnetization The saturation magnetization M^{max} of the ferromagnetic metal nickel is $4.70 \times 10^5\ \text{A/m}$. Calculate the magnetic moment of a single nickel atom. (The density of nickel is $8.90\ \text{g/cm}^3$ and its molar mass is $58.71\ \text{g/mol}$.)

46. Iron The dipole moment associated with an atom of iron in an iron bar has magnitude $2.1 \times 10^{-23}\ \text{J/T}$. Assume that all the atoms in the bar, which is $5.0\ \text{cm}$ long and has a cross-sectional area of $1.0\ \text{cm}^2$, have their dipole moments aligned. (a) What is the magnitude of the dipole moment of the bar? (b) What is the magnitude of the torque that must be exerted to hold this magnet perpendicular to an external field of $1.5\ \text{T}$? (The density of iron is $7.9\ \text{g/cm}^3$.)

47. Earth’s Magnetic Moment The magnetic dipole moment of Earth has magnitude $8.0 \times 10^{22}\ \text{J/T}$. (a) If the origin of this magnetism were a magnetized iron sphere at the center of the Earth, what would be its radius? (b) What fraction of the volume of the Earth would such a sphere occupy? Assume complete alignment of the dipoles. The density of the Earth’s inner core is $14\ \text{g/cm}^3$. The magnetic dipole moment of an iron atom is $2.1 \times 10^{-23}\ \text{J/T}$. (Note: The Earth’s inner core is in fact thought to be in both liquid and solid forms and partly iron, but a permanent magnet as the source of the Earth’s magnetism has been ruled out by several considerations. For one, the temperature is certainly above the Curie point.)

48. Mines and Boreholes Measurements in mines and boreholes indicate that the Earth’s interior temperature increases with depth at the average rate of $30\ \text{C}^\circ/\text{km}$. Assuming a surface temperature of 10°C , at what depth does iron cease to be ferromagnetic? (The Curie temperature of iron varies very little with pressure.)

SEC. 32-8 ■ OTHER MAGNETIC MATERIALS

49. Electron Assume that an electron of mass m and charge magnitude e moves in a circular orbit of radius r about a nucleus. A uniform magnetic field \vec{B} is then established perpendicular to the plane of the orbit. Assuming also that the radius of the orbit does not change and that the change in the speed of the electron due to field \vec{B} is small, find an expression for the change in the orbital magnetic dipole moment of the electron due to the field.

50. Loop Model Figure 32-41 shows a loop model (loop L) for a diamagnetic material. (a) Sketch the magnetic field lines through and about the material due to the bar magnet. (b) What are the

directions of the loop's net magnetic dipole moment $\vec{\mu}$ and the conventional current i in the loop? (c) What is the direction of the magnetic force on the loop?

FIGURE 32-41 ■ Problems 50 and 54.

51. Cylindrical Magnet A magnet in the form of a cylindrical rod has a length of 5.00 cm and a diameter of 1.00 cm. It has a uniform magnetization of 5.30×10^3 A/m. What is the magnitude of its magnetic dipole moment?

52. Paramagnetic Gas A magnetic field of magnitude 0.50 T is applied to a paramagnetic gas whose atoms have an intrinsic magnetic dipole moment of magnitude 1.0×10^{-23} J/T. At what temperature will the mean kinetic energy of translation of the gas atoms be equal to the energy required to reverse such a dipole end for end in this magnetic field?

53. Paramagnetic Salt A sample of the paramagnetic salt to which the magnetization curve of Fig. 32-19 applies is to be tested to see whether it obeys Curie's law. The sample is placed in a uniform 0.50 T magnetic field that remains constant throughout the experiment. The magnetization M is then measured at temperatures ranging from 10 to 300 K. Will Curie's law be valid under these conditions?

54. Paramagnetic Material Repeat Problem 50 for the case in which loop L is the model for a paramagnetic material.

55. Electron's Kinetic Energy An electron with kinetic energy K travels in a circular path that is perpendicular to a uniform magnetic field, the electron's motion is subject only to the force due to the field. (a) Show that the magnetic dipole moment of the electron due to its orbital motion has magnitude $\mu = K/|\vec{B}|$ and that it is in the direction opposite that of \vec{B} . (b) What are the magnitude and direction of the magnetic dipole moment of a positive ion with kinetic energy K_{ion} under the same circumstances? (c) An ionized gas consists of 5.3×10^{21} electrons/m³ and the same number density of ions. Take the average electron kinetic energy to be 6.2×10^{-20} J and the average ion kinetic energy to be 7.6×10^{-21} J. Calculate the magnetization of the gas when it is in a magnetic field of 1.2 T.

56. Magnetization Curve A sample of the paramagnetic salt to which the magnetization curve of Fig. 32-17 applies is held at room temperature (300 K). At what applied magnetic field will the degree

of magnetic saturation of the sample be (a) 50% and (b) 90%? (c) Are these fields attainable in the laboratory?

SEC. 32-9 ■ THE EARTH'S MAGNETISM

57. New Hampshire In New Hampshire the average horizontal component of the Earth's magnetic field in 1912 was $16 \mu\text{T}$ and the average inclination or "dip" was 73° . What was the corresponding magnitude of the Earth's magnetic field?

58. Earth's Field Assume the average value of the vertical component of the Earth's magnetic field is $43 \mu\text{T}$ (downward) for all of Arizona, which has an area of 2.95×10^5 km², and calculate the net magnetic flux through the rest of the Earth's surface (the entire surface excluding Arizona). Is that net magnetic flux outward or inward?

59. Earth's Field Two Use the results of Problem 60 to predict the Earth's magnetic field (both magnitude and inclination) at (a) the geomagnetic equator, (b) a point at geomagnetic latitude 60° , and (c) the north geomagnetic pole.

60. Magnetic Field of Earth The magnetic field of the Earth can be approximated as the magnetic field of a dipole, with horizontal and vertical components, at a point a distance r from the Earth's center, given by

$$B_h = \frac{\mu_0 \mu}{4\pi r^3} \cos \lambda_m, \quad B_v = \frac{\mu_0 \mu}{2\pi r^3} \sin \lambda_m,$$

where λ_m is the *magnetic latitude* (this type of latitude is measured from the geomagnetic equator toward the north or south geomagnetic pole). Assume that the Earth's magnetic dipole moment is $\mu = 8.00 \times 10^{22}$ A · m². (a) Show that the magnitude of the Earth's field at latitude λ_m is given by

$$B = \frac{\mu_0 \mu}{4\pi r^3} \sqrt{1 + 3 \sin^2 \lambda_m}.$$

(b) Show that the inclination ϕ_i of the magnetic field is related to the magnetic latitude λ_m by

$$\tan \phi_i = 2 \tan \lambda_m.$$

Additional Problems

61. Rate of Energy Transfer In Fig. 32-36, a 12.0 V ideal battery, a 20Ω resistor, and an ideal inductor are connected by a switch at time $t = 0$ s. At what rate is the battery transferring energy to the inductor's field at $t = 1.61\tau_L$?

62. Compass Needle You place a magnetic compass on a horizontal surface, allow the needle to settle into equilibrium position, and then give the compass a gentle wiggle to cause the needle to oscillate about that equilibrium position. The frequency of oscillation is 0.312 Hz. The Earth's magnetic field at the location of the compass has a horizontal component of $18.0 \mu\text{T}$. The needle has a magnetic moment of 0.680 mJ/T. What is the needle's rotational inertia about its (vertical) axis of rotation?

63. Induced Current in a Coil A long narrow coil is surrounded by a short wide coil as shown in Fig. 32-42. Both coils have negligible resistance. The short wide coil has a diameter d_S , n_S turns per unit length, and a length S . Its ends are connected through a resistor of resistance R . The long narrow inner coil has a diameter d_L , n_L turns per unit length, and a length L . Its ends are connected across a variable power source.

For each of the partial sentences below, indicate whether they are correctly completed by the phrase greater than ($>$), less than ($<$), or the same as ($=$). If you cannot determine which is the case from the information given, indicate not sufficient information (NSI).

The current through an inner coil is increased from 0.0 amps to 0.1 amps over a period of 10 seconds in a smooth fashion according to the rule

$$i_L(t) = (0.01 \text{ A/s}) t.$$

(a) The magnitude of the current in the long narrow coil at time $t = 1 \text{ s}$ is _____ the current in that coil at time $t = 5 \text{ s}$.

(b) The magnitude of the current in the short wide coil at time $t = 1 \text{ s}$ is _____ the current in that coil at time $t = 5 \text{ s}$.

(c) The magnitude of the current in the long narrow coil at time $t = 1 \text{ s}$ is _____ the current in the short wide coil at that same time.

(d) If the long narrow coil was compressed to half its length (without changing its diameter) before the current was turned on, the current in the short wide coil would be _____ it was without the compression.

64. Inducing Current Figure 32-43 shows a solenoid and two hoops. When the switch is closed, the solenoid carries a current in the direction indicated. The planes of the small loops are parallel to the planes of the hoops of the solenoid.

FIGURE 32-42 ■ Problem 63.

Hoop 1 consists of a single turn of resistive wire that has a resistance per unit length of λ . Hoop 2 consists of N turns of the same wire. Each hoop is a circle of radius r .

(a) The switch is closed and remains closed for a few seconds. Hoop 1 is then moved to the right. Is there a current flow induced? If there is a current, indicate the direction and explain how you figured it out.

(b) The hoops are now returned to their original locations and held fixed. The switch is opened. For a short time, the magnetic field at the hoops decreases like

$B_x(t) = B_x(0) - \gamma t$, FIGURE 32-43 ■ Problem 64.

where γ is a constant with units of gauss per second. Is there a current flow induced in the hoops? If there is a current, indicate the direction.

(c) Calculate the current flow in each hoop for situation (b).

(d) If $B_x(0) = 10 \text{ gauss}$, $\gamma = 2.5 \text{ gauss/s}$, the resistivity of the wire is $1 \mu\Omega/\text{m}$, and the hoops have a radius of 2 cm, calculate the current induced in hoop 1 as the B -field from the solenoid begins to fall.

33

Electromagnetic Oscillations and Alternating Current

When a high-voltage power transmission line requires repair, a utility company cannot just shut it down, perhaps blacking out an entire city. Repairs must be made while the lines are electrically “hot.” The man outside the helicopter in this photograph has just replaced a spacer between 500 kV lines *by hand*, a procedure that requires considerable expertise.

How does he manage this repair without being electrocuted?

The answer is in this chapter.

33-1 Advantages of Alternating Current

So far we have confined our study of electric circuits to **direct current** or **dc** circuits in which the direction of current does not change over time. In reality the vast majority of electric power systems and electrical devices involve **alternating current** or *ac* circuits where the current direction is continuously oscillating back and forth. Why did ac power become so popular? By 1879 the famous American inventor, Thomas Edison, refined the electric lightbulb invented by Humphry Davy in England. Almost overnight, there was high demand in Europe and the United States for the creation of systems for the generation and distribution of electric power.

Edison's quest for a practical lightbulb was apparently motivated by his desire to promote the use of the dc power system that he and his colleagues were developing. Indeed, his dc power station in lower Manhattan quickly became a monopoly, but only temporarily. By 1888 the Serbian immigrant Nikola Tesla (Fig. 33-1) had patented a complete system of alternating current generators, transformers, transmission lines, and induction motors. Shortly thereafter, entrepreneur-inventor George Westinghouse (Fig. 33-2) purchased Tesla's patents. After the Westinghouse Company's ac system was featured at the 1893 Chicago World Fair, more than 80% of all electrical devices were powered by ac circuits.

You already know some of the key factors that render ac power superior to dc. In Section 32-5 we discussed how electricity generated by induction naturally produces alternating current. We discussed how transformers can be used to step up voltages so that power can be transmitted more efficiently over long distances.* There were other factors that favored the Westinghouse system. Alternating current power transmission requires far less copper wire than Edison's dc system. Furthermore, the ac induction motors invented by Tesla were so efficient and easy to manufacture that they quickly became the heart of almost all labor-saving household devices, including water pumps, washing machines, dryers, electric drills, blenders, dishwashers, and garbage disposals.

There are other more recent inventions that we now take for granted that operate on ac circuits. Examples include radio and television transmission (treated in Chapter 34) and reception, computer monitors, and even the graphic equalizers in hi-fi equipment. Thus, without an understanding of ac circuits, it is impossible to understand how modern electrical systems and devices work. So, the major focus of this chapter is to use what you already know about induction and dc circuits to help you understand ac circuits. Resistors, capacitors, and inductors are the basic building blocks of both ac and dc circuits. We have already studied the independent functioning of each. In addition, we learned about dc resistor-capacitor (*RC*) combinations in Chapter 28 and dc resistor-inductor (*RL*) combinations in Chapter 32.

We begin this chapter by deriving equations that quantify the energy and energy density stored in the magnetic field created by current flowing through an inductor. We also review what we learned in Section 28-5 about the energy and energy density stored in a capacitor's electric field due to its charge. This will prepare you to study *electromagnetic oscillations* in several types of ac circuits where energy shuttles back and forth between the magnetic field in an inductor and the electric field in a capacitor.

*The method of repairing high-voltage lines shown in the opening photograph is patented by Scott H. Yenzler and is licensed exclusively to Haverfield Corporation of Gettysburg, Pennsylvania. As the lineman approaches a hot line, the electric field surrounding the line brings his body to nearly the potential of the line. To match the two potentials, he then extends a conducting "wand" to the line. To avoid being electrocuted, he must be isolated from anything electrically connected to the ground. To ensure that his body is always at a single potential—that of the line he is working on—he wears a conducting suit, hood, and gloves, all of which are electrically connected to the line via the wand.

FIGURE 33-1 ■ Nikola Tesla, an eccentric Serbian-American scientist and electrical engineer, invented the first successful ac power generation system.

FIGURE 33-2 ■ George Westinghouse developed the first ac power distribution system in the United States. It was based on Tesla's design. The system went online at Niagara Falls in 1896. After only a few years it was found to be superior to existing dc systems.

FIGURE 33-3 ■ The circuit of Fig. 32-6 with the switch closed on *a*. We apply the loop rule for circuits clockwise, starting at *x*.

33-2 Energy Stored in a \vec{B} -Field

When we pull two particles with opposite signs of charge away from each other, the resulting electric potential energy is stored in the electric field of the particles. We get this energy back from the field by letting the particles move toward each other again. In the same way we can consider energy to be stored in a magnetic field.

To derive a quantitative expression for that stored energy, consider Fig. 33-3, which shows a source of emf \mathcal{E} connected to a resistor R and an inductor L . After a switch is closed, the growth of current can be described by Eq. 32-20, which is restated here for convenience,

$$\mathcal{E} = L \frac{di}{dt} + iR. \quad (33-1)$$

This differential equation follows immediately from the loop rule for potential differences in single-loop circuits. If we multiply each side of this expression by the current i we obtain

$$\mathcal{E}i = L i \frac{di}{dt} + i^2R, \quad (33-2)$$

which has the following physical interpretation in terms of work and energy:

1. If a charge dq passes through the battery of emf \mathcal{E} in Fig. 33-3 in time dt , the battery does work on it in the amount $\mathcal{E} dq$. The rate at which the battery does work is $(\mathcal{E} dq)/dt$, or $\mathcal{E}i$. Thus, the left side of Eq. 33-2 represents the rate at which the emf device delivers energy to the rest of the circuit.
2. The rightmost term in Eq. 33-2 represents the rate at which energy is transformed to thermal energy in the resistor.
3. Energy that is delivered to the circuit but does not appear as thermal energy must, by the conservation-of-energy hypothesis, be stored in the magnetic field of the inductor. Since Eq. 33-2 represents conservation of energy for RL circuits, the middle term must represent the rate dU^{mag}/dt at which energy is stored in the magnetic field.

Thus

$$\frac{dU^{\text{mag}}}{dt} = Li \frac{di}{dt}. \quad (33-3)$$

We can write this as

$$dU^{\text{mag}} = Li di.$$

Integrating yields

$$\int_0^{U^{\text{mag}}} dU^{\text{mag}} = \int_0^i Li di$$

or

$$U^{\text{mag}} = \frac{1}{2}Li^2 \quad (\text{magnetic energy}), \quad (33-4)$$

which represents the total energy stored in the magnetic field of an inductor L carrying a current i . Note the similarity in form between this expression and the expression for the energy a capacitor stores in its electric field due to its capacitance

C and charge q . That equation is given by Eq. 28-21 and restated here for convenience as

$$U^{\text{elec}} = \frac{1}{2} \left(\frac{1}{C} \right) q^2. \quad (33-5)$$

(The variable i corresponds to q , and the constant L corresponds to $1/C$.)

33-3 Energy Density of a \vec{B} -Field

Since a typical inductor has the shape of either a solenoid or a toroid (a solenoid bent into a donut shape) it is often useful to know the magnetic field energy per unit volume stored in the magnetic field of this type of inductor. Consider a length l near the middle of a long solenoid of cross-sectional area A carrying current i . The volume associated with this length is Al . The energy U^{mag} stored by the length l of the solenoid must lie entirely within this volume because the magnetic field outside such a solenoid is approximately zero. Moreover, the stored energy must be uniformly distributed within the solenoid because the magnetic field inside a solenoid is also essentially uniform.

Thus, the energy u^{mag} stored per unit of magnetic field volume is given by

$$u^{\text{mag}} = \frac{U^{\text{mag}}}{Al}.$$

But since

$$U^{\text{mag}} = \frac{1}{2} L i^2,$$

we have

$$u^{\text{mag}} = \frac{L i^2}{2Al} = \left(\frac{L}{l} \right) \frac{i^2}{2A}.$$

Here L/l is the inductance of length l of the solenoid. Since the self-induced emf $\mathcal{E}_L = -L di/dt$ (Eq. 32-2) and $\mathcal{E}_L = -\mu_0 A n^2 l di/dt$ (Eq. 32-1) for an air-filled solenoid, we can replace L/l in the expression above to find

$$u^{\text{mag}} = \frac{1}{2} \mu_0 n^2 i^2, \quad (33-6)$$

where n is the number of turns per unit length. By using Eq. 30-25 ($B = n\mu_0 |i|$) we can write this *energy density* as

$$u^{\text{mag}} = \frac{1}{2} \frac{B^2}{\mu_0} \quad (\text{magnetic energy density}). \quad (33-7)$$

The **magnetic energy density**, u^{mag} , is the density of stored energy at any point where the magnetic field is \vec{B} . Even though we derived it by considering a special case, the solenoid, it turns out that Eq. 33-7 holds for all magnetic fields, no matter how they are generated. Equation 33-7 is comparable to Eq. 28-23; namely,

$$u^{\text{elec}} = \frac{1}{2} \epsilon_0 E^2, \quad (33-8)$$

which gives the energy density (in a vacuum) at any point in an electric field. Note that both u^{mag} and u^{elec} are proportional to the square of the appropriate field, \vec{B} or \vec{E} .

READING EXERCISE 33-1: The table lists the number of turns per unit length, current, and cross-sectional area for three solenoids. Rank the solenoids according to the magnetic energy density within them, greatest first.

Solenoid	Turns per Unit Length	Current	Area
<i>a</i>	$2n_1$	i_1	$2A_1$
<i>b</i>	n_1	$2i_1$	A_1
<i>c</i>	n_1	i_1	$6A_1$

FIGURE 33-4 ■ A series LC circuit, where a switch is thrown from b to a so that an ideal inductor and a charged capacitor are in series.

33-4 LC Oscillations, Qualitatively

We now turn our attention to how electromagnetic oscillations can occur in various types of circuits. We begin with the consideration of a dc circuit. Of the three circuit elements, resistance R , capacitance C , and inductance L , we have so far discussed dc circuits with the series combinations RC (Section 28-9) and RL (Section 32-4). In these two kinds of circuits we found that under certain circumstances, the charge, current, and potential differences across circuit elements can grow or decay exponentially. The exponential nature of the growth and decay curves is the result of energy losses in the resistor. The time constant associated with the exponential growth or decay is denoted by τ , which is either called capacitive or inductive depending on which circuit element is present.

What if there is almost no resistance in a circuit to dissipate energy? We now examine qualitatively the two-element combination LC in a series circuit. Then in Section 33-6 we will derive equations that describe the behavior of the circuit.

We assume that our LC circuit shown in Fig. 33-4 has a negligible resistance. You will see that in this case, the potential difference across the circuit elements is alternately associated with the inductor and capacitor. Why? The sequence of events is as follows:

- This initial state of the circuit at $t = 0$ as shown in Fig. 33-5a. The bar graphs for energy included there indicate that at this instant, with zero current through the inductor and maximum charge on the capacitor, the energy U^{mag} of the magnetic field is zero and the energy U^{elec} of the electric field is a maximum.
- As soon as the switch is thrown from b to a , the potential difference across the capacitor will start a flow of charge from one capacitor plate through the inductor to the other capacitor plate. The back emf generated by the inductor will slow the rate of capacitor discharge. The energy stored in the capacitor's electric field will decrease while the current through the inductor begins to increase its magnetic field energy as shown in Fig. 33-5b. Eventually as the capacitor is fully discharged, all the energy in its electric field will be transformed into energy stored in the magnetic field. At this point there will be no potential difference across the capacitor as shown in Fig. 33-5c.
- Without the potential difference, the current flowing through the inductor will start to decrease. However, in response to this changing current, a self-induced current will be set up through the inductor: this current will be in the same direction as the original current. Thus excess positive charge will begin to build up on the lower capacitor plate while the upper plate will begin to accumulate negative charge as shown in Fig. 33-5d. This will continue until no current flows through the inductor and the charges on the capacitor plates will be opposite in sign to

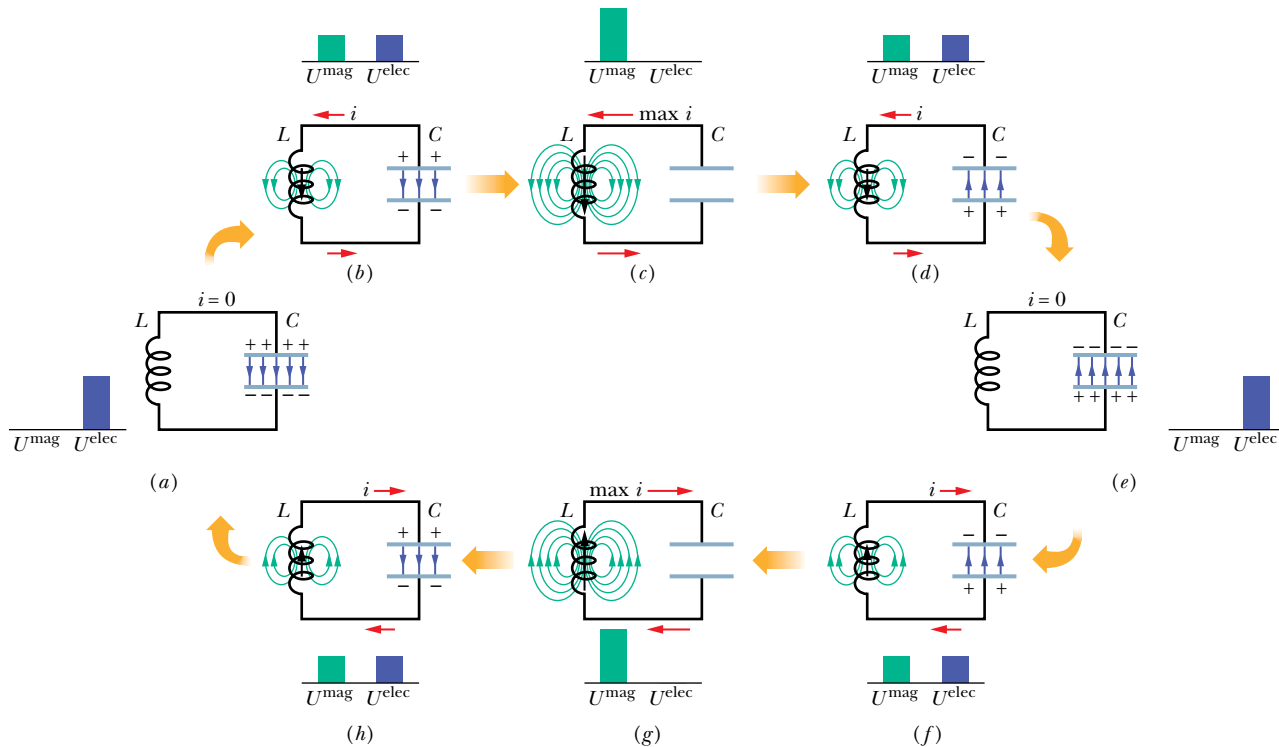

FIGURE 33-5 ■ Stages in a cycle of oscillation of an ideal LC circuit. The small bar graphs show levels of stored magnetic and electric energies. The inductor magnetic field lines and the capacitor electric field lines are shown. (a) Capacitor with maximum charge, no current. (b) Capacitor discharging, current increasing. (c) Capacitor fully discharged, current maximum. (d) Capacitor charging with opposite polarity to that in (a), current decreasing. (e) Capacitor with maximum charge with opposite polarity to that in (a), no current. (f) Capacitor discharging, current increasing with direction opposite that in (b). (g) Capacitor fully discharged, current maximum. (h) Capacitor charging, current decreasing.

that just after the switch was thrown. At this time all the circuit energy is in the capacitor's electric field once again as shown in Fig. 33-5e.

- Events 1 and 2 happen again but with the current flowing in the opposite direction until the capacitor is back to its original state (at $t = 0$) as shown in Fig. 33-5f, g, h, and a. Without a resistor in the circuit to dissipate energy, the maximum current through the inductor and the maximum amount of charge on the capacitor plates do not decay with time. In theory, for a perfectly ideal inductor, these oscillations can continue forever.

In the next section we do a mathematical analysis that fortunately agrees with observations that the current in the inductor i and the charge on the upper capacitor plate q vary *sinusoidally* with time as shown in Fig. 33-6. The resulting oscillations of the capacitor's electric field and the inductor's magnetic field are said to be **electromagnetic oscillations**.

Parts a through h of Fig. 33-5 show succeeding stages of the oscillations in a simple LC circuit. We know that the energy stored in the electric field of the capacitor at any time is given by $U^{\text{elec}} = \frac{1}{2}(q^2/C)$ (Eq. 33-5) where q is the charge on the capacitor at that time. The energy stored in the magnetic field of the inductor at any time is given by $U^{\text{mag}} = \frac{1}{2}L i^2$ (Eq. 33-4) where i is the current through the inductor at that time.

FIGURE 33-6 ■ (a) The charge q on the upper plate of the capacitor in an ideal LC circuit with almost no resistance (Fig. 33-5) as a function of time. (b) The current i in the circuit of Fig. 33-5 (q and i are determined from measurements of ΔV_C and ΔV_R across a very small resistor added to the circuit). The letters refer to the correspondingly labeled oscillation stages in Fig. 33-5.

FIGURE 33-7 ■ An oscilloscope trace showing how the oscillations in an RLC circuit actually die away because energy is dissipated in the resistor as thermal energy.

In an actual LC circuit, the oscillations will not continue indefinitely because there is always some resistance present that will drain energy from the electric and magnetic fields and dissipate it as thermal energy (the circuit becomes warmer). The oscillations, once started, will die away as suggested in Fig. 33-7 (which displays a potential difference vs. time for a similar LC circuit with a resistor added to it). Compare this figure with Fig. 16-27, which shows the decay of mechanical oscillations caused by damping forces acting on a physical pendulum.

READING EXERCISE 33-2: A charged capacitor and an inductor are connected in series at time $t = 0$. In terms of the period T of the resulting sinusoidal oscillations shown in Fig. 33-6, determine how much later the following reach their maximums: (a) the charge on the capacitor; (b) the voltage across the capacitor, with its original polarity; (c) the energy stored in the electric field; and (d) the current. ■

TOUCHSTONE EXAMPLE 33-1: LC Oscillation

A $1.5 \mu\text{F}$ capacitor is charged to 57 V. The charging battery is then disconnected, and a 12 mH coil is connected in series with the capacitor so that LC oscillations occur. What is the maximum current in the coil? Assume that the circuit contains no resistance.

SOLUTION ■ The **Key Ideas** here are these:

1. Because the circuit contains no resistance, the electromagnetic energy of the circuit is conserved as the energy is transferred back and forth between the electric field of the capacitor and the magnetic field of the coil (inductor).
2. At any time t , the energy $U^{\text{mag}}(t)$ of the magnetic field is related to the current $i(t)$ through the coil by Eq. 33-4 ($U^{\text{mag}} = LI^2/2$). When all the energy is stored as magnetic energy, the current is at its maximum value I and that energy is $U_{\text{mag}}^{\text{max}} = LI^2/2$.
3. At any time t , the energy $U^{\text{elec}}(t)$ of the electric field is related to the charge $q(t)$ on the capacitor by Eq. 33-5 ($U^{\text{elec}} = q^2/2C$). When all the energy is stored as electric energy, the charge is at its maximum value Q and that energy is $U_{\text{elec}}^{\text{max}} = Q^2/2C$.

With these ideas, we can now write the conservation of energy as

$$U_{\text{mag}}^{\text{max}} = U_{\text{elec}}^{\text{max}}$$

or

$$\frac{LI^2}{2} = \frac{Q^2}{2C}.$$

Solving for I gives us

$$I = \sqrt{\frac{Q^2}{LC}}.$$

We know L and C , but not Q . However, with Eq. 28-1 ($|q| = C|\Delta V|$) we can relate Q to the maximum potential difference ΔV across the capacitor, which is the initial potential difference of 57 V. Thus, substituting $|Q| = C|\Delta V|$ leads to a maximum current magnitude of

$$\begin{aligned} I &= \Delta V \sqrt{\frac{C}{L}} = (57 \text{ V}) \sqrt{\frac{1.5 \times 10^{-6} \text{ F}}{12 \times 10^{-3} \text{ H}}} \\ &= 0.637 \text{ A} \approx 640 \text{ mA}. \end{aligned} \quad (\text{Answer})$$

33-5 The Electrical–Mechanical Analogy

Let us look a little at an analogy between the ideal oscillating LC system like that shown in Fig. 33-5 and an oscillating block–spring system that experiences no friction forces. Two kinds of energy are involved in the block–spring system. One is potential energy of the compressed or extended spring; the other is kinetic energy of the moving block. These two energies are given by the familiar equations in the left energy column in Table 33-1.

The table also shows, in the right energy column, the two kinds of energy involved in LC oscillations. By looking across the table, we can see an analogy between the forms of the two pairs of energies—the mechanical energies of the block–spring system and the electromagnetic energies of the LC oscillator. The equations for velocity and current at the bottom of the table help us see the details of the analogy. They tell us that

TABLE 33-1
Comparison of the Energy in Two Oscillating Systems

Block–Spring System		LC Oscillator	
Element	Energy	Element	Energy
Spring	Potential, $\frac{1}{2}kx^2$	Capacitor	Electric, $\frac{1}{2}(1/C)q^2$
Block	Kinetic, $\frac{1}{2}mv^2$	Inductor	Magnetic, $\frac{1}{2}Li^2$
	Block velocity, $v = dx/dt$		Circuit current, $i = dq/dt$

the charge q corresponds to the displacement x and the current i corresponds to the block velocity v (in both equations, the former is differentiated to obtain the latter).

These correspondences suggest that in the energy expressions for an LC oscillator, the inverse of the capacitance is mathematically like the spring constant in a block–spring system. It is easy to place charge on the capacitor when $1/C$ is small, just as it's easy to displace a spring when k is small. The inductor is like the block mass. The inductor resists a change of the current in the circuit, and the mass on a spring resists a change in velocity.

In summary,

q corresponds to x , $1/C$ corresponds to k , i corresponds to v , L corresponds to m .

In Section 16-3 we saw that the angular frequency of oscillation of a (frictionless) block–spring system is

$$\omega = \sqrt{\frac{k}{m}} \quad (\text{block–spring system}). \quad (33-9)$$

The correspondences listed above suggest that to find the angular frequency of oscillation for a (resistanceless) LC circuit, k should be replaced by $1/C$ and m by L , yielding

$$\omega = \frac{1}{\sqrt{LC}} \quad (LC \text{ circuit}). \quad (33-10)$$

Experimentally, we find this expression is correct. We derive it more formally in the next section.

READING EXERCISE 33-3: What is the standard unit for angular frequency in Eq. 33-10 above? Show that this expression does in fact yield the correct unit. (*Hint:* The unit of ampere can be written as a coulomb per second. How would one write the units of henry and farad in the fundamental units of kilograms, meters, seconds, and coulombs?) ■

33-6 LC Oscillations, Quantitatively

Here we want to show explicitly that Eq. 33-10 for the angular frequency of LC oscillations is theoretically valid and that the oscillations should be sinusoidal. At the same time, we want to examine even more closely the analogy between LC oscillations and block–spring oscillations. We start by extending somewhat our earlier treatment of the mechanical block–spring oscillator.

The Block–Spring Oscillator – A Review

We analyzed block-spring oscillations in Chapter 16 in terms of energy transfers and did not—at that early stage—derive the fundamental differential equation that governs those oscillations. We do so now.

We can write, for the total energy U of a block–spring oscillator with a massless spring at any instant,

$$U = U^{\text{blk}} + U^{\text{spr}} = \frac{1}{2}mv^2 + \frac{1}{2}kx^2, \quad (33-11)$$

where U^{blk} and U^{spr} are, respectively, the kinetic energy of the moving block and the potential energy of the stretched or compressed spring. If there is no friction—which we assume—the total energy U remains constant with time, even though the values of velocity v and displacement x vary. In more formal language, $dU/dt = 0$. This leads to

$$\frac{dU}{dt} = \frac{d}{dt} \left(\frac{1}{2}mv^2 + \frac{1}{2}kx^2 \right) = mv \frac{dv}{dt} + kx \frac{dx}{dt} = 0. \quad (33-12)$$

However, by definition, $v \equiv dx/dt$ and $dv/dt \equiv d^2x/dt^2$. With these substitutions, Eq. 33-12 becomes

$$m \frac{d^2x}{dt^2} + kx = 0 \quad (\text{block–spring oscillations}). \quad (33-13)$$

Equation 33-13 is the fundamental differential equation that governs the frictionless block–spring oscillations. It involves the displacement x and its second derivative with respect to time.

The general solution to Eq. 33-13—that is, the function $x(t)$ that describes the block–spring oscillations—is (as we saw in Eq. 16-5)

$$x(t) = X \cos(\omega t + \phi) \quad (\text{displacement}), \quad (33-14)$$

where X is the amplitude (or maximum displacement) of the mechanical oscillations undergoing simple harmonic motion, ω is the angular frequency of the oscillations, and ϕ is a phase constant.

The LC Oscillator

Now let us analyze the oscillations of an ideal LC circuit with no resistance. We proceed exactly as we just did for the block–spring oscillator. The total energy U present at any instant in an oscillating LC circuit is given by

$$U = U^{\text{mag}} + U^{\text{elec}} = \frac{1}{2}L i^2 + \frac{1}{2} \left(\frac{1}{C} \right) q^2 \quad (33-15)$$

where U^{mag} is the energy stored in the magnetic field of the inductor and U^{elec} is the energy stored in the electric field of the capacitor. Since we have assumed the circuit resistance to be zero, no energy is transferred to thermal energy and U remains constant with time. In more formal language, dU/dt must be zero. This leads to

$$\frac{dU}{dt} = \frac{d}{dt} \left(\frac{Li^2}{2} + \frac{q^2}{2C} \right) = Li \frac{di}{dt} + \frac{q}{C} \frac{dq}{dt} = 0. \quad (33-16)$$

However, $i = dq/dt$ and $di/dt = d^2q/dt^2$. With these substitutions, Eq. 33-16 becomes

$$L \frac{d^2q}{dt^2} + \frac{1}{C} q = 0 \quad (LC \text{ oscillations}). \quad (33-17)$$

This is the differential equation that describes the oscillations of a resistanceless LC circuit. Careful comparison shows that Eqs. 33-17 and 33-13 have exactly the same mathematical form, differing only in the symbols used.

Charge and Current Oscillations

Since the differential equations are mathematically identical, their solutions must also be mathematically identical. Because q corresponds to x , we can write the general solution of Eq. 33-17, giving $q(t)$ as a function of time, by analogy to Eq. 33-14 as

$$q(t) = Q \cos(\omega t + \phi) \quad (\text{charge}), \quad (33-18)$$

where Q is the amplitude or maximum amount of charge on the capacitor during the charge variations, while ω represents the angular frequency of the electromagnetic oscillations, and ϕ is the phase constant.

Taking the first derivative of Eq. 33-18 with respect to time gives us the time-varying current $i(t)$ of the LC oscillator:

$$i(t) = \frac{dq}{dt} = -\omega Q \sin(\omega t + \phi) \quad (\text{current}). \quad (33-19)$$

The amplitude I of this sinusoidally varying current is

$$I = \omega Q, \quad (33-20)$$

so we can rewrite Eq. 33-19 as

$$i(t) = -I \sin(\omega t + \phi). \quad (33-21)$$

Angular Frequencies

We can test whether Eq. 33-18 is a solution of Eq. 33-17 by substituting it and its second derivative with respect to time into Eq. 33-17. The first derivative of Eq. 33-18 is Eq. 33-19. The second derivative is then

$$\frac{d^2q}{dt^2} = -\omega^2 Q \cos(\omega t + \phi).$$

Substituting for q and d^2q/dt^2 in Eq. 33-17, we obtain

$$-L\omega^2 Q \cos(\omega t + \phi) + \left(\frac{1}{C}\right) Q \cos(\omega t + \phi) = 0.$$

Canceling $Q \cos(\omega t + \phi)$ and rearranging lead to

$$\omega = \frac{1}{\sqrt{LC}}.$$

Thus, Eq. 33-18 is indeed a solution of Eq. 33-17 if ω has the constant value $1/\sqrt{LC}$. Note that this expression for ω is exactly that given by Eq. 33-10, which we arrived at by examining correspondences.

The phase constant ϕ in Eq. 33-18 is determined by the conditions that prevail at any certain time—say, $t = 0$. If the conditions yield $\phi = 0$ at $t = 0$, Eq. 33-18 requires

that $q = Q$ and Eq. 33-19 requires that $i = 0$; these are the initial conditions represented in Fig. 33-5.

Electric and Magnetic Energy Oscillations

The electric energy stored in the LC circuit at any time t is, from Eqs. 33-5 and 33-18,

$$U^{\text{elec}} = \frac{q^2}{2C} = \frac{Q^2}{2C} \cos^2(\omega t + \phi). \quad (33-22)$$

The magnetic energy is, from Eqs. 33-4 and 33-19,

$$U^{\text{mag}} = \frac{1}{2} Li^2 = \frac{1}{2} L \omega^2 Q^2 \sin^2(\omega t + \phi).$$

Substituting for ω from Eq. 33-10 then gives us

$$U^{\text{mag}} = \frac{Q^2}{2C} \sin^2(\omega t + \phi). \quad (33-23)$$

FIGURE 33-8 ■ The stored magnetic energy and electric energy in the circuit of Fig. 33-5 as a function of time. Note that their sum remains constant. T is the period of oscillation.

Figure 33-8 shows plots of $U^{\text{elec}}(t)$ and $U^{\text{mag}}(t)$ for the case of $\phi = 0$. Note that

1. The maximum values of U^{elec} and U^{mag} are both $Q^2/2C$.
2. At any instant the sum of U^{elec} and U^{mag} is equal to $Q^2/2C$, a constant.
3. When U^{elec} is maximum, U^{mag} is zero, and conversely.

READING EXERCISE 33-4: A capacitor in an LC oscillator has a maximum potential difference of 20 V and a maximum energy of 160 μJ . When the capacitor has a potential difference of 5 V and an energy of 10 μJ , what are (a) the emf across the inductor and (b) the energy stored in the magnetic field? ■

TOUCHSTONE EXAMPLE 33-2: LC Oscillation Continued

For the situation described in Touchstone Example 33-1, let the coil (inductor) be connected to the charged capacitor at time $t = 0$. The result is an LC circuit like that in Fig. 33-4.

(a) What is the potential difference $\Delta v_L(t)$ across the inductor as a function of time?

SOLUTION ■ One **Key Idea** here is that the current and potential differences of the circuit undergo sinusoidal oscillations. Another **Key Idea** is that we can still apply the loop rule to this oscillating circuit—just as we did for the nonoscillating circuits of Chapter 27. At any time t during the oscillations, the loop rule and Fig. 33-4 give us

$$\Delta v_L(t) = \Delta v_C(t); \quad (33-24)$$

that is, the potential difference Δv_L across the inductor must always be equal to the potential difference Δv_C across the capacitor, so that the net potential difference around the circuit is zero. Thus, we will

find $\Delta v_L(t)$ if we can find $\Delta v_C(t)$, and we can find $\Delta v_C(t)$ from $q(t)$ with Eq. 28-1 $|q| = C|\Delta V|$.

Because the potential difference $\Delta v_C(t)$ is maximum when the oscillations begin at time $t = 0$, the charge q on the capacitor must also be maximum then. Thus, phase constant ϕ must be zero, so that Eq. 33-18 gives us

$$q = Q \cos \omega t. \quad (33-25)$$

(Note that this cosine function does indeed yield maximum $q (= Q)$ when $t = 0$.) To get the potential difference $\Delta v_C(t)$, we divide both sides of Eq. 33-25 by C to write

$$\frac{q}{C} = \frac{Q}{C} \cos \omega t,$$

and then use Eq. 28-1 to write

$$\Delta v_C = \Delta V_C \cos \omega t. \quad (33-26)$$

Here, ΔV_C is the amplitude of the oscillations in the potential difference Δv_C across the capacitor.

Next, substituting $\Delta v_C = \Delta v_L$ from Eq. 33-24, we find

$$\Delta v_L = \Delta V_C \cos \omega t. \quad (33-27)$$

We can evaluate the right side of this equation by first noting that the amplitude ΔV_C is equal to the initial (maximum) potential difference of 57 V across the capacitor. Then, using the values of L and C from Touchstone Example 33-1, we find ω with Eq. 33-10:

$$\begin{aligned} \omega &= \frac{1}{\sqrt{LC}} = \frac{1}{[(0.012 \text{ H})(1.5 \times 10^{-6} \text{ F})]^{0.5}} \\ &= 7454 \text{ rad/s} \approx 7500 \text{ rad/s}. \end{aligned}$$

Thus, Eq. 33-27 becomes

$$\Delta v_L = (57 \text{ V}) \cos(7500 \text{ rad/s})t. \quad (\text{Answer})$$

(b) What is the maximum rate $(di/dt)^{\max}$ at which the current i changes in the circuit?

SOLUTION ■ The **Key Idea** here is that, with the charge on the capacitor oscillating as in Eq. 33-18, the current is in the form of Eq. 33-19. Because $\phi = 0$, that equation gives us

$$i = -\omega Q \sin \omega t.$$

Then
$$\frac{di}{dt} = \frac{d}{dt}(-\omega Q \sin \omega t) = -\omega^2 Q \cos \omega t.$$

We can simplify this equation by substituting $C\Delta V_C$ for Q (because we know C and ΔV_C but not Q) and $1/\sqrt{LC}$ for ω according to Eq. 33-10. We get

$$\frac{di}{dt} = -\frac{1}{LC} C\Delta V_C \cos \omega t = -\frac{\Delta V_C}{L} \cos \omega t.$$

This tells us that the current changes at a varying (sinusoidal) rate, with its maximum rate of change being

$$\frac{\Delta V_C}{L} = \frac{57 \text{ V}}{0.012 \text{ H}} = 4750 \text{ A/s} \approx 4800 \text{ A/s}. \quad (\text{Answer})$$

33-7 Damped Oscillations in an RLC Circuit

A circuit containing resistance, inductance, and capacitance is called an *RLC circuit*. We shall here discuss only *series RLC circuits* like that shown in Fig. 33-9. With a resistance R present, the total *electromagnetic energy* U of the circuit (the sum of the electric energy and magnetic energy) is no longer constant; instead, it decreases with time as energy is transferred to thermal energy in the resistance. Because of this loss of energy, the oscillations of charge, current, and potential difference continuously decrease in amplitude, and the oscillations are referred to as *damped*. As you will see, they are damped in exactly the same way as those of the damped block–spring oscillator of Section 16-8.

To analyze the oscillations of our *RLC circuit*, we write an equation for the total electromagnetic energy U in the circuit at any instant. Because the resistance does not store electromagnetic energy, we can use Eq. 33-15:

$$U = U_{\text{mag}} + U_{\text{elec}} = \frac{Li^2}{2} + \frac{q^2}{2C}. \quad (33-28)$$

Now, however, this total energy decreases as energy is transferred to thermal energy. The rate of that transfer is, from Eq. 26-11,

$$\frac{dU}{dt} = -i^2 R, \quad (33-29)$$

where the minus sign indicates that U decreases. By differentiating Eq. 33-28 with respect to time and then substituting the result in Eq. 33-29, we obtain

$$\frac{dU}{dt} = Li \frac{di}{dt} + \frac{q}{C} \frac{dq}{dt} = -i^2 R.$$

Substituting dq/dt for i and d^2q/dt^2 for di/dt , we obtain

$$L \frac{d^2q}{dt^2} + R \frac{dq}{dt} + \frac{1}{C} q = 0 \quad (\text{RLC circuit}), \quad (33-30)$$

FIGURE 33-9 ■ A series *RLC circuit*. As the charge contained in the circuit oscillates back and forth through the resistance, electromagnetic energy is dissipated as thermal energy, damping (decreasing the amplitude of) the oscillations.

which is the differential equation that describes damped oscillations in an RLC circuit. The solution to Eq. 33-30 is

$$q = Qe^{-Rt/2L} \cos(\omega't + \phi), \quad (33-31)$$

where

$$\omega' = \sqrt{\omega^2 - (R/2L)^2}, \quad (33-32)$$

with $\omega = 1/\sqrt{LC}$, as with an undamped oscillator. Equation 33-31 tells us how the charge on the capacitor oscillates in a damped RLC circuit. That equation is the electromagnetic counterpart of Eq. 16-37, which gives the displacement of a damped block–spring oscillator.

Equation 33-31 describes a sinusoidal oscillation (the cosine function) with an *exponentially decaying amplitude* $Qe^{-Rt/2L}$ (the factor that multiplies the cosine) as shown in Fig. 33-7. The angular frequency ω' of the damped oscillations is always less than the angular frequency ω of the undamped oscillations; however, we shall here consider only situations for which R is small enough for us to replace ω' with ω .

Let us next find an expression for the energy of the electric field in the capacitor, which is given by Eq. 33-5 ($U^{\text{elec}} = q^2/2C$). By substituting Eq. 33-31 into Eq. 33-5, we obtain

$$U^{\text{elec}} = \frac{q^2}{2C} = \frac{[Qe^{-Rt/2L} \cos(\omega't + \phi)]^2}{2C} = \frac{Q^2}{2C} e^{-Rt/L} \cos^2(\omega't + \phi). \quad (33-33)$$

Thus, the energy of the electric field oscillates according to a cosine-squared term and the amplitude of that oscillation decreases exponentially with time.

If we do a similar derivation for the energy of the magnetic field in the inductor we find that it too oscillates in such a way that its amplitude decreases exponentially in time. Since energy is being traded back and forth between the inductor and the capacitor, the total electromagnetic energy (which is the sum of the electric and magnetic energies) does not oscillate. Instead it just decays exponentially as the total energy is transformed to thermal energy by the total resistance in the circuit.

TOUCHSTONE EXAMPLE 33-3: Decaying Oscillation

A series RLC circuit has inductance $L = 12$ mH, capacitance $C = 1.6$ μF , and resistance $R = 1.5$ Ω .

(a) At what time t will the amplitude of the charge oscillations in the circuit be 50% of its initial value?

SOLUTION ■ The **Key Idea** here is that the amplitude of the charge oscillations decreases exponentially with time t : According to Eq. 33-31, the charge amplitude at any time t is $Qe^{-Rt/2L}$, in which Q is the amplitude at time $t = 0$. We want the time when the charge amplitude has decreased to $0.50Q$ —that is, when

$$Qe^{-Rt/2L} = 0.50Q.$$

Canceling Q and taking the natural logarithms of both sides, we have

$$-\frac{Rt}{2L} = \ln 0.50.$$

Solving for t and then substituting given data yield

$$\begin{aligned} t &= -\frac{2L}{R} \ln 0.50 = -\frac{(2)(12 \times 10^{-3} \text{ H})(\ln 0.50)}{1.5 \Omega} \\ &= 0.0111 \text{ s} \approx 11 \text{ ms}. \end{aligned} \quad (\text{Answer})$$

(b) How many oscillations are completed within this time?

SOLUTION ■ The **Key Idea** here is that the time for one complete oscillation is the period $T' = 2\pi/\omega'$, where the angular frequency for decaying LC oscillations is given by Eq. 33-32 ($\omega' = \sqrt{\omega^2 - (R/2L)^2}$) where

$$\begin{aligned} \omega^2 &= 1/(LC) = 1/[(0.012 \text{ H})(1.6 \times 10^{-6} \text{ F})] \\ &= 52.1 \times 10^6 \text{ (rad/s)}^2, \end{aligned}$$

while

$$\begin{aligned}(R/2L)^2 &= [(1.5 \Omega)/(2)(0.012 \text{ H})]^2 \\ &= 3.91 \times 10^3 (\text{rad/s})^2.\end{aligned}$$

Since $(R/2L)^2 \ll \omega^2$, we can neglect $(R/2L)^2$ compared with ω^2 , so here $\omega' \cong \omega = \sqrt{52.1 \times 10^6 (\text{rad/s}^2)} = 7.22 \times 10^3 \text{ rad/s}$.

The time for one period of the decaying oscillation is then

$$\begin{aligned}T' &= \frac{2\pi}{\omega'} \cong \frac{2\pi}{\omega} = 2\pi/(7.22 \times 10^3 \text{ rad/s}) \\ &= 0.871 \times 10^{-3} \text{ s}.\end{aligned}$$

Thus, in the time interval $\Delta t = 0.0111 \text{ s}$, the number of complete oscillations is

$$\frac{\Delta t}{T'} = \frac{0.0111 \text{ s}}{0.871 \times 10^{-3} \text{ s}} \cong 13. \quad (\text{Answer})$$

Thus, the amplitude decays by 50% in about 13 complete oscillations. This damping is less severe than that shown in Fig. 33-7, where the amplitude decays by a little more than 50% in one oscillation.

33-8 More About Alternating Current

The oscillations in an RLC circuit will not damp out if an external emf device supplies enough energy to make up for the energy dissipated as thermal energy in the resistance R . As we discussed at the beginning of the chapter, the United States and most other countries deliver alternating current or ac electricity. These oscillating emfs and currents vary sinusoidally with time, reversing direction (in North America) 120 times per second and thus having frequency $f = 60 \text{ Hz}$.

At first sight this may seem to be a strange arrangement. We have seen that the drift speed of the conduction electrons in household wiring may typically be $4 \times 10^{-5} \text{ m/s}$. If we now reverse their direction every 1/120th of a second, such electrons can move only about $3 \times 10^{-7} \text{ m}$ in a half-cycle. At this rate, a typical electron can drift past no more than about 10 atoms in the wiring before it is required to reverse its direction. How, you may wonder, can the electron ever get anywhere?

Although this question may be worrisome, it is a needless concern. The conduction electrons do not have to “get anywhere.” This is similar to the idea that the molecules in a spring do not have to move far longitudinally to transmit energy a long distance. Here, the electrons don’t have to move far to have a long-range effect. When we say that the current in a wire is one ampere, we mean that charge passes through any plane cutting across that wire at the rate of one coulomb per second. The speed at which the charge carriers cross that plane does not matter directly; one ampere may correspond to many charge carriers moving very slowly or to a few moving very rapidly.

Furthermore, the signal to the electrons to reverse directions—which originates in the alternating emf provided by the power company’s generator—is propagated along the conductor at a speed close to that of light. All electrons, no matter where they are located, get their reversal instructions at about the same instant. Finally, we note that for many devices, such as lightbulbs and toasters, the direction of motion is unimportant as long as the electrons do move so as to transfer energy to the device via collisions with atoms in the device.

Generator Equations

Figure 33-10 shows a simplified model of an ac generator like that shown in Fig. 32-12. As the conducting loop is forced to rotate through the external magnetic field \vec{B} , a sinusoidally oscillating emf \mathcal{E} is induced in the loop:

$$\mathcal{E} = \mathcal{E}^{\max} \sin \omega^{\text{dr}} t. \quad (33-34)$$

The *angular frequency* ω^{dr} of the emf is equal to the angular speed with which the loop rotates in the magnetic field, the *phase* of the emf is $\omega^{\text{dr}} t$, and the *amplitude* of

FIGURE 33-10 The basic mechanism of an alternating-current generator is a conducting loop rotated in an external magnetic field. In practice, the alternating emf induced in a coil of many turns of wire is made accessible by means of slip rings attached to the rotating loop. Each ring is connected to one end of the loop wire and is electrically connected to the rest of the generator circuit by a conducting brush against which it slips as the loop (and it) rotates.

the emf is \mathcal{E}^{\max} (where the superscript stands for maximum). When the rotating loop is part of a closed conducting path, this emf produces (*drives*) a sinusoidal (alternating) current along the path with the same angular frequency ω^{dr} , which then is called the **driving angular frequency**. Following Eq. 33-21, we can write the current as

$$i = -I \sin(\omega^{\text{dr}} t + \phi) = I \sin(\omega^{\text{dr}} t - \phi'), \quad (33-35)$$

where I is the amplitude or maximum value of the driven current. (The phase $\omega^{\text{dr}} t - \phi'$ of the current is traditionally written with a minus sign instead of as $\omega^{\text{dr}} t + \phi$.) We include the phase constant ϕ' in Eq. 33-35 to emphasize that the current i may not be in phase with the emf \mathcal{E} . (As you will see, the phase constant depends on the circuit to which the generator is connected.) We can also write the current i in terms of the **driving frequency** f^{dr} of the emf, by substituting $2\pi f^{\text{dr}}$ for ω^{dr} in Eq. 33-35.

33-9 Forced Oscillations

We have seen that once started, the charge, potential difference, and current in both undamped LC circuits and damped RLC circuits (with small enough R) oscillate at angular frequency $\omega = 1/\sqrt{LC}$. Such oscillations are said to be *free oscillations* (free of any external emf), and the angular frequency ω is said to be the circuit's **natural angular frequency**.

When the external alternating emf of Eq. 33-34 is connected to an RLC circuit, the oscillations of charge, potential difference, and current are said to be *driven oscillations* or *forced oscillations*. These oscillations always occur at the driving angular frequency ω^{dr} :

No matter what the natural angular frequency ω of a circuit is, forced oscillations of charge, current, and potential difference in the circuit always occur at the driving angular frequency ω^{dr} .

However, as you will see in Section 33-11, the amplitudes of the oscillations very much depend on how close ω^{dr} is to ω . When the two angular frequencies match—a condition known as resonance—the amplitude I of the current in the circuit is maximum.

33-10 Representing Oscillations with Phasors: Three Simple Circuits

FIGURE 33-11 ■ A single-loop circuit containing a resistor, a capacitor, and an inductor. A generator, represented by a sine wave in a circle, produces an alternating emf that establishes an alternating current; the directions of the emf and current are indicated here at only one instant.

Later in this chapter, we shall connect an external alternating emf device to a series RLC circuit as in Fig. 33-11. We shall then find expressions for the amplitude I and phase constant ϕ of the sinusoidally oscillating current in terms of the amplitude \mathcal{E}^{\max} and angular frequency ω^{dr} of the external emf. First, however, let us consider three simpler circuits, each having an external emf and only one other circuit element: R , C , or L . We start with a resistive element (a purely *resistive load*). We continue to use the convention here that uppercase letters such as Q , I , and V represent constants, while lowercase letters represent time-varying quantities such as q , i , and v .

A Resistive Load

Figure 33-12a shows a circuit containing a resistance element of value R and an ac generator with the alternating emf of Eq. 33-34. By the loop rule, we have

$$\mathcal{E} - \Delta v_R = 0.$$

Note that in this context, Δv_R represents a potential difference across the resistance element and not a velocity change. With Eq. 33-34, this gives us

$$\Delta v_R = \mathcal{E}^{\max} \sin \omega^{\text{dr}} t.$$

Because the amplitude ΔV_R of the alternating potential difference (or voltage) across the resistance is equal to the amplitude \mathcal{E}^{\max} of the alternating emf, we can write this as

$$\mathcal{E} = \Delta v_R = \Delta V_R \sin \omega^{\text{dr}} t. \quad (33-36)$$

From the definition of resistance ($R = \Delta v_R/i$), we can now write the current i_R in the resistor as

$$i_R = \frac{\Delta v_R}{R} = \frac{\Delta V_R}{R} \sin \omega^{\text{dr}} t. \quad (33-37)$$

From Eq. 33-35, we can also write this current as

$$i_R = I_R \sin(\omega^{\text{dr}} t - \phi), \quad (33-38)$$

where I_R is the amplitude of the current i_R passing through the resistance. Comparing Eqs. 33-37 and 33-38, we see that for a purely resistive load the phase constant $\phi = 0^\circ$. We also see that the voltage amplitude and current amplitude are related by

$$\Delta V_R = I_R R \quad (\text{resistor}). \quad (33-39)$$

Although we found this relation for the circuit of Fig. 33-12a, it applies to any resistance in any ac circuit.

By comparing Eqs. 33-36 and 33-37, we see that the time-varying quantities Δv_R and i_R are both functions of $\sin \omega^{\text{dr}} t$ with $\phi = 0^\circ$. Thus, these two quantities are *in phase*, which means that their corresponding maxima (and minima) occur at the same times. Figure 33-12b, which is a plot of $\Delta v_R(t)$ and $i_R(t)$, illustrates this fact. Note that Δv_R and i_R do not decay here, because the generator supplies energy to the circuit to make up for the energy dissipated in R .

Since we have chosen to drive our circuits with a voltage that varies as $\sin(\omega t)$, and constant speed motion around a circle has x - and y -components that vary sinusoidally, it is convenient to use a component of a rotating vector to represent our oscillations. Such a rotating vector representation is called a *phasor*. Recall from Section 17-12 that phasors are vectors that rotate around an origin. Those that represent the voltage across and current in the resistor of Fig. 33-12a are shown in Fig. 33-12c at an arbitrary time t . Such phasors have the following properties:

Angular speed: Both phasors rotate counterclockwise about the origin with an angular speed equal to the angular frequency ω^{dr} of both Δv_R and i_R .

Length: The length of each phasor represents the amplitude of the alternating quantity: ΔV_R for the voltage and I_R for the current.

Projection: The projection of each phasor on the *vertical* axis represents the value of the alternating quantity at time t : Δv_R for the voltage and i_R for the current.

Rotation angle: The rotation angle of each phasor is equal to the phase of the alternating quantity at time t . In Fig. 33-12c, the voltage and current are in phase, so their phasors always have the same phase $\omega^{\text{dr}} t$ and the same rotation angle, and thus they rotate together.

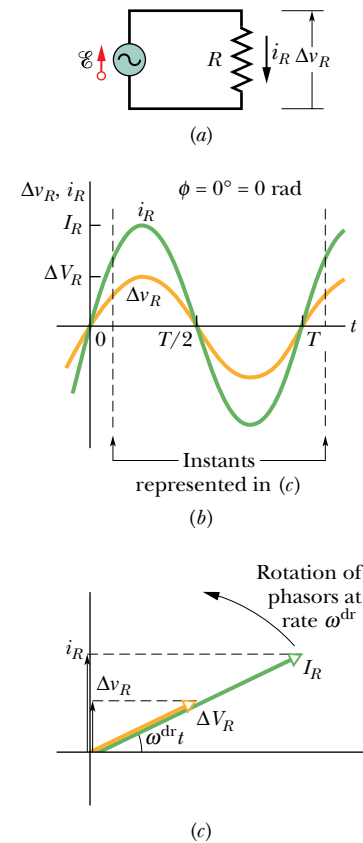

FIGURE 33-12 (a) A resistor is connected across an alternating-current generator. (b) The current i_R and the potential difference Δv_R across the resistor are plotted on the same graph, both versus time t . They are in phase and complete one cycle in one period T . (c) A phasor diagram shows the same thing as (b).

Mentally follow the rotation. Can you see that when the phasors have rotated so that $\omega^{\text{dr}}t = 90^\circ$ (so they point vertically upward), then $\Delta v_R = \Delta V_R$? Equations 33-36 and 33-38 give the same results. For this case, the voltage and the current oscillate together. Hence, it is not especially useful to introduce the phasor representation. However, the value of this representation becomes clearer with more complex situations such as the capacitor and inductor discussed below.

A Capacitive Load

Figure 33-13a shows a circuit containing a capacitance and a generator with the alternating emf of Eq. 33-34. Using the loop rule and proceeding as we did when we obtained Eq. 33-36, we find that the potential difference across the capacitor is

$$\Delta v_C = \Delta V_C \sin \omega^{\text{dr}}t, \quad (33-40)$$

where ΔV_C is the amplitude of the alternating voltage across the capacitor. From the definition of capacitance we can also write

$$q_C = C\Delta v_C = C\Delta V_C \sin \omega^{\text{dr}}t. \quad (33-41)$$

Our concern, however, is with the current rather than the charge. Thus, we differentiate Eq. 33-41 to find

$$i_C = \frac{dq_C}{dt} = \omega^{\text{dr}}C\Delta V_C \cos \omega^{\text{dr}}t. \quad (33-42)$$

We now modify Eq. 33-42 in two ways. First, for reasons of symmetry of notation, we introduce the quantity X_C , called the *capacitive reactance* of a capacitor, defined as

$$X_C = \frac{1}{\omega^{\text{dr}}C} \quad (\text{capacitive reactance}). \quad (33-43)$$

Its value depends not only on the capacitance but also on the driving angular frequency ω^{dr} . We know from the definition of the capacitive time constant ($\tau = RC$) that the SI unit for C can be expressed as seconds per ohm. Applying this to Eq. 33-43 shows that the SI unit of X_C is the *ohm*, just as for resistance R .

Second, we replace $\cos \omega^{\text{dr}}t$ with a phase-shifted sine:

$$\cos \omega^{\text{dr}}t = \sin(\omega^{\text{dr}}t - (-90^\circ)).$$

You can verify this identity by shifting a sine curve in the negative direction by 90° .

With these two modifications, Eq. 33-42 becomes

$$i_C = \left(\frac{\Delta V_C}{X_C} \right) \sin(\omega^{\text{dr}}t + 90^\circ). \quad (33-44)$$

From Eq. 33-35, we can also write the current i_C in C as

$$i_C = I_C \sin(\omega^{\text{dr}}t - \phi), \quad (33-45)$$

where I_C is the amplitude of i_C . Comparing Eqs. 33-44 and 33-45, we see that for a purely capacitive load the phase constant ϕ for the current is -90° . We also see that the voltage amplitude and current amplitude are related by

$$\Delta V_C = I_C X_C \quad (\text{capacitor}). \quad (33-46)$$

FIGURE 33-13 (a) A capacitor is connected across an alternating-current generator. (b) The current in the capacitor leads the voltage by $90^\circ (= \pi/2 \text{ rad})$. (c) A phasor diagram shows the same thing.

Although we found this relation for the circuit of Fig. 33-13a, it applies to any capacitance in any ac circuit. Note that using phasors allowed us to write the equation associated with a capacitor in such a way that it looks just like Ohm's law for a resistor. Although this expression is true for the amplitude of the phasor, the full voltage and current don't look like Ohm's law because of the shift in phase. We'll see in the next case that a similar thing happens for the inductor.

Comparison of Eqs. 33-40 and 33-44, or inspection of Fig. 33-13b, shows that the quantities Δv_C and i_C are 90° , or one-quarter cycle, out of phase. Furthermore, we see that i_C leads Δv_C , which means that, if you monitored the current i_C and the potential difference Δv_C in the circuit of Fig. 33-13a, you would find that i_C reaches its maximum before Δv_C does, by one-quarter cycle.

This relation between i_C and Δv_C is illustrated by the phasor diagram of Fig. 33-13c. As the phasors representing these two quantities rotate counterclockwise together, the phasor labeled I_C does indeed lead that labeled ΔV_C , and by an angle of 90° ; that is, the phasor I_C coincides with the vertical axis one-quarter cycle before the phasor ΔV_C does. Be sure to convince yourself that the phasor diagram of Fig. 33-13c is consistent with Eqs. 33-40 and 33-44.

An Inductive Load

Now let's consider a third situation in which we connect an external alternating emf to a circuit containing just one of our basic circuit elements. Figure 33-14a shows a circuit containing an inductance and a generator with the alternating emf of Eq. 33-34. Using the loop rule and proceeding as we did to obtain Eq. 33-36, we find that the potential difference across the inductance is

$$\Delta v_L = \Delta V_L \sin \omega^{\text{dr}} t, \quad (33-47)$$

where ΔV_L is the amplitude of Δv_L . From Eq. 32-2, we can write the potential difference across an inductance L , in which the current is changing at the rate di_L/dt , as

$$\Delta v_L = L \frac{di_L}{dt}. \quad (33-48)$$

If we combine Eqs. 33-47 and 33-48 we have

$$\frac{di_L}{dt} = \frac{\Delta V_L}{L} \sin \omega^{\text{dr}} t. \quad (33-49)$$

Our concern, however, is with the current rather than with its time derivative. We find the former by integrating Eq. 33-49, obtaining

$$i_L = \int di_L = \frac{\Delta V_L}{L} \int \sin \omega^{\text{dr}} t dt = -\left(\frac{\Delta V_L}{\omega^{\text{dr}} L}\right) \cos \omega^{\text{dr}} t. \quad (33-50)$$

We now modify this equation in two ways. First, for reasons of symmetry of notation, we introduce the quantity X_L , called the **inductive reactance** of an inductor, which is defined as

$$X_L = \omega^{\text{dr}} L \quad (\text{inductive reactance}). \quad (33-51)$$

The value of X_L depends on the driving angular frequency ω^{dr} . The unit of the inductive time constant τ_L indicates that the SI unit of X_L is the *ohm*, just as it is for X_C and for R .

FIGURE 33-14 (a) An inductor is connected across an alternating-current generator. (b) The current in the inductor lags the voltage by $90^\circ (= \pi/2 \text{ rad})$. (c) A phasor diagram shows the same thing.

Second, we replace the function $-\cos \omega^{\text{dr}}t$ in Eq. 33-50 with a phase-shifted sine—namely,

$$-\cos \omega^{\text{dr}}t = \sin(\omega^{\text{dr}}t - (+90^\circ)).$$

You can verify this identity by shifting a sine curve in the positive direction by 90° .

With these two changes, Eq. 33-50 becomes

$$i_L = \left(\frac{\Delta V_L}{X_L} \right) \sin(\omega^{\text{dr}}t - 90^\circ). \quad (33-52)$$

From Eq. 33-35, we can also write this current in the inductance as

$$i_L = I_L \sin(\omega^{\text{dr}}t - \phi), \quad (33-53)$$

where I_L is the amplitude of the current i_L . Comparing Eqs. 33-52 and 33-53, we see that for a purely inductive load the phase constant ϕ for the current is $+90^\circ$. We also see that the voltage amplitude and current amplitude are related by

$$\Delta V_L = I_L X_L \quad (\text{inductor}). \quad (33-54)$$

Although we found this relation for the circuit of Fig. 33-14a, it applies to any inductance in any ac circuit.

Comparison of Eqs. 33-47 and 33-52, or inspection of Fig. 33-14b, shows that the quantities i_L and Δv_L are 90° out of phase. In this case, however, i_L lags Δv_L ; that is, if you monitored the current i_L and the potential difference Δv_L in the circuit of Fig. 33-14a, you would find that i_L reaches its maximum value after Δv_L does, by one-quarter cycle.

The phasor diagram of Fig. 33-14c also contains this information. As the phasors rotate counterclockwise in the figure, the phasor labeled I_L does indeed lag that labeled ΔV_L , and by an angle of 90° . Be sure to convince yourself that Fig. 33-14c represents Eqs. 33-47 and 33-52.

READING EXERCISE 33-5: The figure shows, in (a), a sine curve $S(t) = \sin(\omega^{\text{dr}}t)$ and three other sinusoidal curves $A(t)$, $B(t)$, and $C(t)$, each of the form $\sin(\omega^{\text{dr}}t - \phi)$. (a) Rank the three other curves according to the value of ϕ , most positive first and most negative last. (b) Which curve corresponds to which phasor in (b) of the figure? (c) Which curve leads the others?

33-11 The Series RLC Circuit

We are now ready to apply the alternating emf of Eq. 33-34,

$$\mathcal{E} = \mathcal{E}^{\text{max}} \sin \omega^{\text{dr}}t \quad (\text{applied emf}), \quad (33-55)$$

TABLE 33-2

Phase and Amplitude Relations for Alternating Currents and Voltages

Circuit Element	Symbol	Resistance or Reactance	Phase of the Current	Phase Constant (or Angle ϕ)	Amplitude Relation
Resistor	R	R	In phase with v_R	$0^\circ (= 0 \text{ rad})$	$\Delta V_R = I_R R$
Capacitor	C	$X_C = 1/\omega^{\text{dr}} C$	Leads Δv_C by $90^\circ (= \pi/2 \text{ rad})$	$-90^\circ (= -\pi/2 \text{ rad})$	$\Delta V_C = I_C X_C$
Inductor	L	$X_L = \omega^{\text{dr}} L$	Lags Δv_L by $90^\circ (= \pi/2 \text{ rad})$	$+90^\circ (= +\pi/2 \text{ rad})$	$\Delta V_L = I_L X_L$

to the full RLC circuit of Fig. 33-11. Because R , L , and C are in series, the same current

$$i = I \sin(\omega^{\text{dr}} t - \phi) \quad (33-56)$$

is driven in all three of them. We wish to find the current amplitude I and the phase constant ϕ . The solution is simplified by the use of phasor diagrams.

Table 33-2 summarizes the relations between the current i and the voltage V for each of the three kinds of circuit elements we have considered. When an applied alternating voltage produces an alternating current in them, the current is in phase with the voltage across a resistor, leads the voltage across a capacitor, and lags the voltage across an inductor.

The Current Amplitude

We start with Fig. 33-15*a*, which shows the phasor representing the current of Eq. 33-56 at an arbitrary time t . The length of the phasor is the current amplitude I , the projection of the phasor on the vertical axis is the current i at time t , and the angle of rotation of the phasor is the phase $\omega^{\text{dr}} t - \phi$ of the current at time t .

Figure 33-15*b* shows the phasors representing the voltages across R , L , and C at the same time t . Each phasor is oriented relative to the angle of rotation of current phasor I in Fig. 33-15*a*, based on the information in Table 33-2:

Resistor: Here current and voltage are in phase, so the angle of rotation of voltage phasor ΔV_R is the same as that of phasor I .

Capacitor: Here current leads voltage by 90° , so the angle of rotation of voltage phasor ΔV_C is 90° less than that of phasor I .

Inductor: Here current lags voltage by 90° , so the angle of rotation of voltage phasor ΔV_L is 90° greater than that of phasor I .

FIGURE 33-15 (a) A phasor representing the alternating current in the driven RLC circuit of Fig. 33-11 at time t . The amplitude I , the instantaneous value i , and the phase $\omega^{\text{dr}} t - \phi$ are shown. (b) Phasors representing the voltages across the inductor, resistor, and capacitor, oriented with respect to the current phasor in (a). (c) A phasor representing the alternating emf that drives the current of (a). (d) The emf phasor is equal to the vector sum of the three voltage phasors of (b). Here, voltage phasors ΔV_L and ΔV_C have been added to yield their net phasor ($\Delta V_L - \Delta V_C$).

Figure 33-15*b* also shows the instantaneous voltages Δv_R , Δv_C , and Δv_L across R , C , and L at time t ; those voltages are the projections of the corresponding phasors on the vertical axis of the figure.

Figure 33-15*c* shows the phasor representing the applied emf of Eq. 33-55. The length of the phasor is the emf amplitude \mathcal{E}^{\max} ; the projection of the phasor on the vertical axis is the emf \mathcal{E} at time t , and the angle of rotation of the phasor is the phase $\omega_d t$ of the emf at time t .

From the loop rule we know that at any instant the sum of the voltages Δv_R , Δv_C , and Δv_L is equal to the applied emf \mathcal{E} :

$$\mathcal{E} = \Delta v_R + \Delta v_C + \Delta v_L. \quad (33-57)$$

Thus, at time t the projection \mathcal{E} in Fig. 33-15*c* is equal to the algebraic sum of the projections Δv_R , Δv_C , and Δv_L in Fig. 33-15*b*. In fact, as the phasors rotate together, this equality always holds. This means that phasor \mathcal{E}^{\max} in Fig. 33-15*c* must be equal to the vector sum of the three voltage phasors ΔV_R , ΔV_C , and ΔV_L in Fig. 33-15*b*.

That requirement is indicated in Fig. 33-15*d*, where phasor \mathcal{E}^{\max} is drawn as the sum of phasors ΔV_R , ΔV_L , and ΔV_C . Because phasors ΔV_L and ΔV_C have opposite directions in the figure, we simplify the vector sum by first combining ΔV_L and ΔV_C to form the single phasor $\Delta V_L - \Delta V_C$. Then we combine that single phasor with ΔV_R to find the net phasor. Again, the net phasor must coincide with phasor \mathcal{E}^{\max} , as shown.

Both triangles in Fig. 33-15*d* are right triangles. Applying the Pythagorean theorem to either one yields

$$(\mathcal{E}^{\max})^2 = \Delta V_R^2 + (\Delta V_L - \Delta V_C)^2. \quad (33-58)$$

From the amplitude information displayed in Table 33-2 we can rewrite this as

$$(\mathcal{E}^{\max})^2 = (IR)^2 + (IX_L - IX_C)^2, \quad (33-59)$$

and then rearrange it to the form

$$I = \frac{\mathcal{E}^{\max}}{\sqrt{R^2 + (X_L - X_C)^2}}. \quad (33-60)$$

The denominator in Eq. 33-60 is called the **impedance** Z of the circuit for the driving angular frequency ω^{dr} :

$$Z = \sqrt{R^2 + (X_L - X_C)^2} \quad (\text{impedance defined}). \quad (33-61)$$

We can then write Eq. 33-60 as

$$I = \frac{\mathcal{E}^{\max}}{Z}. \quad (33-62)$$

If we substitute for X_C and X_L from Eqs. 33-43 and 33-51, we can write Eq. 33-60 more explicitly as

$$I = \frac{\mathcal{E}^{\max}}{\sqrt{R^2 + (\omega^{\text{dr}}L - 1/\omega^{\text{dr}}C)^2}} \quad (\text{current amplitude}) \quad (33-63)$$

We have now accomplished half our goal: We have obtained an expression for the current amplitude I in terms of the sinusoidal driving emf and the circuit elements in a series RLC circuit.

The value of I depends on the difference between $\omega^{\text{dr}}L$ and $1/\omega^{\text{dr}}C$ in Eq. 33-63 or, equivalently, the difference between X_L and X_C in Eq. 33-60. In either equation, it does not matter which of the two quantities is greater because the difference is always squared.

The current that we have been describing in this section is the *steady-state current* that occurs after the alternating emf has been applied for some time. When the emf is first applied to a circuit, a brief *transient current* occurs. Its duration (before settling down into the steady-state current) is determined by the time constants $\tau_L = L/R$ and $\tau_C = RC$ as the inductive and capacitive elements “turn on.” This transient current can be large and can, for example, destroy a motor on startup if it is not properly taken into account in the motor’s circuit design.

The Phase Constant

From the right-hand phasor triangle in Fig. 33-15*d* and from Table 33-2 we can write

$$\tan \phi = \frac{\Delta V_L - \Delta V_C}{\Delta V_R} = \frac{IX_L - IX_C}{IR}, \quad (33-64)$$

which gives us

$$\tan \phi = \frac{X_L - X_C}{R} \quad (\text{phase constant}). \quad (33-65)$$

This is the other half of our goal: an equation for the phase constant ϕ in a sinusoidally driven series RLC circuit. In essence, it gives us three different results for the phase constant, depending on the relative values of X_L and X_C :

$X_L > X_C$: The circuit is said to be *more inductive than capacitive*. Equation 33-65 tells us that ϕ is positive for such a circuit, which means that phasor I rotates behind phasor \mathcal{E}^{max} (Fig. 33-16*a*). A plot of \mathcal{E} and i versus time is like that in Fig. 33-16*b*. (The phasors in Figs. 33-16*c* and *d* were drawn assuming $X_L > X_C$.)

$X_C > X_L$: The circuit is said to be *more capacitive than inductive*. Equation 33-65 tells us that ϕ is negative for such a circuit, which means that phasor I rotates ahead of phasor \mathcal{E}^{max} (Fig. 33-16*c*). A plot of \mathcal{E} and i versus time is like that in Fig. 33-16*d*.

$X_C = X_L$: The circuit is said to be in *resonance*, a state that is discussed next. Equation 33-65 tells us that $\phi = 0^\circ$ for such a circuit, which means that phasors \mathcal{E}^{max} and I rotate together (Fig. 33-16*e*). A plot of \mathcal{E} and i versus time is like that in Fig. 33-16*f*.

As an illustration, let us reconsider two extreme circuits. In the *purely inductive circuit* of Fig. 33-14*a*, where X_L is nonzero and $X_C = R = 0$, Eq. 33-65 tells us that $\phi = +90^\circ$ (the greatest value of ϕ), consistent with Fig. 33-14*c*. In the *purely capacitive circuit* of Fig. 33-13*a*, where X_C is nonzero and $X_L = R = 0$, Eq. 33-65 tells us that $\phi = -90^\circ$ (the least value of ϕ), consistent with Fig. 33-13*c*.

Resonance

Equation 33-63 gives the current amplitude I in an RLC circuit as a function of the driving angular frequency ω^{dr} of the external alternating emf. For a given resistance R , that amplitude is a maximum when the quantity $\omega^{\text{dr}}L - 1/\omega^{\text{dr}}C$ in the denominator is zero—that is, when

FIGURE 33-16 Phasor diagrams and graphs of the alternating emf and current for the driven RLC circuit of Fig. 33-11. In the phasor diagram of (a) and the graph of (b), the current i lags the driving emf \mathcal{E} and the current's phase constant ϕ is positive. In (c) and (d), the current i leads the driving emf \mathcal{E} and its phase constant ϕ is negative. In (e) and (f), the current i is in phase with the driving emf \mathcal{E} and its phase constant ϕ is zero.

$$\omega^{\text{dr}}L = \frac{1}{\omega^{\text{dr}}C}$$

or
$$\omega^{\text{dr}} = \frac{1}{\sqrt{LC}} \quad (\text{for maximum } I). \quad (33-66)$$

Because the natural angular frequency ω of the RLC circuit is also equal to $1/\sqrt{LC}$, the maximum value of I occurs when the driving angular frequency matches the natural angular frequency—that is, at resonance. Thus, in an RLC circuit, resonance and maximum current amplitude I occur when

$$\omega^{\text{dr}} = \omega = \frac{1}{\sqrt{LC}} \quad (\text{resonance}). \quad (33-67)$$

Figure 33-17 shows three *resonance curves* for sinusoidally driven oscillations in three series RLC circuits differing only in R . Each curve peaks at its maximum current amplitude I when the ratio $\omega^{\text{dr}}/\omega$ is 1.00, but the maximum value of I decreases with increasing R . (The maximum I is always $\mathcal{E}^{\text{max}}/R$; to see why, combine Eqs. 33-61 and 33-62.) In addition, the curves increase in width (measured in Fig. 33-17 at half the maximum value of I) with increasing R .

To make physical sense of Fig. 33-17, consider how the reactances X_L and X_C change as we increase the driving angular frequency ω^{dr} , starting with a value much less than the natural frequency ω . For small ω^{dr} , reactance $X_L (= \omega^{\text{dr}}L)$ is small and reactance $X_C (= 1/\omega^{\text{dr}}C)$ is large. Thus, the circuit is mainly capacitive and the impedance is dominated by the large X_C , which keeps the current low.

As we increase ω^{dr} , reactance X_C remains dominant but decreases while reactance X_L increases. The decrease in X_C decreases the impedance, allowing the current

FIGURE 33-17 ■ Resonance curves for the driven RLC circuit of Fig. 33-11 with $L = 100 \mu\text{H}$, $C = 100 \text{ pF}$, and three values of R . The current amplitude I of the alternating current depends on how close the driving angular frequency ω^{dr} is to the natural angular frequency ω . The horizontal arrow on each curve measures the curve's width at the half-maximum level, a measure of the sharpness of the resonance. To the left of $\omega^{\text{dr}}/\omega = 1.00$, the circuit is mainly capacitive, with $X_C > X_L$ to the right, it is mainly inductive, with $X_L > X_C$.

to increase, as we see on the left side of any resonance curve in Fig. 33-17. When the increasing X_L and the decreasing X_C reach equal values, the current is greatest and the circuit is in resonance, with $\omega^{\text{dr}} = \omega$.

As we continue to increase ω^{dr} , the increasing reactance X_L becomes progressively more dominant over the decreasing reactance X_C . The impedance increases because of X_L and the current decreases, as on the right side of any resonance curve in Fig. 33-17. In summary, then: The low-angular-frequency side of a resonance curve is dominated by the capacitor's reactance, the high-angular-frequency side is dominated by the inductor's reactance, and resonance occurs between the two regions.

READING EXERCISE 33-6: Here are the capacitive reactance and inductive reactance, respectively, for three sinusoidally driven series RLC circuits: (1) 50Ω , 100Ω ; (2) 100Ω , 50Ω ; (3) 50Ω , 50Ω . (a) For each, does the current lead or lag the applied emf, or are the two in phase? (b) Which circuit is in resonance? ■

TOUCHSTONE EXAMPLE 33-4: Series RLC Circuit

In Fig. 33-11 let $R = 200 \Omega$, $C = 15.0 \mu\text{F}$, $L = 230 \text{ mH}$, $f^{\text{dr}} = 60.0 \text{ Hz}$, and $\mathcal{E}^{\text{max}} = 36.0 \text{ V}$.

(a) What is the current amplitude I ?

SOLUTION ■ The **Key Idea** here is that current amplitude I depends on the amplitude \mathcal{E}^{max} of the driving emf and on the impedance Z of the circuit, according to Eq. 33-62 ($I = \mathcal{E}^{\text{max}}/Z$). Thus, we need to find Z , which depends on the circuit's resistance R , capacitive reactance X_C , and inductive reactance X_L .

The circuit's only resistance is the given resistance R . Its only capacitive reactance is due to the given capacitance. From Table 33-2, ($X_C = 1/\omega^{\text{dr}}C$), with $\omega^{\text{dr}} = 2\pi f^{\text{dr}}$, we can write

$$\begin{aligned} X_C &= \frac{1}{2\pi f^{\text{dr}}C} = \frac{1}{(2\pi)(60.0 \text{ Hz})(15.0 \times 10^{-6} \text{ F})} \\ &= 177 \Omega. \end{aligned}$$

From Table 33-2 ($X_L = \omega^{\text{dr}}L$), with $\omega^{\text{dr}} = 2\pi f^{\text{dr}}$, we can write

$$\begin{aligned} X_L &= 2\pi f^{\text{dr}}L = (2\pi)(60.0 \text{ Hz})(230 \times 10^{-3} \text{ H}) \\ &= 86.7 \Omega. \end{aligned}$$

Thus, the circuit's impedance is

$$\begin{aligned} Z &= \sqrt{R^2 + (X_L - X_C)^2} \\ &= \sqrt{(200 \Omega)^2 + (86.7 \Omega - 177 \Omega)^2} \\ &= 219 \Omega. \end{aligned}$$

We then find

$$|I| = \frac{|\mathcal{E}^{\text{max}}|}{Z} = \frac{36.0 \text{ V}}{219 \Omega} = 0.164 \text{ A}. \quad (\text{Answer})$$

(b) What is the phase constant ϕ of the current in the circuit relative to the driving emf?

SOLUTION ■ The **Key Idea** here is that the phase constant depends on the inductive reactance, the capacitive reactance, and the resistance of the circuit, according to Eq. 33-65. Solving that equation for ϕ leads to

$$\begin{aligned} \phi &= \tan^{-1} \frac{X_L - X_C}{R} = \tan^{-1} \frac{86.7 \Omega - 177 \Omega}{200 \Omega} \\ &= -24.3^\circ = -0.424 \text{ rad}. \quad (\text{Answer}) \end{aligned}$$

The negative phase constant is consistent with the fact that the load is mainly capacitive; that is, $X_C > X_L$.

FIGURE 33-18 (a) A plot of $\sin \theta$ versus θ . The average value over one cycle is zero. (b) A plot of $\sin^2 \theta$ versus θ . The average value over one cycle is $\frac{1}{2}$.

33-12 Power in Alternating-Current Circuits

In the RLC circuit of Fig. 33-11, the source of energy is the alternating-current generator. Some of the energy that it provides is stored in the electric field in the capacitor, some is stored in the magnetic field in the inductor, and some is dissipated as thermal energy in the resistor. In steady-state operation—which we assume—the average energy stored in the capacitor and inductor together remains constant. The net transfer of energy is thus from the generator to the resistor, where electromagnetic energy is dissipated as thermal energy.

The instantaneous rate at which energy is dissipated in the resistor can be written, with the help of Eqs. 27-26 and 33-35, as

$$P = i^2 R = [I \sin(\omega \text{ dr}t - \phi)]^2 R = I^2 R \sin^2(\omega \text{ dr}t - \phi), \quad (33-68)$$

where I is the maximum value of the current.

The *average* rate at which energy is dissipated in the resistor, however, is the average of Eq. 33-68 over time. Although the average value of $\sin \theta$, where θ is any variable, is zero (Fig. 33-18a), the average value of $\sin^2 \theta$ over one complete cycle is $1/2$ (Fig. 33-18b). (Note in Fig. 33-18b how the shaded areas under the curve but above the horizontal line marked $+1/2$ exactly fill in the unshaded spaces below that line.) Thus, we can write, from Eq. 33-68,

$$\langle P \rangle = \frac{I^2 R}{2} = \left(\frac{I}{\sqrt{2}} \right)^2 R. \quad (33-69)$$

The quantity $I/\sqrt{2}$ is defined as the **root-mean-square**, or **rms**, value of the current i in a cycle. The square of the rms current is the average of the squares of the instantaneous currents in a cycle. It represents an effective dc current that would produce the same heating effect as an ac current with a maximum value of I . So,

$$I^{\text{rms}} \equiv \frac{I}{\sqrt{2}} \quad (\text{definition of rms current}). \quad (33-70)$$

We can now rewrite Eq. 33-69 as

$$\langle P \rangle = (I^{\text{rms}})^2 R \quad (\text{average power}). \quad (33-71)$$

Equation 33-71 looks much like Eq. 26-11 for dc currents ($P = i^2 R$); the purpose of defining rms current is that we can use it to compute the average rate of energy dissipation for alternating-current circuits using essentially the same equation we use for dc circuits.

We can also define rms values of voltages and emfs for alternating-current circuits in terms of the maximum values of those quantities in a cycle. So

$$\Delta V^{\text{rms}} = \frac{\Delta V}{\sqrt{2}} \quad (\text{rms voltage}) \quad \text{and} \quad \mathcal{E}^{\text{rms}} = \frac{\mathcal{E}^{\text{max}}}{\sqrt{2}} \quad (\text{rms emf}). \quad (33-72)$$

Alternating-current instruments, such as ammeters and voltmeters, are usually calibrated to read I^{rms} , ΔV^{rms} , and \mathcal{E}^{rms} . Thus, if you plug an alternating-current voltmeter into a household electric outlet and it reads 120 V, it represents an rms voltage. The maximum value of the potential difference at the outlet is $\sqrt{2} \times (120 \text{ V})$, or 170 V.

Because the proportionality factor $1/\sqrt{2}$ in Eqs. 33-70 and 33-72 is the same for all three variables, we can write Eqs. 33-62 and 33-60 as

$$I^{\text{rms}} = \frac{\mathcal{E}^{\text{rms}}}{Z} = \frac{\mathcal{E}^{\text{rms}}}{\sqrt{R^2 + (X_L - X_C)^2}}, \quad (33-73)$$

and, indeed, this is the form that we almost always use.

We can use the relationship $I^{\text{rms}} = \mathcal{E}^{\text{rms}}/Z$ to recast Eq. 33-71 in a useful equivalent way. We write

$$\langle P \rangle = \frac{\mathcal{E}^{\text{rms}}}{Z} I^{\text{rms}} R = \mathcal{E}^{\text{rms}} I^{\text{rms}} \frac{R}{Z}. \quad (33-74)$$

From Fig. 33-15*d*, Table 33-2, and Eq. 33-62, however, we see that R/Z is just the cosine of the phase constant ϕ :

$$\cos \phi = \frac{\Delta V_R}{\mathcal{E}_{\text{max}}} = \frac{IR}{IZ} = \frac{R}{Z}. \quad (33-75)$$

Equation 33-74 then becomes

$$\langle P \rangle = \mathcal{E}^{\text{rms}} I^{\text{rms}} \cos \phi \quad (\text{average power}), \quad (33-76)$$

in which the term $\cos \phi$ is called the **power factor**. Because $\cos \phi = \cos(-\phi)$, Eq. 33-76 is independent of the sign of the phase constant ϕ .

To maximize the rate at which energy is supplied to a resistive load in an *RLC* circuit, we should keep the power factor $\cos \phi$ as close to unity as possible. This is equivalent to keeping the phase constant ϕ in Eq. 33-35 as close to zero as possible. If, for example, the circuit is highly inductive, it can be made less so by putting more capacitance in the circuit, connected in series. Adding capacitive reactance counters the excess inductive reactance in the circuit. This makes Z closer in value to R and so reduces the phase constant and increases the power factor in Eq. 33-76. Power companies place series-connected capacitors throughout their transmission systems to get these results.

READING EXERCISE 33-7: (a) If the current in a sinusoidally driven series *RLC* circuit leads the emf, would we increase or decrease the capacitance to increase the rate at which energy is supplied to the resistance? (b) Will this change bring the resonant angular frequency of the circuit closer to the angular frequency of the emf or move it further away? ■

TOUCHSTONE EXAMPLE 33-5: Power Factor

A series *RLC* circuit, driven with $\mathcal{E}^{\text{rms}} = 120 \text{ V}$ at frequency $f^{\text{dr}} = 60.0 \text{ Hz}$, contains a resistance $R = 200 \Omega$, an inductance with $X_L = 80.0 \Omega$, and a capacitance with $X_C = 150 \Omega$.

(a) What are the power factor $\cos \phi$ and phase constant ϕ of the circuit?

SOLUTION ■ The **Key Idea** here is that the power factor $\cos \phi$ can be found from the resistance R and impedance Z via Eq. 33-75 ($\cos \phi = R/Z$). To calculate Z , we use Eq. 33-61:

$$\begin{aligned} Z &= \sqrt{R^2 + (X_L - X_C)^2} \\ &= \sqrt{(200 \Omega)^2 + (80.0 \Omega - 150 \Omega)^2} = 211.90 \Omega. \end{aligned}$$

Equation 33-75 then gives us

$$\cos \phi = \frac{R}{Z} = \frac{200 \Omega}{211.90 \Omega} = 0.9438 \approx 0.944. \quad (\text{Answer})$$

Taking the inverse cosine then yields

$$\phi = \cos^{-1} 0.944 = \pm 19.3^\circ.$$

Both $+19.3^\circ$ and -19.3° have a cosine of 0.944. To determine which sign is correct, we must consider whether the current leads or lags the driving emf. Because $X_C > X_L$, this circuit is mainly capacitive, with the current leading the emf. Thus, ϕ must be negative:

$$\phi = -19.3^\circ. \quad (\text{Answer})$$

We could, instead, have found ϕ with Eq. 33-65. A calculator would then have given us the complete answer, with the minus sign.

(b) What is the average rate $\langle P \rangle$ at which energy is dissipated in the resistance?

SOLUTION ■ One way to answer this question is to use this **Key Idea**: Because the circuit is assumed to be in steady-state operation, the rate at which energy is dissipated in the resistance is equal to the rate at which energy is supplied to the circuit, as given by Eq. 33-76 ($\langle P \rangle = \mathcal{E}^{\text{rms}} I^{\text{rms}} \cos \phi$).

We are given the rms driving emf \mathcal{E}^{rms} and we know $\cos \phi$ from part (a). To find I^{rms} we use the **Key Idea** that the rms current is determined by the rms value of the driving emf and the circuit's impedance Z (which we know), according to Eq. 33-73:

$$I^{\text{rms}} = \frac{\mathcal{E}^{\text{rms}}}{Z}.$$

Substituting this into Eq. 33-76 then leads to

$$\begin{aligned} \langle P \rangle &= \mathcal{E}^{\text{rms}} I^{\text{rms}} \cos \phi = \frac{(\mathcal{E}^{\text{rms}})^2}{Z} \cos \phi \\ &= \frac{(120 \text{ V})^2}{211.90 \Omega} (0.9438) = 64.1 \text{ W}. \quad (\text{Answer}) \end{aligned}$$

A second way to answer the question is to use the **Key Idea** that the rate at which energy is dissipated in a resistance R depends on the square of the rms current I^{rms} through it, according to Eq. 33-69. We then find

$$\begin{aligned} \langle P \rangle &= (I^{\text{rms}})^2 R = \frac{(\mathcal{E}^{\text{rms}})^2}{Z^2} R \\ &= \frac{(120 \text{ V})^2}{(211.90 \Omega)^2} (200 \Omega) = 64.1 \text{ W}. \quad (\text{Answer}) \end{aligned}$$

(c) What new capacitance C^{new} is needed to maximize $\langle P \rangle$ if the other parameters of the circuit are not changed?

SOLUTION ■ One **Key Idea** here is that the average rate $\langle P \rangle$ at which energy is supplied and dissipated is maximized if the circuit is brought into resonance with the driving emf. A second **Key Idea** is that resonance occurs when $X_C = X_L$. From the given data, we have $X_C > X_L$. Thus, we must decrease X_C to reach resonance. From Eq. 33-43 ($X_C = 1/\omega^{\text{dr}} C$), we see that this means we must increase C to the new value C^{new} .

Using Eq. 33-43, we can write the condition $X_C = X_L$ as

$$\frac{1}{\omega^{\text{dr}} C^{\text{new}}} = X_L.$$

Substituting $2\pi f^{\text{dr}}$ for ω^{dr} (because we are given f^{dr} and not ω^{dr}) and then solving for C^{new} , we find

$$\begin{aligned} C^{\text{new}} &= \frac{1}{2\pi f^{\text{dr}} X_L} = \frac{1}{(2\pi)(60 \text{ Hz})(80.0 \Omega)} \\ &= 3.32 \times 10^{-5} \text{ F} = 33.2 \mu\text{F}. \quad (\text{Answer}) \end{aligned}$$

Following the procedure of part (b), you can show that with C^{new} , $\langle P \rangle$ would then be at its maximum value of 72.0 W.

Problems

SEC. 33-2 ■ ENERGY STORED IN A \vec{B} -FIELD

1. Current Is Zero Suppose that the inductive time constant for the circuit of Fig. 33-19 is 37.0 ms and the current in the circuit is zero at time $t = 0$ s. At what time does the rate at which energy is dissipated in the resistor equal the rate at which energy is being stored in the inductor?

FIGURE 33-19 ■ Problems 1, 2, and 6.

2. Consider the Circuit Consider the circuit of Fig. 33-19. In terms of the inductive time constant, at what instant after the battery is connected will the energy stored in the magnetic field of the inductor be half its steady-state value?

3. Coil Connected in Series A coil is connected in series with a 10.0 k Ω resistor. A 50.0 V battery is applied across the two devices, and the current reaches a value of 2.00 mA after 5.00 ms. (a) Find the inductance of the coil. (b) How much energy is stored in the coil at this same moment?

4. Rates A coil with an inductance of 2.0 H and a resistance of 10 Ω is suddenly connected to a resistanceless battery with $\mathcal{E} = 100$ V. At 0.10 s after the connection is made, what are the rates at which (a) energy is being stored in the magnetic field, (b) thermal energy is appearing in the resistance, and (c) energy is being delivered by the battery?

FIGURE 33-20 ■ Problem 5.

5. Prove That Prove that, after switch S in Fig. 33-20 has been thrown from a to b, all the energy stored in the inductor will ultimately appear as thermal energy in the resistor.

6. Energy Delivered For the circuit of Fig. 33-19, assume that $\mathcal{E} = 10.0$ V, $R = 6.70 \Omega$, and $L = 5.50$ H. The battery is connected at time $t = 0$ s. (a) How much energy is delivered by the battery during the first 2.00 s? (b) How much of this energy is stored in the magnetic field of the inductor? (c) How much of this energy is dissipated in the resistor?

SEC. 33-3 ■ ENERGY DENSITY OF A \vec{B} -FIELD

7. Energy Density A solenoid that is 85.0 cm long has a cross-sectional area of 17.0 cm^2 . There are 950 turns of wire carrying a current of 6.60 A. (a) Calculate the energy density of the magnetic field inside the solenoid. (b) Find the total energy stored in the magnetic field there (neglect end effects).

8. Toroidal Inductor A toroidal inductor with an inductance of 90.0 mH encloses a volume of 0.0200 m^3 . If the average energy density in the toroid is 70.0 J/m^3 , what is the current through the inductor?

9. Magnitude of E -Field What must be the magnitude of a uniform electric field if it is to have the same energy density as that possessed by a 0.50 T magnetic field?

10. Interstellar Space The magnetic field in the interstellar space of our galaxy has a magnitude of about 10^{-10} T . How much energy is stored in this field in a cube 10 light-years on edge? (For scale, note that the nearest star is 4.3 light-years distant and the radius of our galaxy is about 8×10^4 light-years.)

11. Length of Copper Wire A length of copper wire carries a current of 10 A, uniformly distributed through its cross section. Calculate the energy density of (a) the magnetic field and (b) the electric field at the surface of the wire. The wire diameter is 2.5 mm, and its resistance per unit length is $3.3 \Omega/\text{km}$.

12. Circular Loop A circular loop of wire 50 mm in radius carries a current of 100 A. (a) Find the magnetic field strength at the center of the loop. (b) Calculate the energy density at the center of the loop.

SEC. 33-4 ■ LC OSCILLATIONS, QUALITATIVELY

13. What Is the Capacitance What is the capacitance of an oscillating LC circuit if the maximum charge on the capacitor is $1.60 \mu\text{C}$ and the total energy is $140 \mu\text{J}$?

14. Maximum Charge In an oscillating LC circuit, $L = 1.10 \text{ mH}$ and $C = 4.00 \mu\text{F}$. The maximum charge on the capacitor is $3.00 \mu\text{C}$. Find the maximum current.

15. Total Energy An oscillating LC circuit consists of a 75.0 mH inductor and a $3.60 \mu\text{F}$ capacitor. If the maximum charge on the capacitor is $2.90 \mu\text{C}$, (a) what is the total energy in the circuit and (b) what is the maximum current?

16. Electric to Magnetic Energy In a certain oscillating LC circuit the total energy is converted from electric energy in the capacitor to magnetic energy in the inductor in $1.50 \mu\text{s}$. (a) What is the period of oscillation? (b) What is the frequency of oscillation? (c) How long after the magnetic energy is a maximum will it be a maximum again?

17. Maximum Positive Charge The frequency of oscillation of a certain LC circuit is 200 kHz. At time $t = 0 \text{ s}$, plate A of the capacitor has maximum positive charge. At what times $t > 0 \text{ s}$ will (a) plate A again have maximum positive charge, (b) the other plate of the capacitor have maximum positive charge, and (c) the inductor have maximum magnetic field?

SEC. 33-5 ■ THE ELECTRICAL – MECHANICAL ANALOGY

18. SHM A 0.50 kg body oscillates in simple harmonic motion on a spring that, when extended 2.0 mm from its equilibrium, has an 8.0 N restoring force. (a) What is the angular frequency of oscillation? (b) What is the period of oscillation? (c) What is the capacitance of an LC circuit with the same period if L is chosen to be 5.0 H?

19. Energy The energy in an oscillating LC circuit containing a 1.25 H inductor is $5.70 \mu\text{J}$. The maximum charge on the capacitor is $175 \mu\text{C}$. Find (a) the mass, (b) the spring constant, (c) the maximum displacement, and (d) the maximum speed for a mechanical system with the same period.

SEC. 33-6 ■ LC OSCILLATIONS, QUANTITATIVELY

20. Loudspeakers LC oscillators have been used in circuits connected to loudspeakers to create some of the sounds of electronic music. What inductance must be used with a $6.7 \mu\text{F}$ capacitor to produce a frequency of 10 kHz, which is near the middle of the audible range of frequencies?

21. Initially a Maximum In an oscillating LC circuit with $L = 50 \text{ mH}$ and $C = 4.0 \mu\text{F}$, the current is initially a maximum. How long will it take before the capacitor is fully charged for the first time?

22. Single Loop A single loop consists of inductors (L_1, L_2, \dots), capacitors (C_1, C_2, \dots), and resistors (R_1, R_2, \dots) connected in series as shown, for example, in Fig. 33-21a. Show that regardless of the sequence of these circuit elements in the loop, the behavior of this circuit is identical to that of the simple LC circuit shown in Fig. 33-21b. (Hint: Consider the loop rule and see Problem 7 in Chapter 32.)

FIGURE 33-21 ■ Problem 22.

23. Maximum Voltage An oscillating LC circuit consisting of a 1.0 nF capacitor and a 3.0 mH coil has a maximum voltage of 3.0 V. (a) What is the maximum charge on the capacitor? (b) What is the maximum current through the circuit? (c) What is the maximum energy stored in the magnetic field of the coil?

24. Maximum Potential Difference In an oscillating LC circuit in which $C = 4.00 \mu\text{F}$, the maximum potential difference across the capacitor during the oscillations is 1.50 V and the maximum current through the inductor is 50.0 mA. (a) What is the inductance L ? (b) What is the frequency of the oscillations? (c) How much time is required for the charge on the capacitor to rise from zero to its maximum value?

25. Switch Is Thrown In the circuit shown in Fig. 33-22 the switch is kept in position a for a long time. It is then thrown to position b . (a) Calculate the frequency of the resulting oscillating current. (b) What is the amplitude of the current oscillations?

FIGURE 33-22 ■ Problem 25.

26. One Inductor, Two Capacitors You are given a 10 mH inductor and two capacitors, of $5.0 \mu\text{F}$ and $2.0 \mu\text{F}$ capacitance. List the oscillation frequencies that can be generated by connecting these elements in various combinations.

27. Variable Capacitor A variable capacitor with a range from 10 to 365 pF is used with a coil to form a variable-frequency LC

circuit to tune the input to a radio. (a) What ratio of maximum to minimum frequencies may be obtained with such a capacitor? (b) If this circuit is to obtain frequencies from 0.54 MHz to 1.60 MHz, the ratio computed in (a) is too large. By adding a capacitor in parallel to the variable capacitor, this range may be adjusted. What should be the capacitance of this added capacitor, and what inductance should be used to obtain the desired range of frequencies?

28. Energy Stored in Magnetic Field In an oscillating LC circuit, 75.0% of the total energy is stored in the magnetic field of the inductor at a certain instant. (a) In terms of the maximum charge on the capacitor, what is the charge there at that instant? (b) In terms of the maximum current in the inductor, what is the current there at that instant?

29. Capacitor Is Charging In an oscillating LC circuit, $L = 25.0$ mH and $C = 7.80$ μF . At time $t = 0$ s the current is 9.20 mA, the charge on the capacitor is 3.80 μC , and the capacitor is charging. (a) What is the total energy in the circuit? (b) What is the maximum charge on the capacitor? (c) What is the maximum current? (d) If the charge on the capacitor is given by $q = |Q| \cos(\omega t + \phi)$, what is the phase angle ϕ ? (e) Suppose the data are the same, except that the capacitor is discharging at $t = 0$ s. What then is ϕ ?

30. Varied by a Knob An inductor is connected across a capacitor whose capacitance can be varied by turning a knob. We wish to make the frequency of oscillation of this LC circuit vary linearly with the angle of rotation of the knob, going from 2×10^5 to 4×10^5 Hz as the knob turns through 180° . If $L = 1.0$ mH, plot the required capacitance C as a function of the angle of rotation of the knob.

31. Oscillating LC Circuit In an oscillating LC circuit, $L = 3.00$ mH and $C = 2.70$ μF . At $t = 0$ s the charge on the capacitor is zero and the current is 2.00 A. (a) What is the maximum charge that will appear on the capacitor? (b) In terms of the period T of oscillation, how much time will elapse after $t = 0$ until the energy stored in the capacitor will be increasing at its greatest rate? (c) What is this greatest rate at which energy is transferred to the capacitor?

32. Angular Frequency A series circuit containing inductance L_1 and capacitance C_1 oscillates at angular frequency ω . A second series circuit, containing inductance L_2 and capacitance C_2 , oscillates at the same angular frequency. In terms of ω , what is the angular frequency of oscillation of a series circuit containing all four of these elements? Neglect resistance. (*Hint:* Use the formulas for equivalent capacitance and equivalent inductance; see Section 28-4 and Problem 7 in Chapter 32.)

33. Current as Function of Time In an oscillating LC circuit with $C = 64.0$ μF , the current as a function of time is given by $i = (1.60 \text{ A}) \sin[(2500 \text{ rad/s}) t + 0.680 \text{ rad}]$, where t is in seconds. (a) How soon after $t = 0$ s will the current reach its maximum value? What are (b) the inductance L and (c) the total energy?

34. Three Identical Inductors Three identical inductors L and two identical capacitors C are connected in a two-loop circuit as shown in Fig. 33-23. (a) Suppose the currents

FIGURE 33-23 ■ Problem 34.

are as shown in Fig. 33-23a. What is the current in the middle inductor? Write the loop equations and show that they are satisfied if the current oscillates with angular frequency $\omega = 1/\sqrt{LC}$. (b) Now suppose the currents are as shown in Fig. 33-23b. What is the current in the middle inductor? Write the loop equations and show that they are satisfied if the current oscillates with angular frequency $\omega = 1/\sqrt{3LC}$. Because the circuit can oscillate at two different frequencies, we cannot find an equivalent single-loop LC circuit to replace it.

35. Capacitor One, Capacitor Two

In Fig. 33-24, capacitor 1 with $C_1 = 900$ μF is initially charged to 100 V and capacitor 2 with $C_2 = 100$ μF is uncharged. The inductor has an inductance of 10.0 H. Describe in detail how one might charge capacitor 2 to 300 V by manipulating switches S_1 and S_2 .

FIGURE 33-24 ■ Problem 35.

SEC. 33-7 ■ DAMPED OSCILLATIONS IN AN RLC CIRCUIT

36. Damped LC Consider a damped LC circuit. (a) Show that the damping term $e^{-Rt/2L}$ (which involves L but not C) can be rewritten in a more symmetric manner (involving L and C) as $e^{-\pi R(\sqrt{C/L})t/T}$. Here T is the period of oscillation (neglecting resistance). (b) Using (a), show that the SI unit of $\sqrt{L/C}$ is the ohm. (c) Using (a), show that the condition that the fractional energy loss per cycle be small is $R \ll \sqrt{L/C}$.

37. What Resistance What resistance R should be connected in series with an inductance $L = 220$ mH and capacitance $C = 12.0$ μF for the maximum charge on the capacitor to decay to 99.0% of its initial value in 50.0 cycles? (Assume $\omega' \approx \omega$.)

38. Single-Loop Circuit A single-loop circuit consists of a 7.20 Ω resistor, a 12.0 H inductor, and a 3.20 μF capacitor. Initially the capacitor has a charge of 6.20 μC and the current is zero. Calculate the charge on the capacitor N complete cycles later for $N = 5, 10,$ and 100.

39. Oscillating Series RLC In an oscillating series RLC circuit, find the time required for the maximum energy present in the capacitor during an oscillation to fall to half its initial value. Assume $q = Q$ at $t = 0$.

40. No Charge on Capacitor At time $t = 0$ s there is no charge on the capacitor of a series RLC circuit but there is current I through the inductor. (a) Find the phase constant ϕ in Eq. 33-31 for the circuit. (b) Write an expression for the charge q on the capacitor as a function of time t and in terms of the current amplitude and angular frequency ω' of the oscillations.

41. Fraction of Energy Lost In an oscillating series RLC circuit, show that the fraction of the energy lost per cycle of oscillation, $\Delta U/U$, is given to a close approximation by $2\pi R/\omega L$. The quantity $\omega L/R$ is often called the Q of the circuit (for *quality*). A high- Q circuit has low resistance and a low fractional energy loss ($= 2\pi/Q$) per cycle.

SEC. 33-10 ■ REPRESENTING OSCILLATIONS WITH PHASORS: THREE SIMPLE CIRCUITS

42. Amplitude A 1.50 μF capacitor is connected as in Fig. 33-13a to an ac generator with $|\mathcal{E}^{\text{max}}| = 30.0$ V. What is the amplitude of

the resulting alternating current if the frequency of the emf is (a) 1.00 kHz and (b) 8.00 kHz?

43. AC Generator A 50.0 mH inductor is connected as in Fig. 33-14a to an ac generator with $|\mathcal{E}^{\max}| = 30.0$ V. What is the amplitude of the resulting alternating current if the frequency of the emf is (a) 1.00 kHz and (b) 8.00 kHz?

44. Frequency of emf Is A 50 Ω resistor is connected as in Fig. 33-12a to an ac generator with $|\mathcal{E}^{\max}| = 30.0$ V. What is the amplitude of the resulting alternating current if the frequency of the emf is (a) 1.00 kHz and (b) 8.00 kHz?

45. At What Frequency (a) At what frequency would a 6.0 mH inductor and a 10 μ F capacitor have the same reactance? (b) What would the reactance be? (c) Show that this frequency would be the natural frequency of an oscillating circuit with the same L and C .

46. When the Current Is Maximum An ac generator has emf $\mathcal{E} = \mathcal{E}^{\max} \sin \omega^{\text{dr}} t$, with $\mathcal{E}^{\max} = 25.0$ V and $\omega^{\text{dr}} = 377$ rad/s. It is connected to a 12.7 H inductor. (a) What is the maximum value of the current? (b) When the current is a maximum, what is the emf of the generator? (c) When the emf of the generator is -12.5 V and increasing in magnitude, what is the current?

47. At What Time An ac generator has emf $\mathcal{E} = \mathcal{E}^{\max} \sin(\omega^{\text{dr}} t - \pi/4)$, where $\mathcal{E}^{\max} = 30.0$ V and $\omega^{\text{dr}} = 350$ rad/s. The current produced in a connected circuit is $i(t) = I \sin(\omega^{\text{dr}} t - 3\pi/4)$, where $I = 620$ mA. (a) At what time after $t = 0$ does the generator emf first reach a maximum? (b) At what time after $t = 0$ does the current first reach a maximum? (c) The circuit contains a single element other than the generator. Is it a capacitor, an inductor, or a resistor? Justify your answer. (d) What is the value of the capacitance, inductance, or resistance, as the case may be?

48. Generator from Above The ac generator of Problem 46 is connected to a 4.15 μ F capacitor. (a) What is the maximum value of the current? (b) When the current is a maximum, what is the emf of the generator? (c) When the emf of the generator is -12.5 V and increasing in magnitude, what is the current?

SEC. 33-11 ■ THE SERIES RLC CIRCUIT

49. Find Z , ϕ , and I (a) Find Z , ϕ , and I for the situation of Touchstone Example 33-4 with the capacitor removed from the circuit, all other parameters remaining unchanged. (b) Draw to scale a phasor diagram like that of Fig. 33-15d for this new situation.

50. Find Z , ϕ , and I Two (a) Find Z , ϕ , and I for the situation of Touchstone Example 33-4 with the inductor removed from the circuit, all other parameters remaining unchanged. (b) Draw to scale a phasor diagram like that of Fig. 33-15d for this new situation.

51. Find Z , ϕ , and I Three (a) Find Z , ϕ , and I for the situation of Touchstone Example 33-4 with $C = 70.0$ μ F, the other parameters remaining unchanged. (b) Draw a phasor diagram like that of Fig. 33-15d for this new situation and compare the two diagrams closely.

52. Adjustable Frequency In Fig. 33-25, a generator with an adjustable frequency of oscillation is connected to a variable resistance R , a capacitor of $C = 5.50$ μ F, and an inductor of inductance L . The amplitude of the

FIGURE 33-25 ■ Problem 52.

current produced in the circuit by the generator is at half-maximum level when the generator's frequency is 1.30 or 1.50 kHz. (a) What is L ? (b) If R is increased, what happens to the frequencies at which the current amplitude is at half-maximum level?

53. At Resonance In an RLC circuit, can the amplitude of the voltage across an inductor be greater than the amplitude of the generator emf? Consider an RLC circuit with $\mathcal{E}^{\max} = 10$ V, $R = 10$ Ω , $L = 1.0$ H, and $C = 1.0$ μ F. Find the amplitude of the voltage across the inductor at resonance.

54. Emf Is Maximum When the generator emf in Touchstone Example 33-4 is a maximum, what is the voltage across (a) the generator, (b) the resistance, (c) the capacitance, and (d) the inductance? (e) By summing these with appropriate signs, verify that the loop rule is satisfied.

55. Unknown Resistance A coil of inductance 88 mH and unknown resistance and a 0.94 μ F capacitor are connected in series with an alternating emf of frequency 930 Hz. If the phase constant between the applied voltage and the current is 75° , what is the resistance of the coil?

56. Capacitive Reactance An ac generator with $\mathcal{E}^{\max} = 220$ V and operating at 400 Hz causes oscillations in a series RLC circuit having $R = 220$ Ω , $L = 150$ mH, and $C = 24.0$ μ F. Find (a) the capacitive reactance X_C , (b) the impedance Z , and (c) the current amplitude I . A second capacitor of the same capacitance is then connected in series with the other components. Determine whether the values of (d) X_C , (e) Z , and (f) I increase, decrease, or remain the same.

57. Half-Width An RLC circuit such as that of Fig. 33-11 has $R = 5.00$ Ω , $C = 20.0$ μ F, $L = 1.00$ H, and $\mathcal{E}^{\max} = 30.0$ V. (a) At what angular frequency ω^{dr} will the current amplitude have its maximum value, as in the resonance curves of Fig. 33-17? (b) What is this maximum value? (c) At what two angular frequencies ω_1^{dr} and ω_2^{dr} will the current amplitude be half this maximum value? (d) What is the fractional half-width $[(\omega_1^{\text{dr}} - \omega_2^{\text{dr}})/\omega]$ of the resonance curve for this circuit?

58. Generator in Series An ac generator is to be connected in series with an inductor of $L = 2.00$ mH and a capacitance C . You are to produce C by using capacitors of capacitances $C_1 = 4.00$ μ F and $C_2 = 6.00$ μ F, either singly or together. What resonant frequencies can the circuit have, depending on how you use C_1 and C_2 ?

59. Fractional Half-Width Show that the fractional half-width (see Problem 57) of a resonance curve is given by

$$\frac{\Delta\omega^{\text{dr}}}{\omega} = \sqrt{\frac{3C}{L}} R,$$

in which ω is the angular frequency at resonance and $\Delta\omega^{\text{dr}}$ is the width of the resonance curve at half-amplitude. Note that $\Delta\omega^{\text{dr}}/\omega$ increases with R , as Fig. 33-17 shows. Use this formula to check the answer to Problem 57d.

60. Adjustable Frequency Two In Fig. 33-26, a generator with an adjustable frequency of oscillation is connected to resistance $R = 100$ Ω , inductances $L_1 = 1.70$ mH and $L_2 = 2.30$ mH, and capacitances $C_1 = 4.00$ μ F,

FIGURE 33-26 ■ Problem 60.

$C_2 = 2.50 \mu\text{F}$, and $C_3 = 3.50 \mu\text{F}$. (a) What is the resonant frequency of the circuit? (*Hint:* See Problem 7 in Chapter 32.) What happens to the resonant frequency if (b) the value of R is increased, (c) the value of L_1 is increased, and (d) capacitance C_3 is removed from the circuit?

SEC. 33-12 ■ POWER IN ALTERNATING-CURRENT CIRCUITS

61. Thermal Energy What direct current will produce the same amount of thermal energy, in a particular resistor, as an alternating current that has a maximum value of 2.60 A?

62. AC Voltmeter An ac voltmeter with large impedance is connected in turn across the inductor, the capacitor, and the resistor in a series circuit having an alternating emf of 100 V(rms); it gives the same reading in volts in each case. What is this reading?

63. AC Voltage What is the maximum value of an ac voltage whose rms value is 100 V?

64. Give or Take (a) For the conditions in Problem 46c, is the generator supplying energy to or taking energy from the rest of the circuit? (b) Repeat for the conditions of Problem 48c.

65. Average Rate of Dissipation Calculate the average rate of energy dissipation in the circuits of Problems 43, 44, 49, and 50.

66. Energy Is Supplied Show that the average rate at which energy is supplied to the circuit of Fig. 33-11 can also be written as $\langle P \rangle = (\mathcal{E}_{\text{rms}})^2 R/Z^2$. Show that this expression for average power gives reasonable results for a purely resistive circuit, for an RLC circuit at resonance, for a purely capacitive circuit, and for a purely inductive circuit.

67. Air Conditioner An air conditioner connected to a 120 V rms ac line is equivalent to a 12.0Ω resistance and a 1.30Ω inductive reactance in series. (a) Calculate the impedance of the air conditioner. (b) Find the average rate at which energy is supplied to the appliance.

68. Oscillating RLC In a series oscillating RLC circuit, $R = 16.0 \Omega$, $C = 31.2 \mu\text{F}$, $L = 9.20 \text{ mH}$, and $\mathcal{E} = |\mathcal{E}^{\text{max}}| \sin \omega^{\text{dr}} t$ with $|\mathcal{E}^{\text{max}}| = 45.0 \text{ V}$ and $\omega^{\text{dr}} = 3000 \text{ rad/s}$. For time $t = 0.442 \text{ ms}$ find (a) the rate at which energy is being supplied by the generator, (b) the rate at which the energy in the capacitor is changing, (c) the rate at which the energy in the inductor is changing, and (d) the rate at which energy is being dissipated in the resistor. (e) What is the meaning of a negative result for any of (a), (b), and (c)? (f) Show that the results of (b), (c), and (d) sum to the result of (a).

69. Black Box Figure 33-27 shows an ac generator connected to a “black box” through a pair of terminals. The box contains an RLC circuit, possibly even a multiloop circuit, whose elements and connections we do not know. Measurements outside the

FIGURE 33-27 ■ Problem 69.

box reveal that

$$\mathcal{E}(t) = (75.0 \text{ V}) \sin \omega^{\text{dr}} t$$

and

$$i(t) = (1.20 \text{ A}) \sin (\omega^{\text{dr}} t + 42.0^\circ).$$

(a) What is the power factor? (b) Does the current lead or lag the emf? (c) Is the circuit in the box largely inductive or largely capacitive? (d) Is the circuit in the box in resonance? (e) Must there be a capacitor in the box? An inductor? A resistor? (f) At what average rate is energy delivered to the box by the generator? (g) Why don't you need to know the angular frequency ω^{dr} to answer all these questions?

FIGURE 33-28 ■ Problem 70.

70. Average Rate In Fig. 33-28 show that the average rate at which energy is dissipated in resistance R is a maximum when R is equal to the internal resistance r of the ac generator. (In the text discussion we have tacitly assumed that $r = 0$.)

71. Energy Is Dissipated In an RLC circuit such as that of Fig. 33.11 assume that $R = 5.00 \Omega$, $L = 60.0 \text{ mH}$, $f^{\text{dr}} = 60.0 \text{ Hz}$, and $|\mathcal{E}^{\text{max}}| = 30.0 \text{ V}$. For what values of the capacitor would the average rate at which energy is dissipated in the resistance be (a) a maximum and (b) a minimum? (c) What are these maximum and minimum energy dissipation rates? What are (d) the corresponding phase angles and (e) the corresponding power factors?

72. Light Dimmer A typical “light dimmer” used to dim the stage lights in a theater consists of a variable inductor L (whose inductance is adjustable between zero and L^{max}) connected in series with the lightbulb B as shown in Fig. 33-29. The electrical

FIGURE 33-29 ■ Problem 72.

supply is 120 V (rms) at 60.0 Hz; the lightbulb is rated as “120 V, 1000 W.” (a) What L^{max} is required if the rate of energy dissipation in the lightbulb is to be varied by a factor of 5 from its upper limit of 1000 W? Assume that the resistance of the lightbulb is independent of its temperature. (b) Could one use a variable resistor (adjustable between zero and R^{max}) instead of an inductor? If so, what R^{max} is required? Why isn't this done?

73. Sinusoidal Voltage In Fig. 33-30, $R = 15.0 \Omega$, $C = 4.70 \mu\text{F}$, and $L = 25.0 \text{ mH}$. The generator provides a sinusoidal voltage of 75.0 V (rms) and frequency $f = 550 \text{ Hz}$.

FIGURE 33-30 ■ Problem 73.

(a) Calculate the rms current. (b) Find the rms voltages ΔV_{ab} , ΔV_{bc} , ΔV_{cd} , ΔV_{bd} , ΔV_{ad} . (c) At what average rate is energy dissipated by each of the three circuit elements?

34

Electromagnetic Waves

A comet is often referred to as a dirty snowball. As a comet swings around the Sun, ice on its surface vaporizes, releasing trapped dust and charged particles. The “solar wind,” mostly consisting of protons streaming away from the Sun, forces the charged particles released by the comet into a straight “tail” that points radially away from the Sun. The dust continues to travel in the comet’s orbit.

Why does most of the dust released by the comet remain in the tail of dust on the right in the photograph?

The answer is in this chapter.

FIGURE 34-1 ■ James Clerk Maxwell (1831–1879).

34-1 Introduction

At the end of Chapter 31 we presented James Clerk Maxwell's (Fig. 34-1) four equations that synthesized 50 years of research on electricity and magnetism. Maxwell's equations are compact and elegant in the way that they reveal the inherent symmetry between electrical and magnetic phenomena. But their importance also stems from the fact that they led Maxwell and others to predict a wide range of new phenomena. The design of the communication systems that support radio and television broadcasting, cellular phones, and the Internet are all informed by Maxwell's equations. So is much of our understanding of the nature of light. For these reasons, Maxwell's equations are considered to be the crowning achievement of 19th-century theoretical physics.

One of the most incredible outcomes of Maxwell's work was his prediction of electromagnetic waves in 1864, long before investigators were able to generate and detect them. In fact, Maxwell's hypothesis was not taken seriously until almost 25 years later, when Heinrich Hertz first generated and detected electromagnetic waves. We begin this chapter by reviewing the remarkable chain of reasoning that led Maxwell to postulate the existence of this yet unknown type of wave. We also consider why it took Hertz until 1887 to confirm Maxwell's prediction. Next we describe how the electromagnetic wave pulses and continuous waves used for radio transmission are generated. We also examine how and why the orientation of radio and TV antennas is related to an idea called "polarization" of electromagnetic waves.

Maxwell predicted that all electromagnetic waves would move at a speed that was quite close to the measured value for the speed of visible light in air. For this reason he correctly asserted from the beginning that visible light was an electromagnetic wave. We can use what we learn about electromagnetic waves in this chapter to build a foundation for our study of optics in Chapter 35, where we will learn about how light waves interact with lenses and mirrors to form images.

34-2 Maxwell's Prediction of Electromagnetism

Maxwell's prediction of the electromagnetic wave was a result of the way in which he rewrote and reinterpreted the mathematical expressions for experimentally determined laws named after Faraday and Ampère. We start with a review of these two laws.

Generating Fields in the Absence of Conductors

Faraday's law

$$\mathcal{E} = -\frac{d\Phi^{\text{mag}}}{dt} \quad (\text{Eq. 31-6})$$

was originally based on his measurements of the electric currents induced *within a conducting loop* when the magnetic flux enclosed by it changes. The fact that an electric field is needed to produce the current in the conductor led Maxwell to a bold conjecture. He predicted that an electric field would *always* be induced in the region of varying magnetic flux regardless of whether or not a conducting loop was present. Thus, Faraday's law in the more general form shown below should probably be called the Faraday–Maxwell law:

$$\mathcal{E} = \oint \vec{E} \cdot d\vec{s} = -\frac{d\Phi^{\text{mag}}}{dt} \quad (\text{Faraday's law}). \quad (\text{Eq. 31-21})$$

We owe to Faraday and Maxwell the discovery that a changing magnetic field produces an electric field. We owe to Maxwell alone the symmetric prediction that a

changing electric field ought to produce a magnetic field. Maxwell made this prediction by noting a mathematical similarity between Ampère's law, which describes the nature of the magnetic field generated by current flow in a conductor

$$\oint \vec{B} \cdot d\vec{s} = \mu_0 i^{\text{enc}} \quad (\text{Ampère's law}), \quad (\text{Eq. 30-16})$$

and the general formulation of Faraday's law

$$\mathcal{E} = \oint \vec{E} \cdot d\vec{s} = -\frac{d\Phi^{\text{mag}}}{dt} \quad (\text{Faraday's law}). \quad (\text{Eq. 31-21})$$

At this point Maxwell speculated that the magnetic field induced along a closed loop (Ampère's law) was more generally a function of the rate of change of the electric flux enclosed by the loop. He predicted that any region in space with changing electric flux (like that found between plates when a capacitor is charged or discharged) could induce a magnetic field in the region—even without the presence of a conductor. This notion prompted Maxwell in 1861 to invent the concept of displacement current (discussed in Section 31-9). This fictitious current was devised to describe the possible, but as yet unobserved, magnetic effects of changing electric flux. Maxwell incorporated his displacement current concept into the reformulation of Ampère's law that we presented in Section 31-8,

$$\oint \vec{B} \cdot d\vec{s} = \mu_0 \epsilon_0 \frac{d\Phi^{\text{elec}}}{dt} + \mu_0 i^{\text{enc}} \quad (\text{Ampère–Maxwell law}). \quad (\text{Eq. 31-32})$$

Since there was no experimental evidence that changing electric flux could generate a magnetic field in the absence of real current, the proposed Ampère–Maxwell law was perhaps the most remarkable of Maxwell's many predictions.

Note that in free space, with no conductors present, the $\mu_0 i$ term in the expression above (Eq. 31-32) disappears and it becomes symmetric to Faraday's law (Eq. 31-21). The symmetry between these equations provided the basis for Maxwell's belief in the existence of electromagnetic waves almost 25 years before Hertz was able to generate and detect them. To find out why, read on.

Electromagnetic Wave Propagation

Maxwell used the symmetric relationship between Faraday's law and the Ampère–Maxwell law to predict a phenomenon that at first glance seems quite bizarre. He noted that if a changing magnetic field could create a changing electric field, then the changing electric field could, in turn, create another changing magnetic field. These changing fields could continuously generate each other and propagate, carrying “electromagnetic” energy with them.

In his 1861 paper (where he also introduced the displacement current concept) Maxwell rewrote the Faraday and Ampère–Maxwell laws as differential equations and solved them to describe \vec{E} and \vec{B} fields separately as functions of time. This produced differential equations that have the same algebraic form as those that describe the propagation of pressure variations in air (sound waves), ripples on the surface of a pond (water waves), and transverse displacements of a stretched string. Hence, the concept of an “electromagnetic wave” was born.

A rigorous treatment of Maxwell's mathematical description of electromagnetic waves would require us to solve differential equations and interpret the results. These methods are beyond the scope of this text. Instead we present some new results that arise from Maxwell's equations and show that they are consistent with experimental

results. This will provide us with insight into the generation and properties of electromagnetic radiation. For example, one outcome of solving Maxwell's wave equations was the revelation that an electromagnetic wave ought to travel in a vacuum at a speed given by

$$c = \frac{1}{\sqrt{\mu_0 \epsilon_0}} \quad (\text{predicted wave speed in a vacuum}). \quad (34-1)$$

Maxwell was quite surprised to find that the wave speed depends on the familiar electric and magnetic constants, ϵ_0 and μ_0 , previously measured in static, electric, and magnetic experiments. He was equally surprised to find that a calculation of the speed in a vacuum agreed well with what was known at the time to be the speed of light. This led Maxwell to make the additional, rather bold, hypothesis that light was an electromagnetic wave.

34-3 The Generation of Electromagnetic Waves

In this section we give a more detailed description of how electromagnetic waves are generated. Observations summarized in Maxwell's equations reveal that electromagnetic waves (sometimes called "radiation") should be generated by accelerating charges. We begin by considering the generation of radio-frequency waves used for radio and TV transmission. These waves (wavelength $\lambda \approx 1\text{m}$) provide a source of radiation (the emitted waves) that is both macroscopic and of manageable dimensions so that classical physics rules. Some electromagnetic waves, including x-rays, gamma rays, and visible light, are *radiated* (emitted) from sources that are of atomic or nuclear size, where quantum physics rules.

At this point, you may find it helpful to quickly review mechanical waves discussed in Chapter 17. It was there that we first introduced important and pertinent wave-related concepts such as wavelength and frequency. We begin this section by considering the analogy between the generation and propagation of an electromagnetic *wave pulse* and a pulse traveling on a stretched string (Section 17-3) or along the surface of a pond (Section 18-1). We end the section with a discussion of how sinusoidal radio-frequency electromagnetic waves are generated.

An Electromagnetic Wave Pulse

How does a wave pulse propagate? Let's consider a more familiar situation in which a small bucket of water is dumped onto the surface of a pond. The water that is dumped on the pond's surface will undergo a rapid oscillation as it falls and rises again. However, the water that is dumped on the surface cannot undergo this oscillation without causing the ring of water that surrounds it to begin oscillating. This oscillation is passed along to the next ring of surrounding water, and so on. We see a two-dimensional wave crest like that shown in Fig. 18-3 traveling along the pond's surface at a constant speed.

In 1842, prior to Maxwell's prediction of electromagnetic waves, Joseph Henry observed electrical oscillations produced by a spark discharge from a capacitor. Because the theoretical basis for explaining electrical oscillations was not yet developed, the significance of these oscillations was not appreciated. Hertz generated electrical oscillations once again in 1888 using an induction coil to create sparks.

In order to better understand the connection between electromagnetic waves, electric oscillations, and the spark discharges with which Henry and Hertz experimented, we need to pull together ideas from other chapters. First, we know from

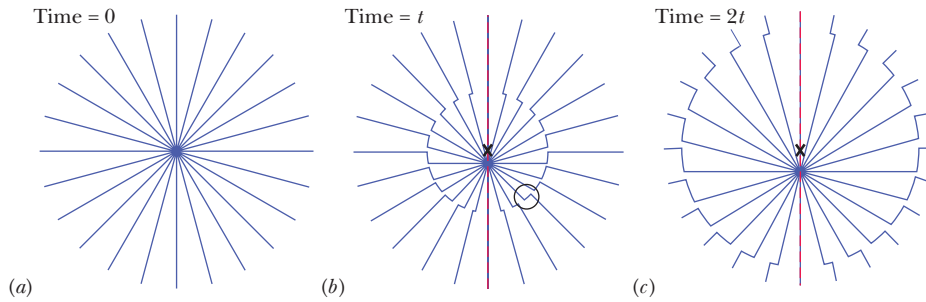

FIGURE 34-2 (a) Electric field lines in the plane of a resting point charge at the exact moment the jerk starts. (b) After an elapsed time t the kink at the interface between the old set of lines and the set associated with the jerk has traveled a distance ct . The original location of the charge is marked with an X and the line of motion is shown with a red dashed line. The region within the small circle is shown enlarged in Fig. 34-3. (c) After a time $2t$, the kink is at a distance $2ct$. (Diagrams adapted from *Electric & Magnetic Interactions: The Movies*, © 1996 Ruth Chabay and Bruce Sherwood, Carnegie Mellon University.)

Section 23-10 that electric field arrows indicate the direction of the electric field. Second, although we do not discuss this until Section 38-3, Einstein's principle of relativity establishes that nothing can travel faster than the speed of light. This includes information about the position of a charge. Keeping these ideas in mind, we can visualize how the field lines from a charge must readjust when the charge undergoes a sudden and brief acceleration like the spark discharge with which Henry and Hertz experimented. Specifically, suppose that at a time $t_1 = 0$ s a point charge initially at rest is suddenly accelerated straight downward and then stopped, all in an extremely short time period Δt . This is shown in Fig. 34-2. The original location of the charge is marked with an "X" in Fig. 34-2b and c.

What happens? As discussed below Maxwell's equations would lead us to predict that the accelerating charge will generate a three-dimensional electromagnetic wave crest. Furthermore, if you consider how this situation is like the momentary acceleration of the bit of mass at the end of a taut string when it is given a quick downward jerk, the generation of a pulse makes some intuitive sense as well. Let's look at the situation more carefully.

Before the acceleration, the electric field lines associated with the charge look just like those depicted Fig. 34-2a. Electromagnetic information travels at the speed of light, so after a time period $\Delta t = t$ the field lines will point to the charge's new position at the end of the acceleration—but only up to a distance ct . This is shown in Fig. 34-2b. Beyond that distance, the field lines will point to the charge's old position because the "news" of the charge's changed position will not have had time to spread that far.

At the distance ct , the field lines will have a kink joining the new set and the old set. This kink is increasingly close to perpendicular to the direction of motion of the wave front the farther you get from the accelerating charge. If we assume that field lines are continuous and that the field vectors are tangent to the line at each point, then the \vec{E} field vectors in the kink are also increasingly perpendicular to the direction of motion of the wavefronts. The kink travels outward at the speed of light so that it has moved to a distance of $2ct$ after a time of $\Delta t = 2t$. This pulse continues to move out at speed c from the original location of the charge. Figure 34-3 shows a magnified view of a circled piece of Fig. 34-2b with extra field vectors drawn in.

In the brief moment that the charge is being accelerated, the "current" created by it is increasing ($di/dt = d^2q/dt^2 > 0$). We can use Ampère's law to determine the direction of the increasing magnetic field associated with this increasing "current." Taking the line of motion to be the direction of our "current" (shown with a red dashed line

FIGURE 34-3 Here more \vec{E} field vectors are assigned to the charge and shown in a magnified view of a circled piece of Fig. 34-2b. The crest of the wave pulse at time t show that the density of electric field lines is higher than the density of lines created when the charge is resting. Note that the \vec{E} field in the kink points in a direction that is nearly perpendicular to the propagating electromagnetic wave pulse.

in Fig. 34-2*b*) and using Ampère's law, we see that the magnetic field points into the page to the left of the line of motion of the charge and out of the page to the right. The direction of these \vec{B} field vectors (into or out of the page) is always perpendicular to that of the \vec{E} field vectors. So, we surmise that the \vec{B} field vectors associated with the kink will point perpendicular to the direction of motion of the kink. There are no propagating \vec{E} or \vec{B} fields along the line of motion of the charge. We define the wave disturbance as the propagation of the \vec{E} field and \vec{B} field vectors that are each perpendicular to the direction of motion of the wave. So, we have an electromagnetic wave pulse that is *transverse*. (See Chapter 17 for a review of wave properties if this last comment is not clear.)

Although this informal consideration of a single wave pulse created by a sudden acceleration of a charge is not rigorous or complete, it does give us a useful qualitative picture of how a pulsed electromagnetic wave might be generated.

Continuous Electromagnetic Wave Generation

How can we generate a continuous electromagnetic wave? What corresponds to the generation of the sinusoidal oscillation in a stretched string as shown in Fig. 17-6? Suppose we cause charges to oscillate back and forth along a line with sinusoidal or simple harmonic motion (SHM). We know from Section 16-4 that these charges will also have a sinusoidal acceleration, and so by the discussion above, we know that they will generate continuous electromagnetic (EM) waves.

Figure 34-4 is a schematic of an apparatus that can be used to generate radio frequency waves. The apparatus is an LC oscillator like that described in Section 33-6, but with a broadcast antenna coupled to it. This oscillator, mentioned in the previous sentence, establishes a sinusoidal current with an angular frequency given by $\omega = 1/\sqrt{LC}$. An ac generator provides a source of energy to compensate for thermal losses in the oscillator circuit and also for the energy carried away by the radiated electromagnetic wave.

The LC oscillator is coupled by a transformer and a transmission line to an *antenna*, which consists essentially of two thin, solid, conducting rods. Through this coupling, the sinusoidally varying current in the oscillator causes charge to oscillate sinusoidally along the antenna rods. The antenna behaves like an electric dipole described in Section 25-8, except that its electric dipole moment along the antenna changes sinusoidally in magnitude and direction over time. Since the charges are oscillating, they are continually accelerating and thereby produce electromagnetic radiation.

Because the dipole moment varies in the antenna in magnitude and direction, the electric and magnetic fields produced by the dipole vary in magnitude and direction. However, the changes in the electric and magnetic fields do not happen everywhere instantaneously. Rather, the changes travel outward from the antenna at the speed of light c . Together the changing fields form an electromagnetic wave that travels away from the antenna at speed c . The angular frequency of this wave, ω , is the same as that of the LC oscillator.

FIGURE 34-4 ■ Apparatus for generating a traveling electromagnetic wave at a “shortwave” radio frequency. An LC oscillator produces a sinusoidal current in an antenna. This generates an oscillating magnetic field and thus an EM wave. P is a distant point at which a detector (consisting of a dipole receiving antenna) could be placed to monitor the wave traveling past it.

FIGURE 34-5 ■ A “snapshot” of some equally spaced planes of a sinusoidal electromagnetic wave traveling in the $+x$ direction. In this particular wave, the darker, vertically oriented \vec{E} field vectors always point along the y axis. The lighter, horizontally oriented \vec{B} field vectors always point along the z axis. The planes are labeled a through h to correspond to the \vec{E} and \vec{B} field vector configurations shown in Fig. 34-6.

The wave moves out in all directions except along the line of motion of the charges. In a direction perpendicular to the antenna the wavefronts will be approximately spherical in shape. If we go to a point that is far from the charge, the spherical wavefronts seem almost flat (just as the Earth seems flat to us because we are so far from its center). If we block all but a small piece of this wavefront, we get what looks like a series of planes marching forward at the speed of light. Hence, we often refer to electromagnetic waves as “plane waves.” Although the plane wave approximation is a simplification of the real situation, it describes the nature of waves quite well when the distance from the source, in this case the antenna, is large compared to the wavelength of electromagnetic wave. The value to us in looking at electromagnetic waves as “plane waves” is that they are simpler to deal with mathematically than spherical waves.

There are several ways to depict a traveling sinusoidal electromagnetic plane wave. One of these is shown in Fig. 34-5. Here we show a “snapshot” of a few equally spaced planes of a sinusoidal electromagnetic wave traveling in the $+x$ direction. In this particular wave, the darker, vertically oriented \vec{E} field vectors always point along the y axis. The lighter, horizontally oriented \vec{B} field vectors always point along the z axis. This diagram emphasizes the fact that, at a given instant, field vectors are the same everywhere in a given y - z plane. The figure also shows that as the wave passes a point in space, the field vector values will sinusoidally vary from a maximum to a minimum and back again. This is shown by the dashed lines representing curves through the tips of the \vec{E} vectors and the \vec{B} vectors at the bottom of each plane. The planes are labeled a through h to correspond to the \vec{E} and \vec{B} field vector configurations shown in Fig. 34-6.

Figure 34-6 shows how the electric field \vec{E} and the magnetic field \vec{B} change with time as one wavelength of the wave sweeps past the distant point P of Fig. 34-4. In each part of Fig. 34-5, the wave is traveling directly along the x axis. There are several key features of any sinusoidal plane electromagnetic wave that are shown in Fig. 34-5 and Fig. 34-6 that are present whenever a plane electromagnetic wave is created with charges that oscillate sinusoidally along a line:

1. The electric and magnetic fields \vec{E} and \vec{B} are always perpendicular to the direction of travel of the wave. Thus, the wave is a *transverse wave*, as discussed in Chapter 17.
2. The electric field is always perpendicular to the magnetic field.
3. The cross product $\vec{E} \times \vec{B}$ always points in the direction of travel of the wave.
4. For a single simple plane wave, the fields always vary sinusoidally over time, just like the transverse waves discussed in Chapter 17. Moreover, the fields vary with the same frequency and are *in phase* (in step) with each other. More complex fields can be described mathematically as a superposition of plane waves.

FIGURE 34-6 ■ (a)–(h) The variation in the electric field \vec{E} and the magnetic field \vec{B} at the distant point P of Fig. 34-4 as one wavelength of the electromagnetic wave shown in Fig. 34-5 travels past it. In this perspective, the wave is traveling directly out of the page. The two fields vary sinusoidally in magnitude and direction. Each of the planes that correspond to parts of this diagram (a)–(h) are also shown in Fig. 34-5.

34-4 Describing Electromagnetic Wave Properties Mathematically

Suppose an electromagnetic wave like that shown in Fig. 34-5 is traveling toward P , the electric field in Fig. 34-5 is oscillating parallel to the y axis, and the magnetic field is then oscillating parallel to the z axis. Then we can represent the electric and magnetic fields mathematically as sinusoidal functions of position x (along the path of the wave) and time t :

$$\vec{E} = \vec{E}^{\max} \sin(kx - \omega t), \quad (34-2)$$

and
$$\vec{B} = \vec{B}^{\max} \sin(kx - \omega t), \quad (34-3)$$

where \vec{E}^{\max} and \vec{B}^{\max} represent the amplitudes of the fields and, as in Chapter 17, ω and k are the angular frequency and wave number, respectively. From these equations, we note that each type of field forms its own wave. Equation 34-2 gives the *electric wave component* of the electromagnetic wave, and Eq. 34-3 gives the *magnetic wave component*. As we already realize from considering Maxwell's formulation, these two wave components cannot exist independently. The wave propagates because a changing electric field creates a changing magnetic field, which generates another changing electric field, and so on.

At this point it is useful to devise a second “snapshot” representation of the plane electromagnetic wave. This is shown in Fig. 34-7b. Instead of emphasizing the planar nature of a selected sample of wave fronts as we did in Fig. 34-5, we show just one vector that represents the length of electric and magnetic field vectors in each sample plane. The curves through the tips of the vectors display the sinusoidal nature of the oscillations described by $\vec{E} = \vec{E}^{\max} \sin(kx - \omega t)$, and $\vec{B} = \vec{B}^{\max} \sin(kx - \omega t)$, (Eqs. 34-2 and 34-3) above. The wave components \vec{E} and \vec{B} are depicted as in phase, perpendicular to each other, and perpendicular to the wave's direction of travel.

Figure 34-7a shows how the new representation is tied to the old one. Only three sample planes with \vec{E} vectors along one line, separated by a half wavelength $\lambda/2 (= \pi/k)$ of the wave, are shown.

In some cases waves are traveling in approximately the same direction and form a beam, such as a laser beam or a beam of radio waves. A beam can be represented with a “ray,” which is just a line showing the direction of motion of the beam. This is also

FIGURE 34-7 (a) A plane electromagnetic wave represented with a ray and three wavefronts separated by a half wavelength $\lambda/2$. (b) The same wave represented in a “snapshot” of its electric field \vec{E} and magnetic field \vec{B} at points on the x axis, along which the wave travels at speed c . As it travels past point P , the fields vary as shown in Fig. 34-5. The dashed rectangle at P is used in Fig. 34-8a.

shown in Fig. 34-7a. “Rays” of light will become increasingly prominent in our discussions of image formations in Chapters 35 and 36.

Interpretation of Fig. 34-7b requires some care. The similar drawings for a transverse wave on a taut string that we discussed in Chapter 17 represented the up and down displacement of sections of the string as the wave passed (*something actually moved*). Figure 34-7b is more abstract. At the instant shown, the electric and magnetic fields each have a certain magnitude and direction (but always perpendicular to the x axis) at each point along the x axis. We choose to represent these vector quantities with a pair of arrows for each point, so we must draw arrows of different lengths for different points, all directed away from the x axis, like thorns on a rose stem. For each line parallel to the x axis there is a similar picture. In viewing figures such as this, it is important to remember that the length of the arrows represents the field values along the line chosen as the x axis. Neither the arrows nor the sinusoidal curves represent a sideways displacement of anything.

A Most Curious Wave

From our previous work with waves in Chapters 17 and 18, we know that the speed of the wave is ω/k (Eq. 17-12). However, it is customary to use the symbol c (rather than v) to denote an electromagnetic wave speed in a vacuum (or air):

All electromagnetic waves, including visible light, have the same speed c in a vacuum. Hence, c is called “the speed of light.”*

The waves we discussed in Chapters 17 and 18 require a *medium* (some material) through which or along which to travel. We had waves traveling along a string, through the Earth, and through the air. Maxwell and other 19th-century investigators assumed there was a medium through which electromagnetic waves traveled. However, we now believe that electromagnetic waves are curiously different in that they require no medium for travel. They can, indeed, travel through a medium such as air or glass, but they can also travel through the vacuum of space between a distant star and the Earth.

Once Albert Einstein proposed the special theory of relativity in 1905, scientists realized that visible light waves and other electromagnetic waves were special entities. The reason is that light has the same speed in any inertial frame of reference. If you send a beam of light along an axis and ask several observers to measure its speed while they move at different speeds along that axis, either in the direction of the light or opposite it, the observers will all measure the *same speed* for the light. This result is an amazing one and quite different from what would have been found if those observers had measured the speed of any other type of wave. For other waves, the speed of the observers relative to the wave would have affected their measurements. The implications of this are striking and include some seemingly bizarre effects that we will learn about in Chapter 38 on special relativity.

As we saw in Chapter 1, the speed of light (any electromagnetic wave) in vacuum has the exact value

$$c = 299\,792\,458 \text{ m/s.}^\dagger$$

The Ratio of \vec{E} to \vec{B} and the Induced Electric Field

We can use Faraday’s law

$$\mathcal{E} = \oint \vec{E} \cdot d\vec{s} = - \frac{d\Phi^{\text{mag}}}{dt}$$

* The letter c comes from the Latin word *celar*, which means “fast”.

† The value is “exact” so the meter could be redefined as a length of path traveled by light in a specified time. (See Section 1-6 for details.)

FIGURE 34-8 (a) As the electromagnetic wave travels rightward past point P in Fig. 34-7, the sinusoidal variation of the magnetic field \vec{B} through a rectangle centered at P induces electric fields along the rectangle. At the instant shown, \vec{B} is decreasing in magnitude and the induced electric field is therefore greater in magnitude on the right side of the rectangle than on the left. (b) The sinusoidal variation of the electric field through this rectangle, located (but not shown) at point P in Fig. 34-8a, induces magnetic fields along the rectangle. The instant shown is that of Fig. 34-8a: \vec{E} is decreasing in magnitude, and the induced magnetic field is greater in magnitude on the right side of the rectangle than on the left.

to find the ratio of the electric and magnetic fields at any location along an electromagnetic wave. We start by considering the dashed rectangle (of dimensions dx and h in Fig. 34-7b) that is fixed at point P on the x axis and in the xy plane. As the electromagnetic wave moves to the right past the rectangle, the magnetic flux Φ^{mag} through the rectangle changes and—according to Faraday’s law of induction—induced electric fields appear throughout the region of the rectangle. We take \vec{E} and $\vec{E} + d\vec{E}$ to be the induced fields along the two long sides of the rectangle. These induced electric fields are, in fact, the electric component of the electromagnetic wave at those points.

Let us consider these fields at the instant when the magnetic wave component passing through the rectangle is the small section marked with red on the line marked “a magnetic field component” in Fig. 34-7b. Just then, the magnetic field through the rectangle points in the positive z direction and is decreasing in magnitude (the magnitude was greater just before the red section arrived). Because the magnetic field is out of the page and decreasing, the magnetic flux Φ^{mag} through the rectangle is also decreasing. According to Faraday’s law, this change in flux is opposed by induced electric fields. This implies that a counterclockwise induced current would appear along the rectangle if it were a conductor (which it is not). This in turn implies that a counterclockwise induced electric field would have to appear along the rectangle. So, the induced electric field vectors \vec{E} and $\vec{E} + d\vec{E}$ are indeed oriented as shown in Fig. 34-8a, with the magnitude of $\vec{E} + d\vec{E}$ greater than that of \vec{E} . Otherwise, the net induced electric field would not act counterclockwise around the rectangle.

Let us now apply Faraday’s law of induction,

$$\oint \vec{E} \cdot d\vec{s} = -\frac{d\Phi^{\text{mag}}}{dt}, \quad (34-4)$$

proceeding counterclockwise around the rectangle of Fig. 34-8a. There is no contribution to the integral from the top or bottom of the rectangle because \vec{E} and $d\vec{s}$ are perpendicular there. The integral then has the value

$$\oint \vec{E} \cdot d\vec{s} = (|\vec{E}| + d|\vec{E}|)h - |\vec{E}|h = h d|\vec{E}|. \quad (34-5)$$

The flux Φ^{mag} through this rectangle is

$$\Phi^{\text{mag}} = |\vec{B}|h dx, \quad (34-6)$$

where $|\vec{B}|$ is the magnitude of \vec{B} within the rectangle and $h dx$ is the area of the rectangle. Differentiating this expression (Eq. 34-6) with respect to t gives

$$\frac{d\Phi^{\text{mag}}}{dt} = h dx \frac{d|\vec{B}|}{dt}. \quad (34-7)$$

If we substitute this result (Eq. 34-7) and $\oint \vec{E} \cdot d\vec{s} = h d|\vec{E}|$ (Eq. 34-5) into Faraday’s law $\oint \vec{E} \cdot d\vec{s} = -d\Phi^{\text{mag}}/dt$ (Eq. 34-4), we find

$$h d|\vec{E}| = -h dx \frac{d|\vec{B}|}{dt}$$

or

$$\frac{d|\vec{E}|}{dx} = -\frac{d|\vec{B}|}{dt}. \quad (34-8)$$

We gather from our electromagnetic wave representations and from $\vec{E} = \vec{E}^{\text{max}} \sin(kx - \omega t)$, and $\vec{B} = \vec{B}^{\text{max}} \sin(kx - \omega t)$ (Eqs. 34-2 and 34-3) that both $|\vec{B}|$

and $|\vec{E}|$ are functions of two variables, x and t . However, in evaluating $d|\vec{E}|/dx$, we can assume that t is constant because we consider only an “instantaneous snapshot.” Also, in evaluating $d|\vec{B}|/dt$ we can assume that x is constant because we are dealing with the time rate of change of $|\vec{B}|$ at a particular place, the point P in Fig. 34-7b. The derivatives under these circumstances are partial derivatives, and Eq. 34-8 must be written

$$\frac{\partial |\vec{E}|}{\partial x} = -\frac{\partial |\vec{B}|}{\partial t}. \quad (34-9)$$

The minus sign in this equation is appropriate and necessary because, although $|\vec{E}|$ is increasing with x at the site of the rectangle in Fig. 34-8, $|\vec{B}|$ is decreasing with t .

From $\vec{E} = \vec{E}^{\max} \sin(kx - \omega t)$ (Eq. 34-2) we have

$$\frac{\partial \vec{E}}{\partial x} = k \vec{E}^{\max} \cos(kx - \omega t)$$

and from $\vec{B} = \vec{B}^{\max} \sin(kx - \omega t)$ (Eq. 34-3)

$$\frac{\partial \vec{B}}{\partial t} = -\omega \vec{B}^{\max} \cos(kx - \omega t).$$

Then $\partial|\vec{E}|/\partial x = -\partial|\vec{B}|/\partial t$ (Eq. 34-9) reduces to

$$k|\vec{E}^{\max}| \cos(kx - \omega t) = \omega|\vec{B}^{\max}| \cos(kx - \omega t). \quad (34-10)$$

The ratio ω/k for a traveling wave is its speed, which we are calling c . Hence, we see that

$$\frac{|\vec{E}^{\max}|}{|\vec{B}^{\max}|} = c \quad (\text{amplitude ratio}). \quad (34-11)$$

If we divide $\vec{E} = \vec{E}^{\max} \sin(kx - \omega t)$ by $\vec{B} = \vec{B}^{\max} \sin(kx - \omega t)$ (Eqs. 34-2 and 34-3) and then substitute into Eq. 34-10, we find that the ratio of magnitudes of the fields at every instant is given by

$$\frac{|\vec{E}|}{|\vec{B}|} = c \quad (\text{magnitude ratio}). \quad (34-12)$$

Induced Magnetic Field and the Equation for Wave Speed

If we use the Ampère–Maxwell law

$$\oint \vec{B} \cdot d\vec{s} = \mu_0 \epsilon_0 \frac{d\Phi^{\text{elec}}}{dt} + \mu_0 i^{\text{enc}},$$

we can find an alternative expression for the wave speed in the case where no real current is present (so $i^{\text{enc}} = 0$ A). We start with Fig. 34-8b, which shows another dashed rectangle at point P of Fig. 34-7; this one is in the xz plane. As the electromagnetic wave moves rightward past this new rectangle, the electric flux Φ^{elec} through the rectangle changes and—according to the Ampère–Maxwell law of induction—induced magnetic fields appear throughout the region of the rectangle. These induced magnetic fields are, in fact, the magnetic field components of the electromagnetic wave.

We see from Fig. 34-7 that at the instant chosen for the magnetic field in Fig. 34-8, the electric field through the rectangle of Fig. 34-8*b* is directed as shown. Recall that at the chosen instant, the magnetic field in Fig. 34-8*a* is decreasing. Because the two fields are in phase, the electric field in Fig. 34-8*b* must also be decreasing, and so must the electric flux Φ^{elec} through the rectangle. By applying the same reasoning we applied to Fig. 34-8*a*, we see that the changing flux Φ^{elec} will induce a magnetic field with vectors \vec{B} and $\vec{B} + d\vec{B}$ oriented as shown in Fig. 34-8*b*, where $\vec{B} + d\vec{B}$ is greater than \vec{B} .

Let us also apply Maxwell's law of induction with no real current present,

$$\oint \vec{B} \cdot d\vec{s} = \mu_0 \epsilon_0 \frac{d\Phi^{\text{elec}}}{dt}, \quad (34-13)$$

by proceeding counterclockwise around the dashed rectangle of Fig. 34-8*b*. Only the long sides of the rectangle contribute to the integral, whose value is

$$\oint \vec{B} \cdot d\vec{s} = -(|\vec{B}| + d|\vec{B}|)h + |\vec{B}|h = -h d|\vec{B}|. \quad (34-14)$$

The flux Φ^{elec} through the rectangle is

$$\Phi^{\text{elec}} = (|\vec{E}|)(h dx), \quad (34-15)$$

where $|\vec{E}|$ is the average magnitude of \vec{E} within the rectangle. Differentiating this expression with respect to t gives

$$\frac{d\Phi^{\text{elec}}}{dt} = h dx \frac{d|\vec{E}|}{dt}.$$

If we substitute this and $\oint \vec{B} \cdot d\vec{s} = -h d|\vec{B}|$ (Eq. 34-14 from above) into Maxwell's law of induction we find that

$$-h d|\vec{B}| = \mu_0 \epsilon_0 \left(h dx \frac{d|\vec{E}|}{dt} \right).$$

Changing to partial-derivative notation as we did before (Eq. 34-9),

$$-\frac{\partial |\vec{B}|}{\partial x} = \mu_0 \epsilon_0 \frac{\partial |\vec{E}|}{\partial t}. \quad (34-16)$$

Again, the minus sign in this equation makes sense because, although \vec{B} is increasing with x at point P in the rectangle in Fig. 34-8*b*, \vec{E} is decreasing with t .

Evaluating this expression by using $\vec{E} = \vec{E}^{\text{max}} \sin(kx - \omega t)$, and $\vec{B} = \vec{B}^{\text{max}} \sin(kx - \omega t)$ (Eqs. 34-2 and 34-3) leads to

$$-k|\vec{B}^{\text{max}}| \cos(kx - \omega t) = -\mu_0 \epsilon_0 \omega |\vec{E}^{\text{max}}| \cos(kx - \omega t),$$

which we can write as

$$\frac{|\vec{E}^{\text{max}}|}{|\vec{B}^{\text{max}}|} = \frac{1}{\mu_0 \epsilon_0 (\omega/k)} = \frac{1}{\mu_0 \epsilon_0 c}.$$

Combining this with $|\vec{E}^{\text{max}}|/|\vec{B}^{\text{max}}| = c$ (Eq. 34-11) leads at once to

$$c = \frac{1}{\sqrt{\mu_0 \epsilon_0}} \quad (\text{wave speed}), \quad (34-17)$$

which is exactly Eq. 34-1.

READING EXERCISE 34-1: The magnetic field \vec{B} through the rectangle of Fig. 34-8a is shown at a different instant in part 1 of the accompanying figure; \vec{B} is directed in the xz plane, parallel to the z axis, and its magnitude is increasing. (a) Complete part 1 by drawing the induced electric fields, indicating both directions and relative magnitudes (as in Fig. 34-8a). (b) For the same instant, complete part 2 of the figure by drawing the electric field of the electromagnetic wave. Also draw the induced magnetic fields, indicating both directions and relative magnitudes (as in Fig. 34-8b).

34-5 Transporting Energy with Electromagnetic Waves

From our experience with capacitors, we know that energy is stored in an electric field. Likewise, from our experience with inductors we know that energy is stored in a magnetic field. So, it makes sense that as an electromagnetic wave moves through space, it carries energy with it. Sunbathers will confirm this hunch. An electromagnetic wave can transport energy and deliver it to a body on which it falls. In this section, we develop an expression that will allow us to quantify the rate per unit area at which energy is transported by an electromagnetic wave. This quantity is a measure of the **intensity** of the electromagnetic wave.

From Chapter 28 on capacitors, we know that the energy per unit area or *energy density* within an electric field is

$$u^{\text{elec}} = \frac{1}{2}\epsilon_0 E^2.$$

Because you also know (from this chapter) that $\vec{E} = c\vec{B}$ and c is such a very large number, you might conclude that the energy associated with the electric field in an electromagnetic wave is much greater than that associated with the magnetic field. That conclusion is incorrect; the densities of the two energies are exactly equal. To show this, we substitute $c\vec{B}$ for \vec{E} ; then we can write

$$u^{\text{elec}} = \frac{1}{2}\epsilon_0 E^2 = \frac{1}{2}\epsilon_0 c^2 B^2.$$

If we now substitute for c with (Eq. 34-1)

$$c = \frac{1}{\sqrt{\epsilon_0 \mu_0}},$$

we get

$$u^{\text{elec}} = \frac{1}{2}\epsilon_0 \frac{1}{\mu_0 \epsilon_0} B^2 = \frac{B^2}{2\mu_0}.$$

In Section 33-3, we found that $B^2/2\mu_0$ is the energy density u^{mag} of a magnetic field \vec{B} . So, we see that $u^{\text{elec}} = u^{\text{mag}}$ everywhere along an electromagnetic wave.

The energy density of the electric field is equal to the energy density of the magnetic field at every instant and for every point along an electromagnetic wave.

The total energy density for the electromagnetic wave is the sum of the energy density associated with the magnet field and the energy density associated with the electric field:

$$u^{\text{tot}} = u^{\text{elec}} + u^{\text{mag}} = \frac{1}{2}\epsilon_0 E^2 + \frac{1}{2\mu_0} B^2.$$

However, since these values are equal to one another, we can also write the total energy density as twice either value:

$$u^{\text{tot}} = 2u^{\text{elec}} = \epsilon_0 E^2$$

or

$$u^{\text{tot}} = 2u^{\text{mag}} = \frac{1}{\mu_0} B^2.$$

This result is quite helpful in developing an expression for the rate of energy (or power) transport across a unit of area perpendicular to the direction of propagation of the electromagnetic wave. At any instant, the **rate of energy transport per unit area** is

$$S = \left(\frac{\text{energy/time}}{\text{area}} \right)^{\text{inst}} = \left(\frac{\text{power}}{\text{area}} \right)^{\text{inst}} \quad (\text{instantaneous}). \quad (34-18)$$

Note that from this we can see that the SI unit for S must be the watt per square meter (W/m^2). Since an electromagnetic wave moves with a speed c , in a time period Δt , the wave travels a distance $c \Delta t$. During that motion, if it passes through a surface of some area A , the volume of space through which the wave passes is $c \Delta t A$. The total energy transported by the wave is the total energy density (electric and magnetic) multiplied by this volume. That is, the total energy (U) transported by the wave to an area A in a time period Δt is

$$U = u^{\text{tot}} c \Delta t A,$$

where

$$u^{\text{tot}} = \epsilon_0 E^2.$$

Hence,

$$U = \epsilon_0 E^2 c \Delta t A.$$

As expressed by Eq. 34-18 above, the rate of energy transport is this total energy transported divided by the area through which the wave travels and the time period. That is,

$$S = \frac{\epsilon_0 E^2 c \Delta t A}{\Delta t A} = \epsilon_0 E^2 c.$$

Since $c^2 = 1/\epsilon_0 \mu_0$, we can multiply this expression by one in the form of $c^2 \epsilon_0 \mu_0$. This gives an alternative expression for the instantaneous energy flow rate:

$$S = \frac{1}{c \mu_0} E^2 = \epsilon_0 c E^2 \quad (\text{instantaneous energy flow rate}). \quad (34-19)$$

By substituting $\vec{E} = \vec{E}^{\text{max}} \sin(kx - \omega t)$ into Eq. 34-19, we could obtain an equation for the energy transport rate as a function of time. More useful in practice, however, is the average energy transported over time. For that, we need to find the time-averaged value of S , written $\langle S \rangle$. We call this quantity the **intensity** I of the wave. Thus the intensity I is

$$I = \langle S \rangle = \left\langle \frac{\text{energy/time}}{\text{area}} \right\rangle = \left\langle \frac{\text{power}}{\text{area}} \right\rangle. \quad (34-20)$$

With $S = E^2/c\mu_0$ (Eq. 34-19), we find

$$I = \langle S \rangle = \frac{1}{c\mu_0} \langle E^2 \rangle = \frac{1}{c\mu_0} \langle (E^{\max})^2 \sin^2(kx - \omega t) \rangle. \quad (34-21)$$

Over a full cycle, the average value of $\sin^2 \theta$, for any angular variable θ , is $\frac{1}{2}$. In addition, we define a new quantity E^{rms} , the root-mean-square value of the electric field magnitude as

$$E^{\text{rms}} \equiv \frac{E^{\max}}{\sqrt{2}}. \quad (34-22)$$

We can then rewrite Eq. 34-21 as

$$I = \frac{1}{c\mu_0} (E^{\text{rms}})^2. \quad (34-23)$$

If we combine the ideas that we have developed above for the rate of energy transported by an electromagnetic wave per unit area with knowledge of the direction in which the wave is traveling, we can define a vector \vec{S} that describes both the energy transport rate S and the direction in which the transfer is occurring. This vector is an important quantity, so we give it a name. It is called the **Poynting vector** after John Henry Poynting (1852–1914), who first discussed its properties.

The direction of the Poynting vector \vec{S} of an electromagnetic wave at any point gives the wave's direction of travel and so the direction of energy transport at that point.

We can combine everything that we have developed in this section into a single expression defining the Poynting vector \vec{S} as

$$\vec{S} = \frac{1}{\mu_0} \vec{E} \times \vec{B} \quad (\text{instantaneous Poynting vector}), \quad (34-24)$$

where magnitude $|\vec{S}|$ of the Poynting vector is the instantaneous intensity of the electromagnetic wave. \vec{E} and \vec{B} are perpendicular to each other in an electromagnetic wave. Hence, the magnitude of $\vec{E} \times \vec{B}$ is $|\vec{E}||\vec{B}|$. Since $|\vec{E}| = c|\vec{B}|$, this is consistent with the expression that we developed above,

$$S = |\vec{S}| = \frac{1}{c\mu_0} E^2,$$

for the magnitude of energy transport rate. You can confirm for yourself that the cross product gives the correct direction for the wave propagation, and hence for the energy transport.

Variation of Intensity with Distance

The intensity variation of electromagnetic radiation with distance is often complex—especially when the source beams the radiation in a particular direction (like a searchlight at a movie premiere). We know that as a wavefront spreads out over a wider surface, its energy density must diminish, but how? Let's consider the simplest case we can imagine. Assume that the source is a *point source* that emits the light **isotropically**—

FIGURE 34-9 ■ A point source S emits electromagnetic waves uniformly in all directions. The spherical wavefronts pass through an imaginary sphere of radius r that is centered on S .

that is, with equal intensity in all directions. The spherical wavefronts spreading from such an isotropic point source S at a particular instant are shown in cross section in Fig. 34-9.

In a vacuum there is no mechanism for dissipation of energy, so it is conserved. Let us center an imaginary sphere of radius r on the source, as shown in Fig. 34-9. All the energy emitted by the source must pass through the sphere. Thus, the rate at which energy is transferred through the sphere by the radiation must equal the rate at which energy is emitted by the source—that is, the power P_s of the source. The intensity I (= power/area) at the sphere must then be

$$I = \frac{P_s}{4\pi r^2}, \quad (34-25)$$

where $4\pi r^2$ is the area of the sphere. This expression tells us that the intensity of the electromagnetic radiation from an isotropic point source decreases with the square of the distance r from the source.

Since from Eq. 34-23 we also know

$$I = \frac{1}{c\mu_0}(E^{\text{rms}})^2,$$

we can equate these two expressions to give

$$\frac{P_s}{4\pi r^2} = \frac{(E^{\text{rms}})^2}{c\mu_0},$$

or

$$(E^{\text{rms}})^2 = \frac{c\mu_0 P_s}{4\pi r^2}.$$

Simplification gives the relationship between the average electric field E^{rms} for a radiating charge, the power of the source P_s and the distance from the source r :

$$E^{\text{rms}} = \sqrt{\frac{c\mu_0 P_s}{4\pi}} \frac{1}{r}. \quad (34-26)$$

This equation tells us that the electric field associated with an isotropic radiation point source falls off as $1/r$, rather than as $1/r^2$ as it does for a static electric field.

READING EXERCISE 34-2: The figure gives the electric field of an electromagnetic wave at a certain point and a certain instant. The wave is transporting energy in the negative z direction. What is the direction of the magnetic field of the wave at that point and instant?

TOUCHSTONE EXAMPLE 34-1: Isotropic Light Source

As we stated in the introduction, visible light is now known to consist of electromagnetic waves. An observer is 1.8 m from an isotropic point light source whose power P_s is 250 W. Calculate the rms values of the electric and magnetic fields due to the source at the position of the observer.

SOLUTION ■ The first two **Key Ideas** here are these:

1. The rms value E^{rms} of the electric field in light is related to the intensity I of the light by $I = (E^{\text{rms}})^2/c\mu_0$.

2. Because the source is a point source emitting light with equal intensity in all directions, the intensity I at any distance r from the source is related to the source's power P_s via Eq. 34-25 ($I = P_s/4\pi r^2$).

Putting these two ideas together gives us

$$I = \frac{P_s}{4\pi r^2} = \frac{(E^{\text{rms}})^2}{c\mu_0},$$

which leads to

$$\begin{aligned} E^{\text{rms}} &= \sqrt{\frac{P_s c \mu_0}{4\pi r^2}} \\ &= \sqrt{\frac{(250 \text{ W})(3.00 \times 10^8 \text{ m/s})(4\pi \times 10^{-7} \text{ H/m})}{(4\pi)(1.8 \text{ m})^2}} \\ &= 48.1 \text{ V/m} \approx 48 \text{ V/m}. \end{aligned} \quad (\text{Answer})$$

The third **Key Idea** here is that magnitudes of the electric field and magnetic field of an electromagnetic wave at any instant and at any point in the wave are related by the speed of light c

according to Eq. 34-12 ($|\vec{E}|/|\vec{B}| = c$). Thus, the rms values of those fields are also related by Eq. 34-12 and we can write

$$\begin{aligned} B^{\text{rms}} &= \frac{E^{\text{rms}}}{c} \\ &= \frac{48.1 \text{ V/m}}{3.00 \times 10^8 \text{ m/s}} \\ &= 1.6 \times 10^{-7} \text{ T}. \end{aligned} \quad (\text{Answer})$$

Note that E^{rms} ($= 48 \text{ V/m}$) is appreciable as judged by ordinary laboratory standards, but B^{rms} ($= 1.6 \times 10^{-7} \text{ T}$) is quite small. This difference helps to explain why most instruments used for the detection and measurement of electromagnetic waves are designed to respond to the electric component of the wave. It is wrong, however, to say that the electric component of an electromagnetic wave is “stronger” than the magnetic component. You cannot compare quantities that are measured in different units. As we have seen, the electric and magnetic components are on an equal basis as far as the propagation of the wave is concerned, because their average energies, which can be compared, are exactly equal.

34-6 Radiation Pressure

Electromagnetic waves carry linear momentum as well as energy. This means that we can exert a pressure—a **radiation pressure**—on an object by shining light on it. However, the pressure must be very small because, for example, you do not feel a camera flash pushing on you when it is used to take your photograph.

To see how Maxwell related radiation pressure to light intensity, let us shine a beam of electromagnetic radiation—visible light, for example—on an object for a time interval Δt . Further, let us assume that the object is free to move and that the radiation is entirely **absorbed** (taken up) by the object. This means that during the interval Δt , the object gains an energy ΔU from the radiation. Maxwell showed that the object also gains linear momentum. As usual we can represent momentum with a lowercase p and an object's momentum change as $\Delta \vec{p} = \vec{p}_2 - \vec{p}_1$. The magnitude $|\Delta \vec{p}|$ of the momentum change of the object is related to the energy change ΔU by

$$|\Delta \vec{p}| = \frac{\Delta U}{c} \quad (\text{total absorption}), \quad (34-27)$$

where c is the speed of light. The direction of the momentum change of the object is the direction of the incident (incoming) beam that the object absorbs.

Instead of being absorbed, the radiation can be reflected by the object; that is, the radiation can be sent off in a new direction as if it bounced off the object. If the radiation is entirely reflected back along its original path, the magnitude of the momentum change of the object is twice that given above, or

$$|\Delta \vec{p}| = \frac{2 \Delta U}{c} \quad (\text{total reflection back along path}). \quad (34-28)$$

In the same way, an object undergoes twice as much momentum change when a perfectly elastic tennis ball is bounced from it as when it is struck by a perfectly inelastic

ball (a lump of wet putty, say) of the same mass and velocity. If the incident radiation is partly absorbed and partly reflected, the momentum change of the object is between $\Delta U/c$ and $2 \Delta U/c$.

From Newton's Second Law, we know that a change in momentum is related to a force by

$$\vec{F} = \frac{|\Delta\vec{p}|}{\Delta t}. \quad (34-29)$$

To find expressions for the force exerted by radiation in terms of the intensity I of the radiation, suppose that a flat surface of area A , perpendicular to the path of the radiation, intercepts the radiation. In time interval Δt , the energy intercepted by area A is

$$\Delta U = IA \Delta t. \quad (34-30)$$

If the energy is completely absorbed, then Eq. 34-27 tells us that $|\Delta\vec{p}| = IA \Delta t/c$. Then with $\vec{F} = |\Delta\vec{p}|/\Delta t$ (Eq. 34-29), the magnitude of the force on the area A is

$$|\vec{F}| = \frac{IA}{c} \quad (\text{total absorption}). \quad (34-31)$$

Similarly, if the radiation is totally reflected back along its original path, Eq. 34-28 tells us that $|\Delta\vec{p}| = 2IA \Delta t/c$ and, from Eq. 34-29,

$$|\vec{F}| = \frac{2IA}{c} \quad (\text{total reflection back along path}). \quad (34-32)$$

If the radiation is partly absorbed and partly reflected, the magnitude of the force on area A is between the values of IA/c and $2IA/c$.

The force per unit area on an object due to radiation is the radiation pressure P . (Note that we represent pressure, as usual, with a capital P .) We can find the pressure for total absorption and total reflection by dividing both sides of each equation (34-31 and 34-32) by A . We obtain

$$P^{\text{absorp}} = \frac{I}{c} \quad (\text{pressure for total wave absorption}), \quad (34-33)$$

and
$$P^{\text{refl}} = \frac{2I}{c} \quad (\text{pressure for total wave reflection back along path}). \quad (34-34)$$

Just as with fluid pressure in Chapter 15, the SI unit of radiation pressure is the pascal (Pa) which equals a newton per square meter (N/m^2).

The development of laser technology has permitted researchers to achieve radiation pressures much greater than, say, that due to a camera flashlamp. This comes about because a beam of laser light—unlike a beam of light from a small lamp filament—can be focused to a tiny spot only a few wavelengths in diameter. This permits the delivery of great amounts of energy and momentum to small objects placed at that spot.

READING EXERCISE 34-3: Light of uniform intensity shines perpendicularly on a totally absorbing surface, fully illuminating the surface. If the area of the surface is decreased, do (a) the radiation pressure and (b) the radiation force on the surface increase, decrease, or stay the same? ■

TOUCHSTONE EXAMPLE 34-2: Comet Dust

When dust is released by a comet, it does not continue along the comet's orbit because radiation pressure from sunlight pushes it radially outward from the Sun. Assume that a dust particle is spherical with radius R , has density $\rho = 3.5 \times 10^3 \text{ kg/m}^3$, and totally absorbs the sunlight it intercepts. For what value of R does the gravitational force \vec{F}^{grav} on the dust particle due to the Sun just balance the radiation force \vec{F}^{rad} on it from the sunlight?

SOLUTION ■ We can assume that the Sun is far enough from the particle to act as an isotropic point source of light. Then because we are told that the radiation pressure pushes the particle radially outward from the Sun, we know that the radiation force \vec{F}^{rad} on the particle is directed radially outward from the center of the Sun. At the same time, the gravitational force \vec{F}^{grav} on the particle is directed radially inward toward the center of the Sun. Thus, we can write the balance of these two forces as

$$|\vec{F}^{\text{rad}}| = |\vec{F}^{\text{grav}}|. \quad (34-35)$$

Let us consider these forces separately.

Radiation force: To evaluate the left side of Eq. 34-35, we use these three **Key Ideas**.

1. Because the particle is totally absorbing, the force magnitude $|\vec{F}^{\text{rad}}|$ can be found from the intensity I of sunlight at the particle's location and the particle's cross-sectional area A , via Eq. 34-31 ($|\vec{F}| = IA/c$).
2. Because we assume that the Sun is an isotropic point source of light, we can use Eq. 34-25 ($I = P_{\text{sun}}/4\pi r^2$) to relate the Sun's power P_{sun} to the intensity I of the sunlight at the particle's distance r from the Sun.
3. Because the particle is spherical, its cross-sectional area A is πR^2 (not half its surface area).

Putting these three ideas together gives us

$$|\vec{F}^{\text{rad}}| = \frac{IA}{c} = \frac{P_{\text{sun}} \pi R^2}{4\pi r^2 c} = \frac{P_{\text{sun}} R^2}{4r^2 c}. \quad (34-36)$$

Gravitational force: The **Key Idea** here is Newton's law of gravitation (Eq. 14-2), which gives us the magnitude of the gravitational force on the particle as

$$|\vec{F}^{\text{grav}}| = \frac{GM_{\text{sun}} m}{r^2}, \quad (34-37)$$

where M_{sun} is the Sun's mass and m is the particle's mass. Next, the particle's mass is related to its density ρ and volume V ($= \frac{4}{3}\pi R^3$, for a sphere) by

$$\rho = \frac{m}{V} = \frac{m}{\frac{4}{3}\pi R^3}.$$

Solving this for m and substituting the result into Eq. 34-37 give us

$$|\vec{F}^{\text{grav}}| = \frac{GM_{\text{sun}} \rho \left(\frac{4}{3}\pi R^3\right)}{r^2}. \quad (34-38)$$

Then substituting Eqs. 34-36 and 34-38 into Eq. 34-35 and solving for R yield

$$R = \frac{3P_{\text{sun}}}{16\pi c \rho GM_{\text{sun}}}.$$

Using the given value of ρ and the known values of G (Appendix B) and M_{sun} (Appendix C), we can evaluate the denominator:

$$\begin{aligned} (16\pi)(3 \times 10^8 \text{ m/s})(3.5 \times 10^3 \text{ kg/m}^3) \\ \times (6.67 \times 10^{-11} \text{ N} \cdot \text{m}^2/\text{kg}^2)(1.99 \times 10^{30} \text{ kg}) \\ = 7.0 \times 10^{33} \text{ N/s}. \end{aligned}$$

Using P_{sun} from Appendix C, we then have

$$R = \frac{(3)(3.9 \times 10^{26} \text{ W})}{7.0 \times 10^{33} \text{ N/s}} = 1.7 \times 10^{-7} \text{ m}. \quad (\text{Answer})$$

Note that this result is independent of the particle's distance r from the Sun.

Dust particles with radius $R \approx 1.7 \times 10^{-7} \text{ m}$ follow an approximately straight path like path b in Fig. 34-10. For larger values of R , comparison of Eqs. 34-36 and 34-38 shows that, because \vec{F}^{grav} varies with R^3 and \vec{F}^{rad} varies with R^2 , the gravitational force \vec{F}^{grav} dominates the radiation force \vec{F}^{rad} . Thus, such particles follow a path that is curved toward the Sun like path c in Fig. 34-10. Similarly, for smaller values of R , the radiation force dominates, and the dust follows a path that is curved away from the Sun like path a . The composite of these dust particles is the dust tail of the comet.

FIGURE 34-10 ■ A comet is now at position 6. Dust it has released at five previous positions has been pushed outward by radiation pressure from sunlight, has taken the dashed paths, and now forms the comet's curved dust tail. Its ion tail points directly away from the Sun.

FIGURE 34-11 (a) The plane of oscillation of a polarized electromagnetic wave. (b) To represent the polarization, we view the plane of oscillation “head-on” and indicate the possible directions of the oscillating electric field with two arrows, which we refer to as a “double arrow.”

FIGURE 34-12 Unpolarized light consists of waves with randomly directed electric fields. Here the waves are all traveling along the same axis, directly out of the page, and all have the same amplitude $|\vec{E}|$.

FIGURE 34-13 Unpolarized light becomes polarized when it is sent through a polarizing sheet. The polarization is then parallel to the polarizing axis of the sheet.

34-7 Polarization

At the beginning of the chapter we talked about a charge oscillating along a line. We observed that the charge’s oscillation produced kinks in its field lines that are interpreted as wavefronts. We noted that the electric field in the kink was perpendicular to the direction of the propagation and pointed along the line of oscillation of the charge. This means that the electric field in the outgoing wave points back and forth in a single direction. It doesn’t wander around pointing in all directions as it would if the electromagnetic wave was the result of many charges oscillating in many different directions. We call such a wave **polarized**. This is an important concept since many of our sources of radiation—such as antennas—impart this property.

Figure 34-11a shows an electromagnetic wave with its electric field oscillating parallel to the vertical y axis. The plane containing the \vec{E} vectors is called the **plane of oscillation** of the wave (hence, the wave is said to be *plane-polarized* parallel to the y axis). We can represent the wave’s polarization (state of being polarized) by showing the direction of the electric field oscillations in a “head-on” view of the plane of oscillation, as in Fig. 34-11b. The two vertical arrows in that figure indicate that as the wave travels past us, its electric field oscillates vertically, continuously changing between being directed up and down along the y axis. VHF (very high frequency) television antennas in England are oriented vertically, but those in North America are horizontal. The difference is due to the direction of oscillation of the electromagnetic waves carrying the TV signal. In England, the transmitting equipment is designed to produce waves that are polarized vertically; that is, their electric field oscillates vertically. Thus, for the electric field of the incident television waves to drive a current along an antenna (and provide a signal to a television set), the antenna must be vertical. In North America, the antenna must be horizontal.

Polarized Light

The electromagnetic waves emitted by a television station all have the same polarization because they are generated by electrons moving up and down (or right and left) along a transmission antenna. On the other hand, electromagnetic waves emitted by any common source of *light* (such as the Sun or a lightbulb) are generated by the individual atoms or molecules that comprise the light source. The fact that light is generated by individual atoms or molecules within an object means that there is no preferred *orientation* associated with the electromagnetic waves that make up the light emerging from a source, even in cases where there is a preferred direction of travel.

We call electromagnetic waves with random orientations (like the light produced by atoms and molecules in the sun) **randomly polarized** or **unpolarized**. This is because the direction of the electric field at a given point in space changes direction quickly and randomly. It is still perpendicular to both the direction of travel of the wave and the magnetic field vector on a moment by moment basis, but its orientation in space changes continuously. Figure 34-12 shows an unpolarized electromagnetic wave traveling into or out of the page. If we try to represent a head-on view of the oscillations over some time period, we do not have a simple drawing with a single double arrow like that of Fig. 34-11b; instead we have a mess of double arrows like that in Fig. 34-12.

We can (and often do) transform randomly polarized (or unpolarized) visible light into polarized light by sending it through a *polarizing sheet*, as is shown in Fig. 34-13. Such sheets, commercially known as Polaroids or Polaroid filters, were invented in 1932 by Edwin Land while he was an undergraduate student. A polarizing sheet consists of certain long molecules embedded in plastic. When the sheet is manufactured, it is

stretched to align the long molecules in parallel rows, like rows in a plowed field. When light is then sent through the sheet, electric field components perpendicular to the long molecules pass through the sheet, while components parallel to the long molecules are absorbed and disappear.

This is not surprising. The electrons surrounding long molecules are more free to move up and down along the molecular axis and absorb the radiation. Those perpendicular to the long axis are not as free to oscillate. We shall not dwell on the orientation of the molecules but, instead, shall assign a *polarizing axis* to the sheet, along which electric field components are passed:

An electric field component parallel to the polarizing axis is passed (*transmitted*) by a polarizing sheet; a component perpendicular to it is absorbed.

Thus, the electric field of the light emerging from the sheet consists of only the components that are parallel to the polarizing axis of the sheet. Hence, the light is polarized in that direction. In Fig. 34-13, the vertical electric field components are transmitted by the sheet; the horizontal components are absorbed. The transmitted waves are then vertically polarized.

In some situations, light is **partially polarized** (its field oscillations are not completely random as in Fig. 34-12 nor are they parallel to a single axis as in Fig. 34-11*b*). Partially polarized light can be viewed as a superposition of plane polarized and unpolarized light waves.

Intensity of Transmitted Polarized Light

We now consider the intensity of light transmitted by a polarizing sheet. We start with unpolarized light, whose electric field oscillations we can resolve into y - and z -components as represented in Fig. 34-12*b*. Further, we can arrange for the y axis to be parallel to the polarizing direction of the sheet. Then only the y -components of the light's electric field are passed by the sheet; the z -components are absorbed. As suggested by Fig. 34-12*b*, if the original waves are randomly oriented, the sum of the y -components and the sum of the z -components are equal. When the z -components are absorbed, half the original intensity I_0 of the light is lost. The intensity I of the emerging polarized light is then

$$I = \frac{1}{2}I_0. \quad (34-39)$$

Let us call this the *one-half rule*; we can use it *only* when the light reaching a polarizing sheet is unpolarized.

Suppose now that the light reaching a polarizing sheet is already polarized. Figure 34-14 shows a polarizing sheet in the plane of the page and the electric field \vec{E} of such a polarized light wave traveling toward the sheet (and thus prior to any absorption). We can resolve \vec{E} into two components relative to the polarizing axis of the sheet: parallel component E_y , is transmitted by the sheet, and perpendicular component E_z is absorbed. Since θ is the angle between \vec{E} and the polarizing axis of the sheet, the transmitted parallel component is

$$E_y = |\vec{E}|\cos\theta. \quad (34-40)$$

Recall that the intensity of an electromagnetic wave (such as our light wave) is proportional to the square of the electric field's magnitude $I = (E^{\text{rms}})^2/c\mu_0$ (Eq. 34-23). In our present case then, the intensity I of the emerging wave is proportional to E_y^2 and

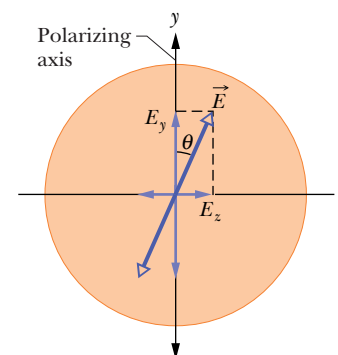

FIGURE 34-14 ■ Polarized light approaching a polarizing sheet. The electric field \vec{E} of the light can be resolved into components E_y (parallel to the polarizing axis of the sheet) and E_z (perpendicular to that axis). Component E_y will be transmitted by the sheet; component E_z will be absorbed. *Note:* The long molecules are oriented perpendicular to the polarizing axis.

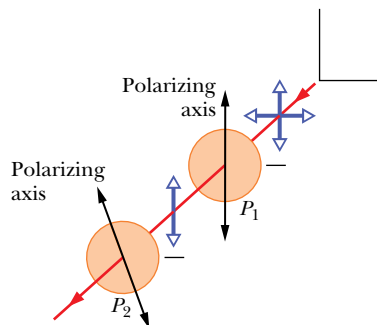

FIGURE 34-15 ■ The light transmitted by polarizing sheet P_1 is vertically polarized, as represented by the vertical double arrow. The amount of that light that is then transmitted by polarizing sheet P_2 depends on the angle between the polarization axis of that light and the polarizing axis of P_2 .

the intensity I_0 of the original wave is proportional to \vec{E}^2 . Hence, from $E_y = |\vec{E}|\cos\theta$ (Eq. 34-40) we can write $I/I_0 = \cos^2\theta$, or

$$I = I_0 \cos^2\theta \quad (\text{Malus' law}). \quad (34-41)$$

This expression was first introduced in the nineteenth century by Étienne Malus, a French mathematician who studied polarized light. So, Eq. 34-41 is called Malus' law or the *cosine-squared rule*. We can use it *only* when the light reaching a polarizing sheet is already polarized. Then the transmitted intensity I is a maximum and is equal to the original intensity I_0 when the original wave is polarized parallel to the polarizing axis of the sheet (when θ in Eq. 34-41 is 0° or 180°). I is zero when the original wave is polarized perpendicular to the polarizing axis of the sheet (when θ is 90°).

Figure 34-15 shows an arrangement in which initially unpolarized light is sent through two polarizing sheets P_1 and P_2 . (Often, the first sheet is called the *polarizer*, and the second the *analyzer*.) Because the polarizing axis of P_1 is vertical, the light transmitted by P_1 to P_2 is polarized vertically. If the polarizing axis of P_2 is also vertical, then all the light transmitted by P_1 is transmitted by P_2 . If the polarizing axis of P_2 is horizontal, none of the light transmitted by P_1 is transmitted by P_2 . We reach the same conclusions by considering only the *relative* orientations of the two sheets: If their polarizing axes are parallel, all the light passed by the first sheet is passed by the second sheet. If those axes are perpendicular (the sheets are said to be *crossed*), no light is passed by the second sheet. These two extremes are displayed with polarized sunglasses in Fig. 34-16.

Finally, if the two polarizing axes of Fig. 34-15 make an angle between 0° and 90° , some of the light transmitted by P_1 will be transmitted by P_2 . The intensity of that light is determined by $I = I_0 \cos^2\theta$ (Eq. 34-41).

Light can be polarized by means other than polarizing sheets, such as by reflection (discussed in Section 34-10) and by scattering from atoms or molecules. In *scattering*, light that is intercepted by an object, such as a molecule, is sent off in many, perhaps random, directions. An example is the scattering of sunlight by molecules in the atmosphere, which gives the sky its general glow.

Although direct sunlight is unpolarized, light from much of the sky is at least partially polarized by such scattering. Bees use the polarization of sky light in navigating to and from their hives. Similarly, the Vikings used it to navigate across the North Sea when the daytime Sun was below the horizon (because of the high latitude of the North Sea). These early seafarers had discovered certain crystals (now called cordierite) that changed color when rotated in polarized light. By looking at the sky through such a crystal while rotating it about their line of sight, they could locate the hidden Sun and thus determine which way was south.

FIGURE 34-16 ■ Polarizing sunglasses consist of sheets whose polarizing axes are vertical when the sunglasses are worn. (a) Overlapping sunglasses transmit light fairly well when their polarizing axes have the same orientation, but (b) they block most of the light when they are crossed.

TOUCHSTONE EXAMPLE 34-3: Polarizing Sheets

Figure 34-17 shows a system of three polarizing sheets in the path of initially unpolarized light. The polarizing axis of the first sheet is parallel to the y axis, that of the second sheet is 60° counterclockwise from the y axis, and that of the third sheet is parallel to the x axis. What fraction of the initial intensity I_0 of the light emerges from the system, and how is that light polarized?

SOLUTION ■ The **Key Ideas** here are these:

1. We work through the system sheet by sheet, from the first one encountered by the light to the last one.
2. To find the intensity transmitted by any sheet, we apply either the one-half rule or the cosine-squared rule, depending on whether the light reaching the sheet is unpolarized or already polarized.
3. The light that is transmitted by a polarizing sheet is always polarized parallel to the polarizing axis of the sheet.

First sheet: The original light wave is represented in Fig. 34-17*b*, using the head-on, double-arrow representation of Fig. 34-11*b*. Be-

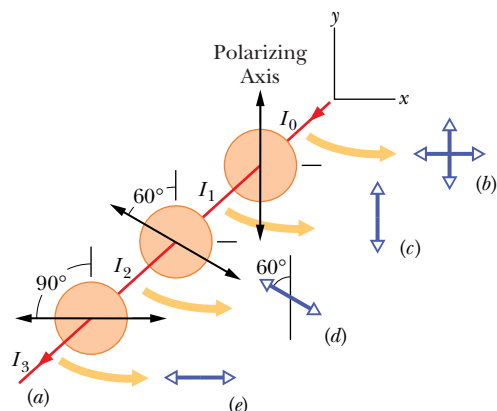

FIGURE 34-17 ■ (a) Initially unpolarized light of intensity I_0 is sent into a system of three polarizing sheets. The intensities I_1 , I_2 , I_3 of the light transmitted by the sheets are labeled. Shown also are the polarizations, from head-on views, of (b) the initial light and the light transmitted by (c) the first sheet, (d) the second sheet, and (e) the third sheet.

cause the light is initially unpolarized, the intensity I_1 of the light transmitted by the first sheet is given by the one-half rule (Eq. 34-39):

$$I_1 = \frac{1}{2}I_0.$$

Because the polarizing axis of the first sheet is parallel to the y axis, the polarization of the light transmitted by it is also, as shown in the head-on view of Fig. 34-17*c*.

Second sheet: Since the light reaching the second sheet is polarized, the intensity I_2 of the light transmitted by that sheet is given by the cosine-squared rule (Eq. 34-41). The angle θ in the rule is the angle between the polarization axis of the entering light (parallel to the y axis) and the polarizing axis of the second sheet (60° counterclockwise from the y axis), and so θ is 60° . Then

$$I_2 = I_1 \cos^2 60^\circ.$$

The polarization of this transmitted light is parallel to the polarizing axis of the sheet transmitting it—that is, 60° counterclockwise from the y axis, as shown in the head-on view of Fig. 34-17*d*.

Third sheet: Because the light reaching the third sheet is polarized, the intensity I_3 of the light transmitted by that sheet is given by the cosine-squared rule. The angle θ is now the angle between the polarization axis of the entering light (Fig. 34-17*d*) and the polarizing axis of the third sheet (parallel to the x axis), and so $\theta = 30^\circ$. Thus,

$$I_3 = I_2 \cos^2 30^\circ.$$

This final transmitted light is polarized parallel to the x axis (Fig. 34-17*e*). We find its intensity by substituting first for I_2 and then for I_1 in the equation above:

$$\begin{aligned} I_3 &= I_2 \cos^2 30^\circ = (I_1 \cos^2 60^\circ) \cos^2 30^\circ \\ &= \left(\frac{1}{2}I_0\right) \cos^2 60^\circ \cos^2 30^\circ = 0.094I_0. \end{aligned}$$

Thus, $\frac{I_3}{I_0} = 0.094$. (Answer)

That is to say, 9.4% of the initial intensity emerges from the three-sheet system.

If we now remove the second sheet, what fraction of the initial intensity emerges from the system?

34-8 Maxwell's Rainbow

In Maxwell's time (the mid-1800s), the visible, infrared, and ultraviolet forms of light were the only electromagnetic waves known. Spurred on by Maxwell's work, however, Heinrich Hertz discovered what we now call radio waves and verified that they move through the laboratory at the same speed as visible light.

As Fig. 34-18 shows, we now know a wide *spectrum* (or range) of electromagnetic waves, referred to by one imaginative writer as “Maxwell's rainbow” but generally referred to as “light” or “electromagnetic radiation” by physicists.

FIGURE 34-18 ■ The electromagnetic spectrum.

Consider the extent to which we are bathed in electromagnetic waves throughout this spectrum. The Sun, whose radiations define the environment in which we as a species have evolved and adapted, is the dominant source. We are also crisscrossed by radio, television and cellular phone signals. Microwaves from radar systems and from telephone relay systems may reach us. There are electromagnetic waves from lightbulbs, from the heated engine blocks of automobiles, from x-ray machines, from lightning flashes, and from buried radioactive materials. Beyond this, radiation reaches us from stars and other objects in our galaxy and from other galaxies. Electromagnetic waves also travel in the other direction. Television signals, transmitted from the Earth since about 1950, have now transmitted news about us (along with episodes of *I Love Lucy*) to whatever technically sophisticated inhabitants there may be on the planets that encircle the nearest 400 or so stars.

In the wavelength scale in Fig. 34-18 (and similarly the corresponding frequency scale), each scale marker represents a change in wavelength (and correspondingly in frequency) by a factor of 10. The scale is open-ended; the wavelengths of electromagnetic waves have no inherent upper or lower bounds.

There are many regions of the electromagnetic spectrum in Fig. 34-18, including radio waves, infrared light produced by the thermal motion of charged particles, visible and ultraviolet light emitted by energetic atoms, x rays that are generated when charged particles collide with solid matter, and gamma rays that originate inside atomic nuclei. These regions denote roughly defined wavelength ranges within which certain kinds of sources and detectors of electromagnetic waves are in common use. Other regions of Fig. 34-18, such as those labeled television and AM radio, represent specific wavelength bands assigned by law for certain commercial or other purposes. There are no gaps in the electromagnetic spectrum—and all electromagnetic waves, no matter where they lie in the spectrum, travel through *free space* (vacuum) with the same speed c .

The visible region of the spectrum is of course of particular interest to us. Figure 34-19 shows the relative sensitivity of the human eye to visible light of various wavelengths. The center of the visible region is about 555 nm, which produces the sensation that we call yellow-green.

FIGURE 34-19 ■ The relative sensitivity of the average human eye to electromagnetic waves at different wavelengths. This portion of the electromagnetic spectrum to which the eye is sensitive is called visible light.

The limits of this visible spectrum are not well defined because the eye sensitivity curve approaches the zero-sensitivity line asymptotically at both long and short wavelengths. If we take the limits, arbitrarily, as the wavelengths at which eye sensitivity has dropped to 1% of its maximum value, these limits are about 430 and 690 nm. However, the eye can detect electromagnetic waves somewhat beyond these limits if they are intense enough.

Problems

SEC. 34-3 ■ THE GENERATION OF ELECTROMAGNETIC WAVES

- 1. What Inductance** What inductance must be connected to a 17 pF capacitor in an oscillator capable of generating 550 nm (i.e., visible) electromagnetic waves? Comment on your answer.
- 2. Wavelength** What is the wavelength of the electromagnetic wave emitted by the oscillator–antenna system of Fig. 34-4 if $L = 0.253 \mu\text{H}$ and $C = 25.0 \text{ pF}$?

SEC. 34-4 ■ DESCRIBING ELECTROMAGNETIC WAVE PROPERTIES MATHEMATICALLY

- 3. Electric Field** The electric field of a certain plane electromagnetic wave is given by $E_x = 0$; $E_y = 0$; $E_z = (2.0 \text{ V/m}) \cos[(\pi \times 10^{15} \text{ s}^{-1})(t - x/c)]$, with $c = 3.0 \times 10^8 \text{ m/s}$. The wave is propagating in the positive x direction. Write expressions for the components of the magnetic field of the wave.
- 4. Plane Wave** A plane electromagnetic wave has a maximum electric field of $3.20 \times 10^{-4} \text{ V/m}$. Find the maximum magnetic field.

SEC. 34-5 ■ TRANSPORTING ENERGY WITH ELECTROMAGNETIC WAVES

- 5. Neodymium–Glass Lasers** Some neodymium–glass lasers can provide 100 terawatts of power in 1.0 ns pulses at a wavelength of $0.26 \mu\text{m}$. How much energy is contained in a single pulse?
- 6. Poynting Vector** Show, by finding the direction of the Poynting vector \vec{S} , that the directions of the electric and magnetic fields at all points in Figs. 34-6 to 34-8 are consistent at all times with the assumed directions of propagation.
- 7. Radiation Emitted** The radiation emitted by a laser spreads out in the form of a narrow cone with circular cross section. The angle θ of the cone (see Fig. 34-20) is called the *full-angle beam divergence*. An argon laser, radiating at 514.5 nm, is aimed at the Moon in a ranging experiment. If the beam has a full-angle beam divergence of $0.880 \mu\text{rad}$, what area on the Moon's surface is illuminated by the laser?

FIGURE 34-20 ■ Problem 7.

- 8. Closest Neighbor** Our closest stellar neighbor, Proxima Centauri, is 4.3 lightyears away. It has been suggested that TV programs from our planet have reached this star and may have been viewed by the hypothetical inhabitants of a hypothetical planet orbiting it. Suppose a television station on Earth has a power of 1.0 MW. What is the intensity of its signal at Proxima Centauri?

- 9. Plane Radio Wave** In a plane radio wave the maximum value of the electric field component is 5.00 V/m. Calculate (a) the maximum value of the magnetic field component and (b) the wave intensity.

- 10. Intensity** What is the intensity of a plane traveling electromagnetic wave if $|\vec{B}^{\text{max}}|$ is $1.0 \times 10^{-4} \text{ T}$?

- 11. Maximum Electric Field** The maximum electric field at a distance of 10 m from anisotropic point light source is 2.0 V/m. What are (a) the maximum value of the magnetic field and (b) the average intensity of the light there? (c) What is the power of the source?

- 12. Sunlight** Sunlight just outside the Earth's atmosphere has an intensity of 1.40 kW/m^2 . Calculate $|\vec{E}^{\text{max}}|$ and $|\vec{B}^{\text{max}}|$ for sunlight there, assuming it to be a plane wave.

- 13. An Airplane** An airplane flying at a distance of 10 km from a radio transmitter receives a signal of intensity $10 \mu\text{W/m}^2$. Calculate (a) the amplitude of the electric field at the airplane due to this signal, (b) the amplitude of the magnetic field at the airplane, and (c) the total power of the transmitter, assuming the transmitter to radiate uniformly in all directions.

- 14. Frank Drake** Frank D. Drake, an investigator in the SETI (Search for Extra-Terrestrial Intelligence) program, once said that the large radio telescope in Arecibo, Puerto Rico, "can detect a signal which lays down on the entire surface of the earth a power of only one picowatt." (a) What is the power that would be received by the Arecibo antenna for such a signal? The antenna diameter is 300 m. (b) What would be the power of a source at the center of our galaxy that could provide such a signal? The galactic center is $2.2 \times 10^4 \text{ ly}$ away. Take the source as radiating uniformly in all directions.

- 15. Isotropic Point Source** An isotropic point source emits light at wavelength 500 nm, at the rate of 200 W. A light detector is positioned 400 m from the source. What is the maximum rate $\partial B/\partial t$ at which the magnetic component of the light changes with time at the detector's location?

- 16. Magnetic Component** The magnetic component of an electromagnetic wave in vacuum has an amplitude of 85.8 nT and an angular wave number of 4.00 m^{-1} . What are (a) the frequency of the wave, (b) the rms value of the electric component, and (c) the intensity of the light?

- 17. Magnetic Component Two** The magnetic component of a polarized wave of light is

$$B_x = (4.0 \times 10^{-6} \text{ T}) \sin[(1.57 \times 10^7 \text{ m}^{-1})y + \omega t]$$

- Parallel to which axis is the light polarized? What are the (b) frequency and (c) intensity of the light?

18. Rms Value of Electric Component An electromagnetic wave with a wavelength of 450 nm travels through vacuum in the negative direction of a y axis with its electric component directed parallel to the x axis. The rms value of the electric component is 5.31×10^{-6} V/m. Write an equation for the magnetic component in the form of Eq. 34-3, but complete with numbers.

19. Direct Solar Radiation The intensity of direct solar radiation that is not absorbed by the atmosphere on a particular summer day is 100 W/m^2 . How close would you have to stand to a 1.0 kW electric heater to feel the same intensity? Assume that the heater radiates uniformly in all directions.

20. Isotropic Point Source Two The intensity I of light from an isotropic point light source is determined as a function of the distance r from the source. Figure 34-21 gives intensity I versus the inverse square r^{-2} of that distance. What is the power of the source?

FIGURE 34-21 ■ Problem 20.

21. What Is the Power During a test, a NATO surveillance radar system, operating at 12 GHz and 180 kW of power, attempts to detect an incoming stealth aircraft at 90 km. Assume that the radar beam is emitted uniformly over a hemisphere. (a) What is the intensity of the beam when it reaches the aircraft's location? The aircraft reflects radar waves as though it has a cross-sectional area of only 0.22 m^2 . (b) What is the power of the aircraft's reflection? Assume that the beam is reflected uniformly over a hemisphere. Back at the radar site, what are the (c) intensity, (d) maximum value of the electric field vector, and (e) rms value of the magnetic field of the reflected (and now detected) radar beam?

22. Average Energy Transport Show that in a plane traveling electromagnetic wave the intensity—that is, the average rate of energy transport per unit area—is given by

$$\langle S \rangle = \frac{(E^{\max})^2}{2\mu_0 c} = \frac{(B^{\max})^2}{2\mu_0}.$$

SEC. 34-6 ■ RADIATION PRESSURE

23. High-Power Laser High-power lasers are used to compress a plasma (a gas of charged particles) by radiation pressure. A laser generating pulses of radiation of peak power 1.5 GW is focused onto 1.0 mm^2 of high-electron-density plasma. Find the pressure exerted on the plasma if the plasma reflects all the light pulses directly back along their paths.

24. Black Cardboard A black, totally absorbing piece of cardboard of area $A = 2.0 \text{ cm}^2$ intercepts light with an intensity of 10 W/m^2 from a camera strobe light. What radiation pressure is produced on the cardboard by the light?

25. Radiation Pressure What is the radiation pressure 1.5 m away from a 500 W lightbulb? Assume that the surface on which the pressure is exerted faces the bulb and is perfectly absorbing and that the bulb radiates uniformly in all directions.

26. Radiation from the Sun Radiation from the Sun reaching the Earth (just outside the atmosphere) has an intensity of 1.4 kW/m^2 . (a) Assuming that the Earth (and its atmosphere) behaves like a flat disk perpendicular to the Sun's rays and that all the incident energy is

absorbed, calculate the force on the Earth due to radiation pressure. (b) Compare it with the force due to the Sun's gravitational attraction.

27. Electromagnetic Wave A plane electromagnetic wave, with wavelength 3.0 m, travels in vacuum in the positive x direction with its electric field \vec{E} , of amplitude 300 V/m, directed along the y axis. (a) What is the frequency f of the wave? (b) What are the direction and amplitude of the magnetic field associated with the wave? (c) What are the values of k and ω if $\vec{E} = \vec{E}^{\max} \sin(kx - \omega t)$? (d) What is the time-averaged rate of energy flow in watts per square meter associated with this wave? (e) If the wave falls on a perfectly absorbing sheet of area 2.0 m^2 , at what rate is momentum delivered to the sheet and what is the radiation pressure exerted on the sheet?

28. Helium–Neon Laser A helium–neon laser of the type often found in physics laboratories has a beam power of 5.00 mW at a wavelength of 633 nm. The beam is focused by a lens to a circular spot whose effective diameter may be taken to be equal to 2.00 wavelengths. Calculate (a) the intensity of the focused beam, (b) the radiation pressure exerted on a tiny perfectly absorbing sphere whose diameter is that of the focal spot, (c) the force exerted on this sphere, and (d) the magnitude of the acceleration imparted to it. Assume a sphere density of $5.00 \times 10^3 \text{ kg/m}^3$.

29. Normally Incident Prove, for a plane electromagnetic wave that is normally incident on a plane surface, that the radiation pressure on the surface is equal to the energy density in the incident beam. (This relation between pressure and energy density holds no matter what fraction of the incident energy is reflected.)

30. Laser Beam In Fig. 34-22, a laser beam of power 4.60 W and diameter 2.60 mm is directed upward at one circular face (of diameter $d < 2.60 \text{ mm}$) of a perfectly reflecting cylinder, which is made to “hover” by the beam's radiation pressure. The cylinder's density is 1.20 g/cm^3 . What is the cylinder's height H ?

FIGURE 34-22 ■ Problem 30.

31. Small Spaceship A small spaceship whose mass is $1.5 \times 10^3 \text{ kg}$ (including an astronaut) is drifting in outer space with negligible gravitational forces acting on it. If the astronaut turns on a 10 kW laser beam, what speed will the ship attain in 1.0 day because of the momentum carried away by the beam?

32. Average Pressure Prove that the average pressure of a stream of bullets striking a plane surface perpendicularly is twice the kinetic energy density in the stream outside the surface. Assume that the bullets are completely absorbed by the surface. Contrast this with Problem 29.

33. Particle in Solar System A particle in the solar system is under the combined influence of the Sun's gravitational attraction and the radiation force due to the Sun's rays. Assume that the particle is a sphere of density $1.0 \times 10^3 \text{ kg/m}^3$ and that all the incident light is absorbed. (a) Show that, if its radius is less than some critical radius R , the particle will be blown out of the solar system. (b) Calculate the critical radius.

34. Radiation Propelled It has been proposed that a spaceship might be propelled in the solar system by radiation pressure, using a large sail made of foil. How large must the sail be if the radiation force is to be equal in magnitude to the Sun's gravitational attraction? Assume that the mass of the ship + sail is 1500 kg, that the

sail is perfectly reflecting, and that the sail is oriented perpendicular to the Sun's rays. See Appendix C for needed data. (With a larger sail, the ship is continually driven away from the Sun.)

35. Totally Absorbing Someone plans to float a small, totally absorbing sphere 0.500 m above an isotropic point source of light, so that the upward radiation force from the light matches the downward gravitational force on the sphere. The sphere's density is 19.0 g/cm^3 and its radius is 2.00 mm. (a) What power would be required of the light source? (b) Even if such a source were made, why would the support of the sphere be unstable?

36. frac Radiation of intensity I is normally incident on an object that absorbs a fraction *frac* of it and reflects the rest back along the original path. What is the radiation pressure on the object?

SEC. 34-7 ■ POLARIZATION

37. Unpolarized Light A beam of unpolarized light of intensity 10 mW/m^2 is sent through a polarizing sheet as in Fig. 34-13. (a) Find the maximum value of the electric field of the transmitted beam. (b) What radiation pressure is exerted on the polarizing sheet?

38. Magnetic Field Equations The magnetic field equations for an electromagnetic wave in vacuum are $B_x = B \sin(ky + \omega t)$, $B_y = B_z = 0$. (a) What is the direction of propagation? (b) Write the electric field equations. (c) Is the wave polarized? If so, in what direction?

39. Three Polarizing Sheets In Fig. 34-23, initially unpolarized light is sent through three polarizing sheets whose polarizing axes make angles of $\theta_1 = 40^\circ$, $\theta_2 = 20^\circ$, and $\theta_3 = 40^\circ$ with the direction of the y axis. What percentage of the light's initial intensity is transmitted by the system? (*Hint*: Be careful with the angles.)

FIGURE 34-23 ■ Problems 39 and 40.

40. Initially Unpolarized In Fig. 34-23, initially unpolarized light is sent through three polarizing sheets whose polarizing axes make angles of $\theta_1 = \theta_2 = \theta_3 = 50^\circ$ with the direction of the y axis. What percentage of the initial intensity is transmitted by the system of the three sheets? (*Hint*: Be careful with the angles.)

41. Vertically Polarized A horizontal beam of vertically polarized light of intensity 43 W/m^2 is sent through two polarizing sheets. The polarizing axis of the first is at 70° to the vertical, and that of the second is horizontal. What is the intensity of the light transmitted by the pair of sheets?

42. Two Polarizing Sheets A beam of polarized light is sent through a system of two polarizing sheets. Relative to the polarization axis of that incident light, the polarizing axes of the sheets are at angles θ for the first sheet and 90° for the second sheet. If 0.10 of the incident intensity is transmitted by the two sheets, what is θ ?

43. Partially Polarized A beam of partially polarized light can be considered to be a mixture of polarized and unpolarized light. Suppose we send such a beam through a polarizing filter and then

rotate the filter through 360° while keeping it perpendicular to the beam. If the transmitted intensity varies by a factor of 5.0 during the rotation, what fraction of the intensity of the original beam is associated with the beam's polarized light?

44. What Is the Intensity Suppose that in Problem 41 the initial beam is unpolarized. What then is the intensity of the transmitted light?

45. Rotate the Polarization We want to rotate the direction of polarization of a beam of polarized light through 90° by sending the beam through one or more polarizing sheets. (a) What is the minimum number of sheets required? (b) What is the minimum number of sheets required if the transmitted intensity is to be more than 60% of the original intensity?

46. At a Beach At a beach the light is generally partially polarized due to reflections off sand and water. At a particular beach on a particular day near sundown, the horizontal component of the electric field vector is 2.3 times the vertical component. A standing sunbather puts on polarizing sunglasses; the glasses eliminate the horizontal field component. (a) What fraction of the light intensity received before the glasses were put on now reaches the sunbather's eyes? (b) The sunbather, still wearing the glasses, lies on his side. What fraction of the light intensity received before the glasses were put on now reaches his eyes?

47. Four Polarizing Sheets An unpolarized beam of light is sent through a stack of four polarizing sheets, oriented so that the angle between the polarizing directions of adjacent sheets is 30° . What fraction of the incident intensity is transmitted by the system?

48. Four Polarizing Sheets Two In Fig. 34-24, unpolarized light with an intensity of 25 W/m^2 is sent into a system of four polarizing sheets. What is the intensity of the light that emerges from the system?

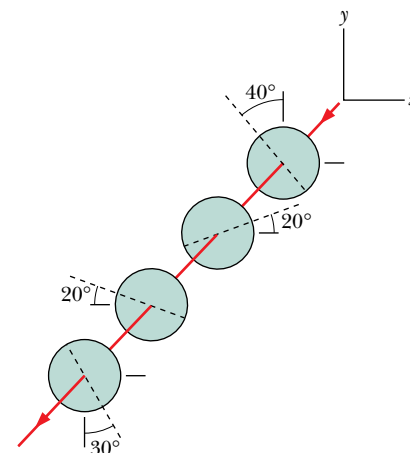

FIGURE 34-24 ■ Problem 48.

49. Two Polarizing Sheets Two A beam of unpolarized light is sent through two polarizing sheets placed one on top of the other. What must be the angle between the polarizing directions of the sheets if the intensity of the transmitted light is to be one-third the incident intensity?

50. Two Polarizing Sheets Three In Fig. 34-25a, unpolarized light is

FIGURE 34-25 ■ Problem 50.

sent through a system of two polarizing sheets. The angles θ_1 and θ_2 of the polarizing axes of the sheets are measured counterclockwise from the positive direction of the y axis (they are not drawn to scale in the figure). Angle θ_1 is fixed but angle θ_2 can be varied. Figure 34-25b gives the intensity of the light emerging from sheet 2 as a function of θ_2 . (The scale of the intensity axis is not indicated.) What percentage of the light's initial intensity is transmitted by the two-sheet system when $\theta_2 = 90^\circ$?

FIGURE 34-26 ■ Problem 51.

51. Three Polarizing Sheets Two In Fig. 34-26, light that is initially unpolarized is sent into a system of three polarizing sheets. What fraction of the initial light intensity emerges from the system?

52. Three Polarizing Sheets Three In Fig. 34-27a, unpolarized light is sent through a system of three polarizing sheets. The angles θ_1 , θ_2 , and θ_3 of the polarizing axes of the sheets are measured counterclockwise from the positive direction of the y axis (they are not drawn to scale). Angles θ_1 and θ_3 are fixed but angle θ_2 can be varied. Figure 34-27b gives the intensity of the light emerging from sheet 3 as a function of θ_2 . (The scale of the intensity axis is not indicated.) What percentage of the light's initial intensity is transmitted by the three-sheet system when $\theta_2 = 90^\circ$?

FIGURE 34-27 ■ Problems 52 and 54.

53. Three Polarizing Sheets Four

A system of three polarizing sheets is shown in Fig. 34-29. When initially unpolarized light is sent into the system, the intensity of the transmitted light is 5.0% of the initial intensity. What is the value of θ ?

54. Three Polarizing Sheets Five In Fig. 34-27a, unpolarized light is sent through a system of three polarizing sheets. The angles θ_1 , θ_2 , and θ_3 of the polarizing axes of the sheets are measured counterclockwise from the positive direction of the y axis (they are not drawn to scale). Angles θ_1 and θ_3 are fixed but angle θ_2 can be varied. Figure 34-27b gives the intensity of the light emerging from sheet 3 as a function of θ_2 . (The scale of the intensity axis is not indicated.) What percentage of the light's initial intensity is transmitted by the three-sheet system when $\theta_2 = 30^\circ$?

FIGURE 34-28 ■ Problem 52.

SEC. 34-8 ■ MAXWELL'S RAINBOW

55. How Long (a) How long does it take a radio signal to travel 150 km from a transmitter to a receiving antenna? (b) We see a full Moon by reflected sunlight. How much earlier did the light that enters our eye leave the Sun? The Earth–Moon and Earth–Sun distances are 3.8×10^5 km and 1.5×10^8 km. (c) What is the round-trip travel time for light between the Earth and a spaceship orbiting Saturn, 1.3×10^9 km distant? (d) The Crab nebula, which is about 6500 light-years (ly) distant, is thought to be the result of a supernova explosion recorded by Chinese astronomers in A.D. 1054. In approximately what year did the explosion actually occur?

FIGURE 34-29 ■ Problem 53.

56. Project Seafarer Project Seafarer was an ambitious proposal to construct an enormous antenna, buried underground on a site about 10 000 km² in area. Its purpose was to transmit signals to submarines while they were deeply submerged. If the effective wavelength were 1.0×10^4 Earth radii, what would be (a) the frequency and (b) the period of the radiations emitted? Ordinarily, electromagnetic radiations do not penetrate very far into conductors such as seawater.

57. At What Wavelengths (a) At what wavelengths does the eye of a standard observer have half its maximum sensitivity? (b) What are the wavelength, frequency, and period of the light for which the eye is the most sensitive?

58. Helium–Neon Laser Two A certain helium–neon laser emits red light in a narrow band of wavelengths centered at 632.8 nm and with a “wavelength width” (such as on the scale of Fig. 34-18) of 0.0100 nm. What is the corresponding “frequency width” for the emission?

59. Speed of Light One method for measuring the speed of light, based on observations by Roemer in 1676, consisted of observing the apparent times of revolution of one of the moons of Jupiter. The true period of revolution is 42.5 h. (a) Taking into account the finite speed of light, how would you expect the apparent time for one revolution to change as the Earth moves in its orbit from point x to point y in Fig. 34-30? (b) What observations would be needed to compute the speed of light? Neglect the motion of Jupiter in its orbit. Figure 34-30 is not drawn to scale.

FIGURE 34-30 ■ Problem 59.

Additional Problems

60. Wave of Frequency An electromagnetic wave with frequency 400 terahertz travels through vacuum in the positive direction of an x axis. The wave is polarized, with its electric field directed parallel to the y axis, with amplitude E^{\max} . At time $t = 0$, the electric field at point P on the x axis has a value of $+E^{\max}/4$ and is decreasing with time. What is the distance along the x axis from point P to the first point with $E = 0$ if we search in (a) the negative direction and (b) the positive direction of the x axis?

61. Earth's Surface At the Earth's surface, what intensity of light is needed to suspend a totally absorbing spherical particle against its own weight if the mass of the particle is 2.0×10^{-13} kg and its radius is $2.0 \mu\text{m}$?

62. Tracking a Plane Wave in a Box An oscillating current in an antenna is producing an electromagnetic wave. The region shown in Fig. 34-31 enclosed by a dashed box (not to scale) is far from the antenna. In it, the field produced is well approximated by a plane wave traveling in the z direction and having its E -field pointed along the x direction (using the coordinate system shown).

(a) You perform a series of measurements of the electric field at the origin of your coordinate system and obtain a result that points in the y direction and is well represented by the function

$$E(t) = E_0 \cos(\omega t).$$

What result would you find if instead of at the origin, you repeated the experiment at a point with coordinates $\{0, 0, z\}$? Explain how you know.

(b) What result would you get if you made your measurements at a point in the box with coordinates $\{2, 3, z\}$ cm? (The point is still well within the dashed box.)

(c) For what values of z would you find exactly the same result as you found at the origin?

FIGURE 34-31 ■ Problem 62.

63. Electromagnetic Light After completing the construction of his equations for electromagnetism, Maxwell proposed that visible light was actually an electromagnetic wave. Discuss whether or not this is plausible and what evidence there is for his hypothesis.

64. E-Field and String Pulses Compare and contrast the propagation of a pulse on a string and an electromagnetic pulse shown in Fig. 34-32. In particular, address the similarities and differences for (a) how the pulse “knows” to move from one position to the next; (b) what will happen if the wave is passed through a slit. (See the figure.)

FIGURE 34-32 ■ Problem 64.

65. Measuring the Speed of Light à la Galileo Galileo tried to measure the speed of light by having two people stand on hills about 5 km apart. Each would hold a shuttered lantern. The first would open his lantern and when the second saw the light, he would open his lantern. The first person would then measure how much time it took between the time he first opened his lantern and the time he saw the light returning.

(a) How much time would it take the light to travel between the two hills?

(b) Is this a good way to measure the speed of light? Support your argument with a brief explanation that includes some quantitative discussion of the uncertainty in the measurement.

66. Solar Power for Your House The amount of energy from the sun that reaches the ground is on the order of 1 kW/m^2 . Use this information to estimate the area you would need for a solar energy collector to provide all the electricity in your house. Explain carefully your assumptions and reasoning.

67. Boiling Water in a Microwave Most of you have had the experience of using a microwave oven to boil a cup of water. [If you have not, ask a friend or roommate to help you estimate the time in part (a)]. According to a Pyrex measuring cup that is marked in both English and SI units, one cup contains about 230 ml.

(a) From the amount of time it takes to heat one cup of water from room temperature to boiling in a microwave oven, estimate the power that the oven delivers to the water in watts (joules/second).

(b) Assuming that electromagnetic radiation is flowing into the cup in the microwave from all sides, estimate the electromagnetic energy flux, S , in W/m^2 .

(c) From the flux you calculated in (b), estimate the strength of the electric and magnetic fields in a microwave oven.

68. Speed of Light and the GPS System Although light appears to travel at a speed that is for all practical purposes infinite, for some modern purposes the time delay due to light travel time is of great importance. The Global Positioning System (GPS) allows you to determine your position from comparison of the time delays between radio signals from 4 satellites at a height of 20,000 km above the surface of the earth. (There are actually 24 of these satellites. Your GPS picks out the closest 4 to your current position.) In order to get some idea of how important the speed of light is in establishing your position with one of these gadgets, make some simple assumptions. Assume that a satellite is almost directly overhead. Then figure out how far the satellite will move in the time it takes light (the radio signal) to get from the satellite to your GPS receiver. This

estimates how far off the reading of your position would be if your device didn't include the speed of light in its calculations. To do this:

- (a) Figure out what speed the satellite must be traveling to be in a circular orbit.
- (b) Estimate the time it would take for a radio signal to get from the satellite to your receiver.
- (c) Estimate how far the satellite would move in that time. If you ignore light travel time, this tells about how wrong you would get the satellite's position (and therefore how wrong you would get your position).

69. Laser Eye Surgery Laser eye surgery is carried out by delivering highly intense bursts of energy using electromagnetic waves. A typical laser used in such surgery has a wavelength of 190 nm (ultraviolet light) and produces bursts of light that last for 1 ms. The laser delivers an energy of 0.5 mJ to a circular spot on the cornea with a diameter of 1 mm. (The light is well approximated by a plane wave for the short distance between the laser and the cornea.)

- (a) Assuming that the energy of a single pulse is delivered to a volume of the cornea about 1 mm^3 , and assuming that the pulses are delivered so quickly that the energy deposited has no time to

flow out of that volume, how many pulses are required to raise the temperature of that volume from 20°C to 100°C ? (Assume that the cornea has a heat capacity similar to that of water.)

- (b) Estimate the maximum strength of the electric field in one of these pulses.

70. Insolation of the Earth The power radiated by the sun is $3.9 \times 10^{26} \text{ W}$. The Earth orbits the Sun in a nearly circular orbit of radius $1.5 \times 10^{11} \text{ m}$. The Earth's axis of rotation is tilted by 23° relative to the plane of the orbit (see Fig. 34-33) so sunlight does not strike the equator perpendicularly.

FIGURE 34-33 ■ Problem 70.

- (a) At the time of year depicted in Fig. 34-33, what power strikes a 1 m^2 patch of horizontal flat land at the equator at the point P ?

- (b) Will a 1 m^2 patch of horizontal flat land at the point R or S receive more radiation?

- (c) Explain how your answer to part (b) tells you at which of the points R or S it is summer or winter.

Images

Edouard Manet's *A Bar at the Folies-Bergère* has enchanted viewers ever since it was painted in 1882. Part of its appeal lies in the contrast between an audience ready for entertainment and a bartender whose eyes betray her fatigue. Its appeal also depends on subtle distortions of reality that Manet hid in the painting—distortions that give an eerie feel to the scene even before you recognize what is “wrong.”

Can you find those subtle distortions of reality?

The answer is in this chapter.

35-1 Introduction

In Chapter 34 we began our study of electromagnetic waves. In this chapter, our focus is on electromagnetic image formation. Although most of us are familiar with optical images of visible light created by lenses and mirrors, image formation occurs in many other regions of the electromagnetic spectrum, including x rays, ultraviolet and infrared light, microwaves, and radio waves. In this chapter we will concentrate on images formed by visible light.

Electromagnetic waves with wavelengths that are within or near the visually detectable range (typically 400 to 700 nanometers) are commonly referred to as **light**. Visible light and its interaction with materials in our everyday world is of obvious importance. For many species, the ability to **see** (the visual system of an organism's formation of a mental image that is based on the detection of light) is often a necessary condition for survival. Light-based (or **optical**) instruments including eyeglasses, microscopes, and mirrors are important to most people on a daily basis. Whether these instruments have allowed you or someone around you to read the words on a page, diagnose a bacterial infection, or detect the car behind you as you back up in the parking lot, an optical instrument has inevitably impacted your life today. The human eye is an optical instrument.

In Chapter 34, we focused on the wave nature of electromagnetic radiation. In this chapter we will use a simplified wave model call the *ray model* of light. Although a light wave spreads as it moves away from its source, we can often approximate its travel as being in a straight line. For example, we did so in Chapter 34 for the light wave in Fig. 34-7a. This straight-line approximation is the basis of the ray model of light in which light waves are represented as lines called **rays** or **beams**. The study of the properties of light waves under this approximation is called *geometrical optics*. It is a perfectly productive (and simpler) approach to understanding how optical instruments function. We will use it extensively in this chapter.

In order to understand how the optical instruments that are so important in our lives work, we first need to understand some fundamental concepts related to the way light interacts with objects around us. For example,

1. Each small area on the surface of most ordinary objects scatters incident light rays in many directions. So anyone who has a line of sight to parts of an object's surface that are illuminated can see them.
2. Objects with smooth surfaces act as mirrors that reflect a light ray in a single direction rather than scattering it.
3. In transparent materials that are uniform like glass, plastic, air, and water, a ray of light travels in a straight line. However, light rays that cross an interface between two different transparent materials at an angle change direction at that interface.
4. When your eye receives neighboring rays of light that are diverging slightly, your brain assumes that the rays are coming from a common point. This is how your brain constructs a visual model of your surroundings.

In the first few sections of this chapter, we discuss “reflection” and “refraction.” These are the two fundamental scattering processes that can occur when light strikes an object with a smooth surface such as a mirror or polished glass. This discussion will provide the foundation required to understand image formation by simple mirrors and lenses, which is covered in Sections 35-6 to 35-10. Finally, we will use our understanding of mirrors and lenses to consider more complex optical devices like microscopes and telescopes. We will continue to use both the wave model and the ray model of light in Chapters 36 and 37.

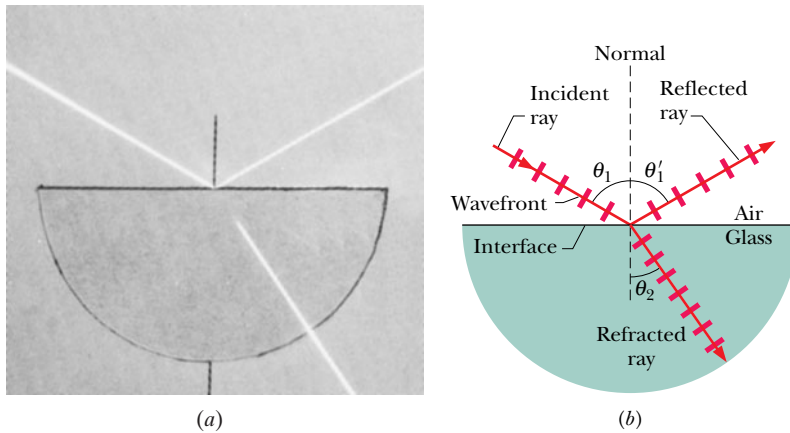

FIGURE 35-1 (a) A black-and-white photograph showing the reflection and refraction of an incident beam of light by a horizontal plane glass surface. At the bottom surface, which is curved, the beam is perpendicular to the surface, so the refraction there does not bend the beam. (Note: It is not possible to view a beam of light from the side as it passes through air or a lens. The path of the beams are visible because they are skimming along a piece of paper that is underneath the lens.) (b) A representation of (a) using rays. The angles of incidence (θ_1), of reflection (θ'_1), and of refraction (θ_2) are marked.

35-2 Reflection and Refraction

The black-and-white photograph in Fig. 35-1a shows an example of light waves traveling in approximately straight lines. A narrow beam of incoming light (the **incident beam**), angled downward from the left and traveling through air, encounters a *plane* (flat) glass surface. Part of the light seems to bounce off the smooth glass surface, forming a smooth glass **reflected beam** directed upward toward the right. The rest of the light travels through the surface and into the glass, forming a **refracted beam** directed downward to the right. Since the surface of the glass is smooth and the glass is uniform, the refracted light forms a beam rather than being scattered in many directions. Because light can travel through the glass like this, the glass is said to be *transparent*; that is, we can see through it. (In this chapter we shall consider only transparent materials with smooth surfaces.)

The passage of light from one homogeneous surface to another with a smooth surface (for example, from air to glass) is called **refraction**, and the light is said to be refracted. Unless an incident beam of light is perpendicular to a surface, refraction at the surface (or **interface**) changes the light's direction of travel. For this reason, the beam is said to be “bent” by the refraction. Note that as shown in Fig. 35-1a, the bending occurs only at the surface.

In Figure 35-1b, the beams of light in the photograph are represented with an *incident ray*, a *reflected ray*, and a *refracted ray* (and wave fronts). Each ray is oriented with respect to a line, called the **normal**, that is perpendicular to the surface at the point of reflection and refraction. In Fig. 35-1b, the **angle of incidence** is θ_1 , the **angle of reflection** is θ'_1 , and the **angle of refraction** is θ_2 . These are all measured *relative to the normal* as a line perpendicular to the surface. The plane containing the incident ray and the normal is the plane of incidence, which is in the plane of the page in Fig. 35-1b.

Experiment shows that reflection and refraction from smooth transparent surfaces are governed by two laws:

Law of reflection: A reflected ray lies in the plane of incidence and has an angle of reflection equal to the angle of incidence. In Fig. 35-1b, this means that

$$\theta'_1 = \theta_1 \quad (\text{reflection from a smooth surface}). \quad (35-1)$$

(We shall now usually drop the prime on the angle of reflection.) As we will see in the sections that follow, the law of reflection is the fundamental basis for understanding image formation from any kind of mirror. Hence, this simple statement is really quite important.

TABLE 35-1
Some Indices of Refraction^a

Medium	Index	Medium	Index
Vacuum	Exactly 1	Typical crown glass	1.52
Air (STP) ^b	1.00029	Sodium chloride	1.54
Water (20°C)	1.33	Polystyrene	1.55
Acetone	1.36	Carbon disulfide	1.63
Ethyl alcohol	1.36	Heavy flint glass	1.65
Sugar solution (30%)	1.38	Sapphire	1.77
Fused quartz	1.46	Heaviest flint glass	1.89
Sugar solution (80%)	1.49	Diamond	2.42

^aFor a wavelength of 589 nm (yellow sodium light).

^bSTP means “standard temperature (0°C) and pressure (1 atm).”

Law of refraction (or Snell’s law): A refracted ray lies in the plane of incidence and has an angle of refraction θ_2 that is related to the angle of incidence θ_1 by

$$n_2 \sin \theta_2 = n_1 \sin \theta_1 \quad (\text{refraction in a transparent medium}). \quad (35-2)$$

Here each of the symbols n_1 and n_2 is a dimensionless constant, called the index of refraction, that is associated with a medium involved in the refraction. We derive this equation, called Snell’s law, in Chapter 36. As we shall discuss there, the index of refraction, n , of a medium is equal to c/v , where v is the speed of light in that medium and c is its speed in vacuum.

Table 35-1 gives the indices of refraction for visible light of vacuum and some common substances. For vacuum, n is defined to be exactly 1; for air, n is very close to 1.0 (an approximation we shall often make). No material used in basic optical devices has an index of refraction less than 1.

We can rearrange Eq. 35-2 as

$$\sin \theta_2 = \frac{n_1}{n_2} \sin \theta_1 \quad (35-3)$$

to compare the angle of refraction θ_2 with the angle of incidence θ_1 . We can then see that the relative value of θ_2 depends on the relative values of n_2 and n_1 . In fact, we can have three basic results:

1. If n_2 is equal to n_1 , then θ_2 is equal to θ_1 . In this case, refraction does not bend the light beam, which continues in the undeflected direction, as in Fig. 35-2a.
2. If n_2 is greater than n_1 , then θ_2 is less than θ_1 . In this case, refraction bends the light beam away from the undeflected direction and toward the normal, as in Fig. 35-2b.

FIGURE 35-2 ■ Light refracting from a medium with an index of refraction n_1 and into a medium with an index of refraction n_2 . (a) The beam does not bend when $n_2 = n_1$; the refracted light then travels in the *undeflected direction* (the dotted line), which is the same as the direction of the incident beam. The beam bends (b) toward the normal when $n_2 > n_1$ and (c) away from the normal when $n_2 < n_1$.

3. If n_2 is less than n_1 , then θ_2 is greater than θ_1 . In this case, refraction bends the light beam away from the undeflected direction and away from the normal, as in Fig. 35-2c.

Refraction cannot bend a beam so much that the refracted ray is on the same side of the normal as the incident ray.

Chromatic Dispersion

The index of refraction n encountered by light in any medium except a vacuum depends on the wavelength of the light. The dependence of n on wavelength implies that when a light beam consists of rays of different wavelengths, the rays will be refracted at different angles by a surface; that is, the light will be spread out by the refraction. This spreading of light is called **chromatic dispersion**, in which “chromatic” refers to the colors associated with the individual wavelengths (as discussed in Section 34-8) and “dispersion” refers to the spreading of the light according to its wavelengths. The refractions of Figs. 35-1 and 35-2 do not show chromatic dispersion because the beams are *monochromatic* (of a single wavelength or color).

Generally, the index of refraction of a given medium is *greater* for a shorter wavelength (corresponding to, say, blue light) than for a longer wavelength (say, red light). As an example, Fig. 35-3 shows how the index of refraction of fused quartz depends on the wavelength of light. Such dependence means that when a beam with waves of both blue and red light is refracted through a surface, such as from air into quartz or vice versa, the blue *component* (the ray corresponding to the wave of blue light) bends more than the red component.

A beam of *white light* consists of components of all (or nearly all) the colors in the visible spectrum with approximately uniform intensities. When you see such a beam, you perceive white rather than the individual colors. In Fig. 35-4a, a beam of white light in air is incident on a glass surface. (Because the pages of this book are white, a beam of white light is represented with a gray ray here. Also, a beam of monochromatic light is generally represented with a red ray.) Of the refracted light in Fig. 35-4a, only the red and blue components are shown. Because the blue component is bent more than the red component, the angle of refraction θ_{2b} for the blue component is *smaller* than the angle of refraction θ_{2r} for the red component. (Remember, angles are measured relative to the normal.) In Fig. 35-4b, a ray of white light in glass is incident on a glass–air interface. Again, the blue component is bent more than the red component, but now θ_{2b} is greater than θ_{2r} .

To increase the color separation, we can use a solid glass prism with a triangular cross section, as in Fig. 35-5a. The dispersion at the first surface (on the left in Fig. 35-5a, b) is then enhanced by that at the second surface.

The most charming example of chromatic dispersion is a rainbow. As shown in Fig. 35-6, when white sunlight is intercepted by a falling raindrop, some of the light re-

FIGURE 35-3 ■ The index of refraction as a function of wavelength for fused quartz. The graph indicates that a beam of short-wavelength light, for which the index of refraction is higher, is bent more upon entering or leaving quartz than a beam of long-wavelength light.

FIGURE 35-4 ■ Chromatic dispersion of white light. The blue component is bent more than the red component. (a) Passing from air to glass, the blue component ends up with the smaller angle of refraction. (b) Passing from glass to air, the blue component ends up with the greater angle of refraction.

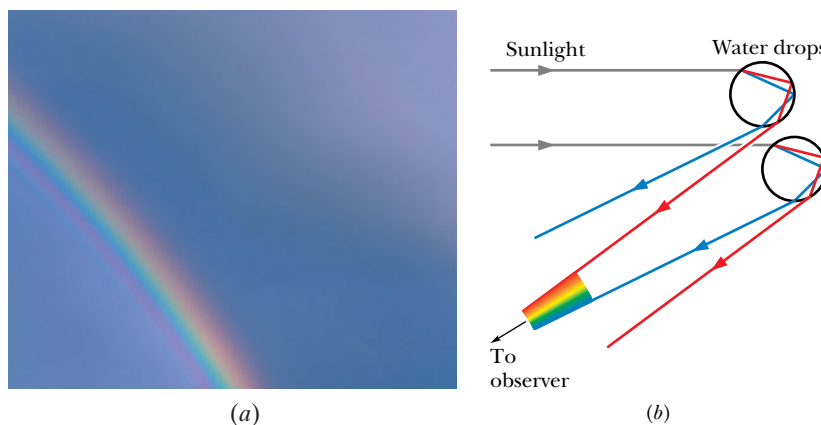

FIGURE 35-5 ■ (a) A triangular prism separating white light into its component colors. (b) Chromatic dispersion occurs at the first surface and is increased at the second surface.

fracts into the drop and then reflects from the drop's inner surface, via total internal reflection (discussed in the next section). Finally it refracts out of the drop (Fig. 35-6). As with a prism, the first refraction separates the sunlight into its component colors, and the second refraction increases the separation.

The rainbow you see is formed by light that emerges from many drops; the red comes from drops angled slightly higher in the sky, the blue from drops angled slightly lower, and the intermediate colors from drops at intermediate angles. All the drops sending separated colors to you are angled at about 42° from a point that is directly opposite the Sun in your view. If the rainfall is extensive and brightly lit, you see a circular arc of color, with red on top and blue on bottom. Your rainbow is a personal one, because another observer intercepts light from other drops.

FIGURE 35-6 ■ (a) A rainbow is always a circular arc that is centered on the direction you would look if you looked directly away from the Sun. Under normal conditions, you are lucky if you see a long arc, but if you are looking downward from an elevated position, you might actually see a full circle. (b) The separation of colors when sunlight refracts into and out of falling raindrops leads to a rainbow. The figure shows the situation for the Sun on the horizon (the rays of sunlight are then horizontal). The paths of red and blue rays from two drops are indicated. Many other drops also contribute red and blue rays, as well as the intermediate colors of the visible spectrum.

READING EXERCISE 35-1: Which of the three drawings (if any) show physically possible refraction?

TOUCHSTONE EXAMPLE 35-1: Reflection and Refraction

(a) In Fig. 35-7a, a beam of monochromatic light reflects and refracts at point A on the interface between material 1 with index of refraction $n_1 = 1.33$ and material 2 with index of refraction $n_2 = 1.77$. The incident beam makes an angle of 50° with the interface. What is the angle of reflection at point A ? What is the angle of refraction there?

SOLUTION ■ The **Key Idea** of any reflection is that the angle of reflection is equal to the angle of incidence. Further, both angles are measured between the corresponding light ray and a normal to the interface at the point of reflection. In Fig. 35-7a, the normal at point A is drawn as a dashed line through the point. Note that the angle of incidence θ_1 is not the given 50° but rather is $90^\circ - 50^\circ = 40^\circ$. Thus, the angle of reflection is

$$\theta_1' = \theta_1 = 40^\circ. \quad (\text{Answer})$$

The light that passes from material 1 into material 2 undergoes refraction at point A on the interface between the two materials. The **Key Idea** of any refraction is that we can relate the angle of incidence, the angle of refraction, and the indexes of refraction of the two materials via Eq. 35-2:

$$n_2 \sin \theta_2 = n_1 \sin \theta_1. \quad (35-4)$$

FIGURE 35-7 (a) Light reflects and refracts at point A on the interface between materials 1 and 2. (b) The light that passes through material 2 reflects and refracts at point B on the interface between materials 2 and 3 (air).

Again we measure angles between light rays and a normal, here at the point of refraction. Thus, in Fig. 35-7a, the angle of refraction is the angle marked θ_2 . Solving Eq. 35-4 for θ_2 gives us

$$\begin{aligned} \theta_2 &= \sin^{-1}\left(\frac{n_1}{n_2} \sin \theta_1\right) = \sin^{-1}\left(\frac{1.33}{1.77} \sin 40^\circ\right) \\ &= 28.88^\circ \approx 29^\circ. \end{aligned} \quad (\text{Answer})$$

This result means that the beam swings toward the normal (it was at 40° to the normal and is now at 29°). The reason is that when the light travels across the interface, it moves into a material with a greater index of refraction.

(b) The light that enters material 2 at point A then reaches point B on the interface between material 2 and material 3, which is air, as shown in Fig. 35-7b. The interface through B is parallel to that through A . At B , some of the light reflects and the rest enters the air. What is the angle of reflection? What is the angle of refraction into the air?

SOLUTION ■ We first need to relate one of the angles at point B with a known angle at point A . Because the interface through point B is parallel to that through point A , the incident angle at B must be equal to the angle of refraction θ_2 , as shown in Fig. 35-7b. Then for reflection, we use the same **Key Idea** as in (a): the law of reflection. Thus, the angle of reflection at B is

$$\theta_2' = \theta_2 = 28.88^\circ \approx 29^\circ. \quad (\text{Answer})$$

Next, the light that passes from material 2 into the air undergoes refraction at point B , with refraction angle θ_3 . Thus, the **Key Idea** here is again to apply the law of refraction, but this time by writing Eq. 35-4 as

$$n_3 \sin \theta_3 = n_2 \sin \theta_2. \quad (35-5)$$

Solving for θ_3 then leads to

$$\begin{aligned} \theta_3 &= \sin^{-1}\left(\frac{n_2}{n_3} \sin \theta_2\right) = \sin^{-1}\left(\frac{1.77}{1.00} \sin 28.88^\circ\right) \\ &= 58.75^\circ \approx 59^\circ. \end{aligned} \quad (\text{Answer})$$

This result means that the beam swings away from the normal (it was at 29° to the normal and is now at 59°). The reason is that when the light travels across the interface, it moves into a material (air) with a lower index of refraction.

35-3 Total Internal Reflection

Figure 35-8 shows rays of monochromatic light from a point source S in glass incident on the interface between the glass and air. For ray a , which is perpendicular to the interface, part of the light reflects at the interface and the rest travels through it with no change in direction.

FIGURE 35-8 ■ Total internal reflection of light from a point source S in glass occurs for all angles of incidence greater than the critical angle θ_c . At the critical angle, shown at point e , the refracted ray points along the air–glass interface.

For rays b through e , which have progressively larger angles of incidence at the interface, there are also both reflection and refraction at the interface. As the angle of incidence increases, the angle of refraction increases; for ray e it is 90° , which means that the refracted ray points directly along the interface. The angle of incidence that gives this situation is called the critical angle θ_c . For angles of incidence larger than θ_c , such as for rays f and g , there is no refracted ray and all the light is reflected; this effect is called total internal reflection.

To find θ_c , we use Eq. 35-2; we arbitrarily associate subscript 1 with the glass and subscript 2 with the air, and then we substitute θ_c for θ_1 and 90° for θ_2 , finding

$$n_1 \sin \theta_c = n_2 \sin 90^\circ,$$

which gives us

$$\theta_c = \sin^{-1} \frac{n_2}{n_1} \quad (\text{critical angle}). \quad (35-6)$$

FIGURE 35-9 ■ Light sent into one end of an optical fiber like those shown here is transmitted to the opposite end with little loss of light through the sides of the fiber.

Because the sine of an angle cannot exceed unity, n_2 cannot exceed n_1 in this equation. This restriction tells us that total internal reflection cannot occur when the incident light is in the medium of lower index of refraction. If source S were in the air in Fig. 35-8, all its rays that are incident on the air–glass interface (including f and g) would be both reflected and refracted at the interface.

Total internal reflection has found many applications in medical technology. For example, a physician can search for an ulcer in the stomach of a patient by running two thin bundles of *optical fibers* (Fig. 35-9) down the patient's throat. Light introduced at the outer end of one bundle undergoes repeated total internal reflection within the fibers so that, even though the bundle provides a curved path, most of the light ends up exiting the other end and illuminating the interior of the stomach. Some of the light reflected from the interior then comes back up the second bundle in a similar way, to be detected and converted to an image on a monitor's screen for the physician to view.

TOUCHSTONE EXAMPLE 35-2: Triangular Prism

Figure 35-10 shows a triangular prism of glass in air; an incident ray enters the glass perpendicular to one face and is totally reflected at the far glass–air interface as indicated. If θ_1 is 45° , what can you say about the index of refraction n of the glass?

SOLUTION ■ One **Key Idea** here is that because the light ray is totally reflected at the interface, the critical angle θ_c for that interface must be less than the incident angle of 45° . A second **Key**

Idea is that we can relate the index of refraction n of the glass to θ_c with the law of refraction, Eq. 35-2. Substituting $n_2 = 1$ (for the

FIGURE 35-10 ■ The incident ray i is totally internally reflected at the glass–air interface, becoming the reflected ray r .

air) and $n_1 = n$ (for the glass) into Eq. 35-2 yields

$$\theta_c = \sin^{-1} \frac{n_2}{n_1} = \sin^{-1} \frac{1}{n}.$$

Because θ_c must be less than the incident angle of 45° , and the sine function is increasing between 0° and 90° ,

$$\sin^{-1} \frac{1}{n} < 45^\circ,$$

which gives us

$$\frac{1}{n} < \sin 45^\circ$$

or

$$n > \frac{1}{\sin 45^\circ} = 1.4. \quad (\text{Answer})$$

The index of refraction of the glass must be greater than 1.4; otherwise, total internal reflection would not occur for the incident ray shown.

35-4 Polarization by Reflection

As we discuss in Chapter 34, you can increase and decrease the glare you see in sunlight that has been reflected from, say, water by looking through a polarizing sheet (such as a polarizing sunglass lens) and then rotating the sheet's polarizing axis around your line of sight. You can do so because reflected light is fully or partially polarized by the reflection from a surface.

Figure 35-11 shows a ray of unpolarized light incident on a glass surface. Let us resolve the electric field vectors of the light into two components. The *perpendicular components* are perpendicular to the plane of incidence and thus also to the page in Fig. 35-11; these components are represented with dots (as if we see the tips of the vectors). The *parallel components* are parallel to the plane of incidence and the page; they are represented with double-headed arrows. Because the light is unpolarized, these two components are of equal magnitude.

In general, the reflected light also has both components but with unequal magnitudes. This means that the reflected light is partially polarized—the electric fields oscillating along one direction have greater amplitudes than those oscillating along other directions. However, when the light is incident at a particular incident angle, called the *Brewster angle* θ_B , the reflected light has only perpendicular components, as shown in Fig. 35-11. The reflected light is then fully polarized perpendicular to the plane of incidence. The parallel components of the incident light do not disappear; they and perpendicular components form the light that is refracted through the glass surface.

Glass, water, and the other dielectric materials discussed in Section 28-6 can partially and fully polarize light by reflection. When you intercept sunlight reflected from such a surface, you see a bright spot (the glare) on the surface where the reflection takes place. If the surface is horizontal as in Fig. 35-11, the reflected light is partially or fully polarized horizontally. To eliminate such glare from horizontal surfaces, the lenses in polarizing sunglasses are mounted with their polarizing direction vertical.

Brewster's Law

For light incident at the Brewster angle θ_B , we find experimentally that the reflected and refracted rays are perpendicular to each other. Because the reflected ray is reflected at the angle θ_B in Fig. 35-11 and the refracted ray is at an angle $\theta_2 = \theta_r$, we have

$$\theta_B + \theta_r = 90^\circ. \quad (35-7)$$

These two angles can also be related with Eq. 35-2. Arbitrarily assigning subscript 1 in Eq. 35-2 to the material through which the incident and reflected rays travel, we have, from that equation,

$$n_1 \sin \theta_B = n_2 \sin \theta_r.$$

- Component perpendicular to page
- ◄► Component parallel to page

FIGURE 35-11 A ray of unpolarized light in air is incident on a glass surface at the Brewster angle θ_B . The electric fields along that ray have been resolved into components perpendicular to the page (the plane of incidence) and components parallel to the page. The reflected light consists only of components perpendicular to the page and is thus polarized in that direction. The refracted light consists of the original components parallel to the page and weaker components perpendicular to the page; this light is partially polarized.

Combining these equations leads to

$$n_1 \sin \theta_B = n_2 \sin(90^\circ - \theta_B) = n_2 \cos \theta_B,$$

which gives us

$$\theta_B = \tan^{-1} \frac{n_2}{n_1} \quad (\text{Brewster angle}). \quad (35-8)$$

(Note carefully that the subscripts in Eq. 35-8 are not arbitrary because of our decision as to their meaning.) If the incident and reflected rays travel *in air*, we can approximate n_1 as unity and let n represent n_2 in order to write Eq. 35-8 as

$$\theta_B = \tan^{-1} n \quad (\text{only if } n_1 = 1). \quad (35-9)$$

This simplified version of Eq. 35-8 is also named after Sir David Brewster, who verified both equations experimentally in 1812.

35-5 Two Types of Image

Up to this point, most of our study of physics in general and optics in particular has been focused on understanding physical phenomena. We have not had to pay particular attention to the role of the observer in determining information about the physical system. (Even though there always is such an observer assumed, we also assume the measurements can be made gently enough so as not to disturb the system so the observer can be ignored.) That will need to change now. In studying image formation, we cannot be concerned only with what happens to the light. We must also be concerned with what it looks like to the observer. For this reason, we have to think about how your eyes and brain interpret the signals they receive. This new concern with the observer continues as we move into the study of relativity in Chapter 38 and as you move into quantum physics in your later studies.

For you to see an object, your eye must intercept some of the light rays spreading from the object and then redirect them onto the retina at the rear of the eye. Your visual system, starting with the retina and ending with the visual cortex at the rear of your brain, automatically and subconsciously processes the information provided by the light. That system identifies edges, orientations, textures, shapes, and colors and then rapidly brings to your consciousness an **image** (a reproduction derived from light) of the object; you perceive and recognize the object as being in the direction from which the light rays came and at the proper distance.

Your visual system goes through this processing and recognition even if the light rays do not come directly from the object, but instead reflect toward you from a mirror or refract through the lenses in a pair of binoculars. However, independent of whether the light rays come directly from an object or indirectly from a reflection or refraction event, the visual system in the human brain always forms an image as follows:

The apparent location of an object is the common point from which the diverging straight line light rays seem to have come (even if the light rays have actually been bent). See Figs. 35-13 and 35-14 for examples.

For example, if the light rays have been reflected toward you from a standard flat mirror, the object appears to be behind the mirror because the rays you intercept come from that direction. Of course, the object is not back there. This type of image, which is called a **virtual image**, truly exists only on your retina but nevertheless is *said* to exist at the perceived location.

A **real image** differs in that it can be formed on a surface, such as a card or a movie screen. You can see a real image (otherwise movie theaters would be empty), but the existence of the image does not depend on your seeing it and it is present even if you are not.

In this chapter we explore several ways in which virtual and real images are formed by reflection (as with mirrors) and refraction (as with lenses). We also distinguish between the two types of image more carefully. We start by considering an example of a natural virtual image.

A Common Mirage

A common example of a virtual image is a pool of water that appears to lie on the road some distance ahead of you on a sunny day, but that you can never reach. The pool is a *mirage* (a type of illusion), formed by light rays coming from the low section of the sky in front of you (Fig. 35-12*a*). As the rays approach a road that has been heated by the Sun, they travel through progressively warmer air that has been heated by the road. With an increase in air temperature, the speed of light in air increases slightly and, correspondingly, the index of refraction of the air closer to the road decreases continuously. Thus, as the rays descend, encountering progressively smaller indices of refraction, they gradually bend more and more toward the horizontal (Fig. 35-12*b*).

Once a ray is horizontal, somewhat above the road's surface, it still bends because the lower portion of each associated wave front is in slightly warmer air and is moving slightly faster than the upper portion of the wavefront (Fig. 35-12*c*). This nonuniform motion of the wavefronts bends the ray upward. As the ray then ascends, it continues to bend upward through progressively greater indexes of refraction (Fig. 35-12*d*).

If some of this light enters your eyes, your visual system automatically infers that it originated along a backward extension of the rays you have intercepted and, to make sense of the light, assumes that it came from the road surface. If the light happens to be bluish from blue sky, the mirage appears bluish, like water. Because the air is probably turbulent due to the heating, the mirage shimmies, as if water waves were present. The bluish coloring and the shimmy enhance the illusion of a pool of water, but you are actually seeing a virtual image of a low section of the sky.

FIGURE 35-12 ■ (a) A ray from a low section of the sky refracts through air that is heated by a road (without reaching the road). An observer who intercepts the light perceives it to be from a pool of water on the road. (b) Bending (exaggerated) of a light ray descending across an imaginary boundary from warm air to warmer air. (c) Shifting of wavefronts and associated bending of a ray, which occurs because the lower ends of wavefronts move faster in warmer air. (d) Bending of a ray ascending across an imaginary boundary to warm air from warmer air.

FIGURE 35-13 ■ A point source of light O , called the object, is a perpendicular distance o in front of a plane mirror. Light rays reaching the mirror from O reflect from the mirror. If your eye intercepts some of the reflected rays, you perceive a point source of light I to be behind the mirror, at a perpendicular distance i . The perceived source I is a virtual image of object O .

FIGURE 35-14 ■ Two rays from Fig. 35-13. Ray Oa makes an arbitrary angle θ with the normal to the mirror surface. Ray Ob is perpendicular to the mirror.

FIGURE 35-15 ■ A “pencil” of rays from O enters the eye after reflection at the mirror. Only a small portion of the mirror near a is involved in this reflection. The light appears to originate at point I behind the mirror.

35-6 Plane Mirrors

A **mirror** is a very smooth surface that can reflect a beam of light (or other electromagnetic radiation) in one direction instead of either scattering it widely in many directions or absorbing it. A shiny metal surface acts as a mirror; a concrete wall does not. In this section we examine the images that a **plane mirror** (a flat reflecting surface) can produce.

Figure 35-13 shows a point source of light O , which we shall call the *object*, at a perpendicular distance o in front of a plane mirror. The light that is incident on the mirror is represented with rays spreading from O .

Caution: Since O is a point while o is a distance, it is important to distinguish between the two, not to confuse them with zero, and to write each one differently.

The reflection of that light is represented with reflected rays spreading from the mirror. If we extend the reflected rays backward (behind the mirror), we find that the extensions intersect at a point that is a perpendicular distance i behind the mirror.

If you look into the mirror of Fig. 35-13, your eyes intercept some of the reflected light. To make sense of what you see, you perceive a point source of light located at the point of intersection of the extensions. This point source is the image I of object O . It is called a point image because it is a point, and it is a virtual image because the rays do not actually pass through it. (As you will see, rays do pass through a point of intersection for a real image.) Your eyes (and brain) trace the rays back to their apparent intersection point and are fooled into thinking that’s where the object is.

Figure 35-14 shows two rays selected from the many rays in Fig. 35-13. One reaches the mirror at point b , perpendicularly. The other reaches it at an arbitrary point a , with an angle of incidence θ . The extensions of the two reflected rays are also shown. The right triangles aOb and aIb have a common side and three equal angles and are thus congruent, so their horizontal sides are congruent. That is,

$$Ib = Ob, \quad (35-10)$$

where Ib and Ob are the distances from the mirror to the image and the object, respectively. Equation 35-10 tells us that the image is as far behind the mirror as the object is in front of it. By convention (that is, to get our equations to work out), *object distances* o are taken to be positive quantities, and image distances i for virtual images (as here) are taken to be negative quantities. Thus, Eq. 35-10 can be written as $|i| = o$, or as

$$i = -o \quad (\text{plane mirror}). \quad (35-11)$$

Only rays that are fairly close together can enter the eye after reflection at a mirror. For the eye position shown in Fig. 35-15, only a small portion of the mirror near point a (a portion smaller than the pupil of the eye) is useful in forming the image. To find this portion, close one eye and look at the mirror image of a small object such as the tip of a pencil. Then move your fingertip over the mirror surface until you cannot see the image. Only light coming from that small portion of the mirror under your fingertip produced the image.

Extended Objects

In Fig. 35-16, an extended object O , represented by an upright arrow, is at perpendicular distance o in front of a plane mirror. Each small portion of the object that faces

the mirror acts like the point source O of Figs. 35-13 and 35-14. If you intercept the light reflected by the mirror, you perceive a virtual image I that is a composite of the virtual point images of all those portions of the object and seems to be at distance i behind the mirror. Distances i and o are related by Eq. 35-11.

We can also locate the image of an extended object as we did for a point object in Fig. 35-13: we draw some of the rays that reach the mirror from the top of the object, draw the corresponding reflected rays, and then extend those reflected rays behind the mirror until they intersect to form an image of the top of the object. We then do the same for rays from the bottom of the object. As shown in Fig. 35-16, we find that virtual image I has the same orientation and *height* (measured parallel to the mirror) as object O .

FIGURE 35-16 ■ An extended object O and its virtual image I in a plane mirror.

Manet's *A Bar at the Folies-Bergère*

In *A Bar at the Folies-Bergère* you see the barroom via reflection by a large mirror on the wall behind the woman tending bar, but the reflection is subtly wrong in three ways. First note the bottles at the left. Manet painted their reflections in the mirror but misplaced them, painting them farther toward the front of the bar than they should be.

Now note the reflection of the woman. Since your view is from directly in front of the woman, her reflection should be behind her, with only a little of it (if any) visible to you; yet Manet painted her reflection well off to the right. Finally, note the reflection of the man facing her. He must be you, because the reflection shows that he is directly in front of the woman, and thus he must be the viewer of the painting. You are looking into Manet's work and seeing your reflection well off to your right. The effect is eerie because it is not what we expect from either a painting or a mirror.

READING EXERCISE 35-2: In the figure you look into a system of two vertical parallel mirrors A and B separated by distance d . A grinning gargoyle is perched at point O , a distance $0.2d$ from mirror A . Each mirror produces a *first* (least deep) image of the gargoyle. Then each mirror produces a *second* image with the object being the first image in the opposite mirror. Then each mirror produces a *third* image with the object being the second image in the opposite mirror, and so on—you might see hundreds of grinning gargoyle images. How deep behind mirror A are the first, second, and third images in mirror A ?

READING EXERCISE 35-3: Is an object in a mirror reversed left to right? How does this happen? Why isn't it also upside down? If you look at your image in a flat mirror, your left hand becomes your right hand, but your head and feet are not interchanged. Can you explain why?

35-7 Spherical Mirrors

We turn now from images produced by plane mirrors to images produced by mirrors with curved surfaces. In particular, we shall consider spherical mirrors, which are simply mirrors in the shape of a small section of the surface of a sphere. A plane mirror is in fact a spherical mirror with an infinitely large *radius of curvature*. This is like treating a small piece of the Earth as if it were flat. If the Earth has a large enough radius, we can't tell the difference.

A plane mirror fooled your visual system into thinking an object was in a different place than it really was by bending the rays so they didn't come directly from the

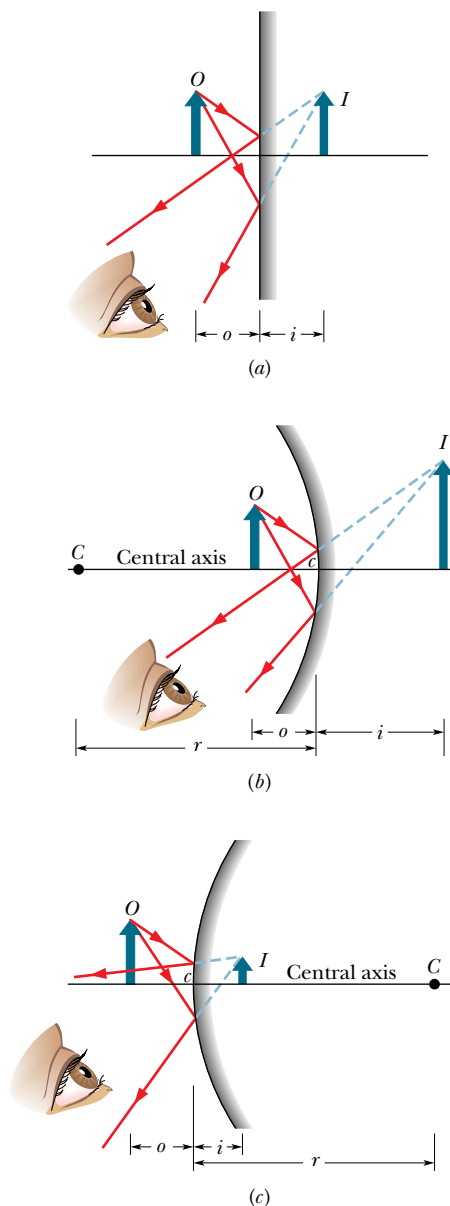

FIGURE 35-17 (a) An object O forms a virtual image I in a plane mirror. (b) If the mirror is bent so that it becomes *concave*, the image moves farther away and becomes larger. (c) If the plane mirror is bent so that it becomes *convex*, the image moves closer and becomes smaller.

object in straight lines. A curved mirror does even more interesting things by bending the rays in a different way.

Making a Spherical Mirror

We start with the plane mirror of Fig. 35-17a, which faces leftward toward an object O and an observer. We make a **concave mirror** by curving the mirror's surface so it is concave (“caved in”) as in Fig. 35-17b. Curving the surface in this way changes several characteristics of the mirror and the image it produces of the object:

1. The *center of curvature* C (the center of the sphere of which the mirror's surface is part) was infinitely far from the plane mirror; it is now closer and in front of the concave mirror.
2. The *field of view*—the extent of the scene that is reflected to the observer—was wide for the plane mirror; it is now smaller.
3. The image of the object was as far behind the plane mirror as the object was in front; the image is farther behind the concave mirror; that is, $|i|$ is greater.
4. The height or size of the image was equal to the height or size of the object for the plane mirror. The height of the image is now greater than the height of the object. This feature is why many makeup mirrors and shaving mirrors are concave—they produce a larger image of a face.

We can make a **convex mirror** by curving a plane mirror so its surface is *convex* (“flexed out”) as in Fig. 35-17c. Curving the surface in this way:

1. Moves the center of curvature C to *behind* the mirror.
2. *Increases* the field of view. It is wider with a convex mirror than with a plane mirror.
3. Moves the image of the object *closer* to the mirror as compared to the plane mirror.
4. *Shrinks* the size of the image. It is now smaller than the actual size of the object.

Side view mirrors on cars and store surveillance mirrors are usually convex to take advantage of the increase in the field of view—more of the store can then be monitored with a single mirror.

In looking at Fig. 35-17b and c, you should note that when both surfaces of a curved mirror are reflective, the side the observer is on determines whether the mirror is convex or concave.

Focal Points of Spherical Mirrors

In order to figure out how a ray of light reflects from a curved mirror, we will look at a very small region of mirror around the point that the ray we are considering strikes. For the small enough region, the mirror looks flat (like a bit of the Earth looks flat although it is actually curved). Then, we use our plane mirror principle from above: angle of incidence is equal to angle of reflection (Eq. 35-1). To do this, first we need to draw a normal to the surface of the mirror at the point that the ray strikes. Then,

For a spherical mirror, the reflected ray is in the plane determined by the incident ray and the normal to the surface. The angle between the normal and the reflected ray is equal to the angle between the normal and the incident ray.

For a plane mirror, the magnitude of the image distance i is always equal to the object distance o . Before we can determine how these two distances are related for a spherical mirror, we find it convenient to consider the reflection of light from an object O located an effectively infinite distance in front of a spherical mirror, on the mirror's *central axis*. That axis extends through the center of curvature C and the center c of the mirror. Because of the great distance between the object and the mirror, the light waves spreading from the object are nearly plane waves when they reach the mirror along the central axis. This means that the rays representing the light waves are all parallel to the central axis when they reach the mirror.

When these parallel rays reach a concave mirror like that of Fig. 35-18a, those near the central axis are reflected through a common point F ; two of these reflected rays are shown in the figure. If we placed a (small) card at F , a point image of the infinitely distant object O would appear on the card since rays actually converge at that point. (This would occur for any infinitely distant object.) Point F is called the **focal point** (or **focus**) of the mirror, and its distance from the center of the mirror is the **focal length** f of the mirror.

If we now substitute a convex mirror for the concave mirror, we find that the parallel rays are no longer reflected through a common point. Instead, they diverge as shown in Fig. 35-18b. However, if your eye or a camera lens intercepts some of the reflected light, you perceive the light as originating from a point source behind the mirror. Although no rays actually converge behind the convex mirror, this perceived source is located where extensions of the reflected rays pass through a common point (F in Fig. 35-18b). That point is the focal point (or focus) F of the convex mirror, and its distance from the mirror surface is the focal length f of the mirror. If we placed a card at this focal point, an image of object O would not appear on the card, so this focal point is a virtual focal point and is *not* like that of a concave mirror.

To distinguish the actual focal point of a concave mirror from the perceived focal point of a convex mirror, the former is said to be a *real focal point* and the latter is said to be a *virtual focal point*. Moreover, the focal length f of a concave mirror is taken to be a positive quantity, and that of a convex mirror a negative quantity. For mirrors of both types, the focal length f is related to the radius of curvature r of the mirror by

$$f = \frac{1}{2}r \quad (\text{spherical mirror}), \quad (35-12)$$

where, consistent with the signs for the focal length, r is a positive quantity for a concave mirror and a negative quantity for a convex mirror.

35-8 Images from Spherical Mirrors

With the focal point of a spherical mirror defined, we can find the relation between image distance i and object distance o for concave and convex spherical mirrors. We discussed the law of reflection (Eq. 35-1) in Section 35-2. This law states that the angle of reflection is equal to the angle of incidence. It alone is the foundation required to understand the change in direction of light rays at the surface of a mirror. Ultimately, it is the direction of the reflected light rays that determines where the image is perceived to be located.

We begin by placing the object O *inside the focal point* of the concave mirror—that is, between the mirror and its focal point F (Fig. 35-19a). An observer can then see a virtual image of O in the mirror: The image appears to be behind the mirror, and it has the same orientation as the object.

If we now move the object away from the mirror until it is at the focal point, the image moves farther back from the mirror until it is at infinity (Fig. 35-19b).

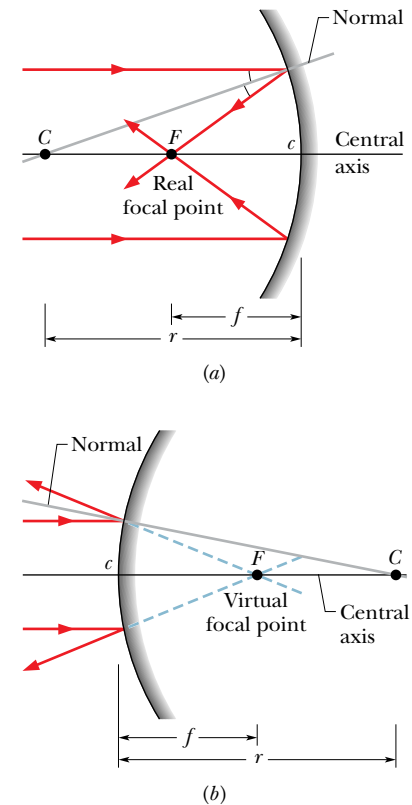

FIGURE 35-18 (a) In a concave mirror, incident parallel light rays are brought to a real focus at F , on the same side of the mirror as the light rays. (b) In a convex mirror, incident parallel light rays seem to diverge from a virtual focus at F , on the side of the mirror opposite the light rays.

FIGURE 35-19 ■ (a) An object O inside the focal point of a concave mirror, and its virtual image I . (b) The object at the focal point F . (c) The object outside the focal point, and its real image I .

The image is then ambiguous and imperceptible because neither the rays reflected by the mirror nor the ray extensions behind the mirror cross to form an image of O .

If we next move the object *outside the focal point*—that is, farther away from the mirror than the focal point—the rays reflected by the mirror converge to form an *inverted* image of object O (Fig. 35-19c) in front of the mirror. That image moves in from infinity as we move the object farther outside F . If you were to hold a card at the position of the image, the rays converging at that point would scatter in all directions, when those scattered rays entered your eyes, your brain would see them as coming from the card, and so an image of the object would appear on the card. In this case, the image is said to be *focused* on the card by the mirror. (The verb “focus,” which in this context means to produce an image, differs from the noun “focus,” which is another name for the focal point.) Because this image can actually appear on a surface, it is a real image—the rays actually intersect to create the image, regardless of whether an observer is present. The image distance i of a real image is a positive quantity, in contrast to that for a virtual image. We also see that

Real images form on the side of a mirror where the object is, and virtual images form on the opposite side.

As we shall prove in Section 35-8, when light rays from an object make only small angles with the central axis of a spherical mirror and the proper sign conventions are chosen, a simple equation relates the object distance o , the image distance i , and the focal length f :

$$\frac{1}{o} + \frac{1}{i} = \frac{1}{f} \quad (\text{spherical mirror}). \quad (35-13)$$

We assume such small angles in figures such as Fig. 35-19, but for clarity the rays are drawn with exaggerated angles. With that assumption, Eq. 35-13 applies to any concave, convex, or plane mirror. For a convex or plane mirror, only a virtual image can be formed, regardless of the object’s location on the central axis. As shown in the example of a convex mirror in Fig. 35-17c, the image is always on the opposite side of the mirror from the object and has the same orientation as the object.

The size of an object or image, as measured *perpendicular* to the mirror’s central axis, is called the object or image *height*. Let h represent the height of the object and h' the height of the image. Then the ratio h'/h is called the **lateral magnification** m produced by the mirror. However, by convention, the lateral magnification always includes a plus sign when the image orientation is the same as that of the object and a minus sign when the image orientation is opposite that of the object (that is, upside down). For this reason, we write the formula for m as

$$|m| = \frac{h'}{h} \quad (\text{lateral magnification}). \quad (35-14)$$

TABLE 35-2
Organizing Table for Mirrors

Mirror Type	Object Location	Image			Sign			
		Location	Type	Orientation	of f	of r	of i	of m
Plane	Anywhere							
Concave	Inside F							
	Outside F							
Convex	Anywhere							

We shall soon prove that the lateral magnification can also be written as

$$m = -\frac{i}{o} \quad (\text{lateral magnification}). \quad (35-15)$$

For a plane mirror for which $i = -o$, we have $m = +1$. The magnification of 1 means that the image is the same size as the object. The plus sign means that the image and the object have the same orientation. For the concave mirror of Fig. 35-19c, $m \approx -1.5$.

Equations 35-12 through 35-15 hold for all plane mirrors, concave spherical mirrors, and convex spherical mirrors. In addition to those equations, you have been asked to absorb a lot of information about these mirrors, and you should organize it for yourself by filling in Table 35-2. Under Image Location, note whether the image is on the *same* side of the mirror as the object or on the opposite side. Under Image Type, note whether the image is *real* or *virtual*. Under Image Orientation, note whether the image has the *same* orientation as the object or is *inverted*. Under Sign, give the sign of the quantity or fill in \pm if the sign is ambiguous. You will need this organization to tackle homework or examinations.

Locating Images by Drawing Rays

Figures 35-20a and b show an object O in front of a concave mirror. In general, a point on an object puts out a spray of rays in all directions. For most of these rays, we need a protractor to calculate where a ray that hits our mirror (and later in the

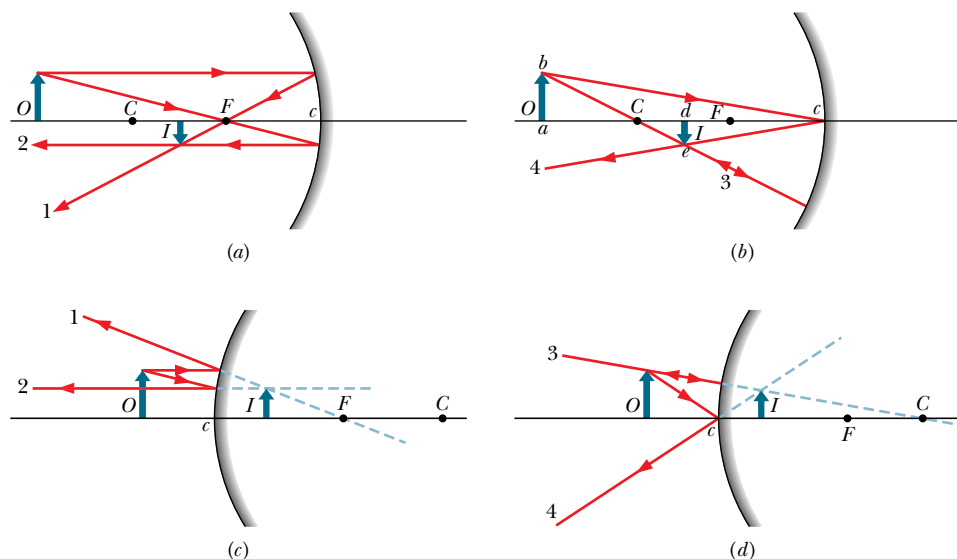

FIGURE 35-20 (a, b) Four rays that can easily be drawn to find the image of an object in a concave mirror. For the object position shown, the image is real, inverted, and smaller than the object. (c, d) Four similar rays for the case of a convex mirror. For a convex mirror, the image is always virtual, oriented like the object, and smaller than the object. [In (c), ray 2 is initially directed toward focal point F . In (d), ray 3 is initially directed toward center of curvature C .]

chapter, our lens) will go. But for four special rays, we can easily draw where they are going to go, using the focal point and symmetry. We can graphically locate the image of any off-axis point of the object by drawing a *ray diagram* with any two of four special rays through the point:

1. A ray that is initially parallel to the central axis reflects through the focal point F (ray 1 in Fig. 35-20a).
2. A ray that reflects from the mirror after passing through the focal point emerges parallel to the central axis (ray 2 in Fig. 35-20a).
3. A ray that reflects from the mirror after passing through the center of curvature C returns along itself (ray 3 in Fig. 35-20b).
4. A ray that reflects from the mirror at its intersection c with the central axis is reflected symmetrically about that axis (ray 4 in Fig. 35-20b).

The image of the point is at the intersection of the two special rays you choose. The image of the object can then be found by locating the images of two or more of its off-axis points. You need to modify the descriptions of the rays slightly to apply them to convex mirrors, as in Figs. 35-20c and *d*. By referring to Figs. 35-20c and *d*, you can easily write a description of what happens to rays 1, 2, 3, and 4 as they are reflected from a convex mirror.

Proof of Equation 35-15

We are now in a position to derive Eq. 35-15 ($m = -i/o$), the equation for the lateral magnification of an object reflected in a mirror. Consider ray 4 in Fig. 35-20b. It is reflected at point c so that the incident and reflected rays make equal angles with the axis of the mirror at that point.

The two right triangles abc and cde in the figure are similar, so we can write

$$\frac{de}{ab} = \frac{cd}{ca}.$$

The quantity on the left (apart from the question of sign) is the lateral magnification m produced by the mirror. Since we indicate an inverted image as a *negative* magnification, we symbolize this as $-m$. However, $cd = i$ and $ca = o$, so we have at once

$$m = -\frac{i}{o} \quad (\text{magnification}), \quad (35-16)$$

which is the relation we set out to prove.

READING EXERCISE 35-4: Use Figs. 35-20c and *d* to modify the rays developed for a concave mirror to describe what happens to rays 1, 2, 3, and 4 when they are incident on a convex mirror. ■

READING EXERCISE 35-5: A Central American vampire bat, dozing on the central axis of a spherical mirror, is magnified by $m = -4$. Is its image (a) real or virtual, (b) inverted or of the same orientation as the bat, and (c) on the same side of the mirror as the bat or on the opposite side? ■

TOUCHSTONE EXAMPLE 35-3: Tarantula

A tarantula of height h sits cautiously before a spherical mirror whose focal length has absolute value $|f| = 40$ cm. The image of the

tarantula produced by the mirror has the same orientation as the tarantula and has height $h' = 0.20h$.

(a) Is the image real or virtual, and is it on the same side of the mirror as the tarantula or the opposite side?

SOLUTION ■ The **Key Idea** here is that because the image has the same orientation as the tarantula (the object), it must be virtual and on the opposite side of the mirror. (You can easily see this result if you have filled out Table 35-2).

(b) Is the mirror concave or convex, and what is its focal length f , sign included?

SOLUTION ■ We *cannot* tell the type of mirror from the type of image, because both types of mirror can produce virtual images. Similarly, we cannot tell the type of mirror from the sign of the focal length f , as obtained from Eq. 35-12 or 35-13, because we lack enough information to use either equation. However—and this is the **Key Idea** here—we can make use of the magnification information. We know that the ratio of image height h' to object height h is 0.20. Thus, from Eq. 35-14 we have

$$|m| = \frac{h'}{h} = 0.20.$$

Because the object and image have the same orientation, we know that m must be positive: $m = +0.20$. Substituting this into Eq. 35-15 and solving for, say, i gives us

$$i = -0.20o,$$

which does not appear to be of help in finding f . However, it is helpful if we substitute it into Eq. 35-13. That equation gives us

$$\frac{1}{f} = \frac{1}{i} + \frac{1}{o} = \frac{1}{-0.20o} + \frac{1}{o} = \frac{1}{o}(-5 + 1),$$

from which we find

$$f = -o/4.$$

Now we have it: Because o is positive, f must be negative, which means that the mirror is convex with

$$f = -40 \text{ cm.} \quad (\text{Answer})$$

35-9 Spherical Refracting Surfaces

We now turn from images formed by reflections to images formed by refraction through smooth surfaces of transparent materials, such as glass. We've seen that curved mirrors scatter light rays so that our eyes see them in new and different ways—in different places, of different sizes, and perhaps upside down. But the most powerful applications of the bending of light rays come when we consider the effect of the refraction of rays passing through transparent materials. We can then understand how the human eye works and construct optical devices with which we can look at objects and bring them into focus (eye glasses), make them bigger (microscopes and telescopes), or create images for storing (cameras). We shall consider only spherical surfaces, with radius of curvature r and center of curvature C . The light will be emitted by a point object O in a medium with index of refraction n_1 ; it will refract through a spherical surface into a medium of index of refraction n_2 .

To determine where the image forms (that is, whether it is real or virtual), we need to once again consider the change in direction of the rays of light that strike the refracting surface. However, as opposed to image formation by mirrors where we are concerned with reflected rays, we are concerned here with the ray that enters the refracting material and is bent (refracted). The final answer to whether the image is virtual (assuming that an observer intercepts the rays) or real (no observer necessary) depends on the relative values of n_1 and n_2 and on the geometry of the situation. Specifically, to understand image formation by spherical refracting surfaces, we draw a normal to the surface. Then,

The refracted ray is in the plane determined by the incident ray and the normal. The relationship between the angle of refraction and the angle of incidence is represented in the law of refraction (or Snell's law): $n_1 \sin \theta_1 = n_2 \sin \theta_2$ (Eq. 35-2).

Six possible results are shown in Fig. 35-21. In each part of the figure, the medium with the greater index of refraction is shaded, and an object O is located on a central axis passing through the center of curvature of the refracting surface. O is always in

This insect has been entombed in amber for about 25 million years. Because we view the insect through a curved refracting surface, the image we see does not coincide with the insect.

FIGURE 35-21 ■ Six possible ways in which an image can be formed by refraction through a spherical surface of radius r and center of curvature C . The surface separates a medium with index of refraction n_1 from a medium with index of refraction n_2 . The point object O is always in the medium with n_1 , to the left of the surface. The material with the lesser index of refraction is unshaded (think of it as being air, and the other material as being glass). Real images are formed in (a) and (b); virtual images are formed in the other four situations.

the medium with index of refraction n_1 , to the left of the refracting surface. In each part, a representative ray is shown refracting through the surface. Another ray along the axis has $\theta_1 = 0$, which means $\theta_2 = 0$, so it is undeviated. The undeviated ray on the central axis and the ray refracting from an off-axis surface point along the central axis and suffice to determine the position of the image in each case.

At the point of refraction of each ray, the normal to the refracting surface is a radial line through the center of curvature C . Because of the refraction, the ray bends toward the normal if it is entering a medium of greater index of refraction, and away from the normal if it is entering a medium of lesser index of refraction. If the refracted ray is then directed toward the central axis, it and other (undrawn) rays will form a real image on that axis. If it is directed away from the central axis, it cannot form a real image; however, backward extensions of it and other refracted rays can form a virtual image, provided (as with mirrors) some of those rays are intercepted by an observer.

Real images I are formed (at image distance i) in parts *a* and *b* of Fig. 35-21, where the refraction directs the ray *toward* the central axis. Virtual images are formed in parts *c* and *d*, where the refraction directs the ray *away* from the central axis. Note that, in these four parts, real images are formed when the object is relatively far from the refracting surface, and virtual images are formed when the object is nearer the refracting surface. In the final situations (Figs. 35-21*e* and *f*), refraction always directs the ray away from the central axis and virtual images are always formed, regardless of the object distance.

Note the following major difference from reflected images:

For a single spherical refracting surface, real images form on the side of a refracting surface that is opposite the object, and virtual images form on the same side as the object.

In Section 35-12, we shall show that (for light rays making only small angles with the central axis)

$$\frac{n_1}{o} + \frac{n_2}{i} = \frac{n_2 - n_1}{r}. \quad (35-17)$$

Just as with mirrors, the object distance o is positive, and the image distance i is positive for a real image and negative for a virtual image. However, to keep all the signs correct in Eq. 35-17, we must use the following rule for the sign of the radius of curvature r :

When the object faces a convex refracting surface, the radius of curvature r is positive. When it faces a concave surface, r is negative.

Be careful: This is just the reverse of the sign convention we have for mirrors. Figure 35-20a shows the case of a image formation by a mirror in which the values of o , i , r , and f are all positive. Figure 35-21a shows the case of image formation by a lens in which these values are all positive. Also, don't forget that we write o , which is a distance, differently than O , which is a point, and 0, which is zero. Be careful not to confuse these quantities.

READING EXERCISE 35-6: A bee is hovering in front of the concave spherical refracting surface of a glass sculpture. (a) Which of the general situations of Fig. 35-21 is like this situation? (b) Is the image produced by the surface real or virtual, and is it on the same side as the bee or the opposite side? ■

TOUCHSTONE EXAMPLE 35-4: Jurassic Mosquito

A Jurassic mosquito is discovered embedded in a chunk of amber, which has index of refraction 1.6. One surface of the amber is spherically convex with radius of curvature 3.0 mm (Fig. 35-22). The mosquito head happens to be on the central axis of that surface and, when viewed along the axis, appears to be buried 5.0 mm into the amber. How deep is it really?

FIGURE 35-22 ■ A piece of amber with a mosquito from the Jurassic period, with the head buried at point O . The spherical refracting surface at the right end, with center of curvature C , provides an image I to an observer intercepting rays from the object at O .

SOLUTION ■ The **Key Idea** here is that the head only appears to be 5.0 mm into the amber because the light rays that the observer intercepts are bent by refraction at the convex amber surface. The image distance i differs from the actual object distance o according to Eq. 35-17. To use that equation to find the actual object distance, we first note:

1. Because the object (the head) and its image are on the same side of the refracting surface, the image must be virtual and so $i = -5.0$ mm.
2. Because the object is always taken to be in the medium of index of refraction n_1 , we must have $n_1 = 1.6$ and $n_2 = 1.0$.
3. Because the object faces a concave refracting surface, the radius of curvature r is negative and so $r = -3.0$ mm.

Making these substitutions in Eq. 35-17,

$$\frac{n_1}{o} + \frac{n_2}{i} = \frac{n_2 - n_1}{r},$$

yields
$$\frac{1.6}{o} + \frac{1.0}{-5.0 \text{ mm}} = \frac{1.0 - 1.6}{-3.0 \text{ mm}}$$

and
$$o = 4.0 \text{ mm.} \quad (\text{Answer})$$

35-10 Thin Lenses

A **lens** is a transparent object with two refracting surfaces whose central axes coincide. The common central axis is the central axis of the lens. When a lens is surrounded by air, light refracts from the air into the lens, crosses through the lens, and

then refracts back into the air. Each refraction can change the direction of travel of the light.

A lens that causes light rays initially parallel to the central axis to converge is (reasonably) called a **converging lens**. If, instead, it causes such rays to diverge, the lens is a **diverging lens**. When an object is placed in front of a lens of either type, refraction by the lens's surface of light rays from the object can produce an image of the object.

We shall consider only the special case of a **thin lens**—that is, a lens in which the thickest part is thin compared to the object distance o , the image distance i , and the radii of curvature r_1 and r_2 of the two surfaces of the lens. We shall also consider only light rays that make small angles with the central axis (they are exaggerated in the figures here). In Section 35-12 we shall prove that for such rays, a thin lens has a focal length f . Moreover, i and o are related to each other by

$$\frac{1}{f} = \frac{1}{o} + \frac{1}{i} \quad (\text{thin lens}), \quad (35-18)$$

which is the same form of equation we had for mirrors. We shall also prove that when a thin lens with index of refraction n is surrounded by air, this focal length f is given by

$$\frac{1}{f} = (n - 1) \left(\frac{1}{r_1} - \frac{1}{r_2} \right) \quad (\text{thin lens in air}), \quad (35-19)$$

which is often called the *lens maker's equation*. Here r_1 is the radius of curvature of the lens surface nearer the object, and r_2 is that of the other surface. The signs of these radii are found with the rules in Section 35-9 for the radii of spherical refracting surfaces. If the lens is surrounded by some medium other than air (say, corn oil) with index of refraction n_{medium} , we replace n in Eq. 35-19 with n/n_{medium} . Keep in mind the basis of Eqs. 35-18 and 35-19:

A lens can produce an image of an object only if it bends light rays, but it can bend light rays only if its index of refraction differs from that of the surrounding medium.

Figure 35-23a shows a thin lens with convex outer surfaces, or *sides*. Once again, we figure out how the rays of light will be bent by taking a small part of the lens, near where the ray hits, and treating it as flat surface. Then, using the law of refraction (Snell's law, Eq. 35-2) which tells us $n_1 \sin \theta_1 = n_2 \sin \theta_2$, we know how the rays will be bent.

When rays that are parallel to the central axis of the lens are sent through the lens, they refract twice, as is shown enlarged in Fig. 35-23b. This double refraction causes the rays to converge and pass through a common point F_2 at a distance f from the center of the lens. Hence, this lens is a converging lens; further, a *real* focal point (or focus) exists at F_2 (because the rays really do pass through it), and the associated focal length is f . When rays parallel to the central axis are sent in the opposite direction through the lens, we find another real focal point at F_1 on the other side of the lens. For a thin lens, these two focal points are equidistant from the lens.

Because the focal points of a converging lens are real, we take the associated focal lengths f to be positive, just as we do with a real focus of a concave mirror. However, signs in optics can be tricky, so we had better check this in Eq. 35-19. The left side of that equation is positive if f is positive; how about the right side? We examine it term by term. Because the index of refraction n of glass or any other material is greater than 1, the term $(n - 1)$ must be positive. Because the source of the light (which is the object) is at the left and faces the convex left side of the lens, the

FIGURE 35-23 (a) Rays initially parallel to the central axis of a converging lens are made to converge to a real focal point F_2 by the lens. The lens is thinner than drawn, with a width like that of the vertical line through it, where we shall consider all the bending of rays to occur. (b) An enlargement of the top part of the lens of (a); normals to the surfaces are shown dashed. Note that both refractions of the ray at the surfaces bend the ray downward, toward the central axis. (c) The same initially parallel rays are made to diverge by a diverging lens. Extensions of the diverging rays pass through a virtual focal point F_2 . (d) An enlargement of the top part of the lens of (c). Note that both refractions of the ray at the surfaces bend the ray upward, away from the central axis.

radius of curvature r_1 of that side must be positive according to the sign rule for refracting surfaces. Similarly, because the object faces a concave right side of the lens, the radius of curvature r_2 of that side must be negative. Thus, the term $(1/r_1 - 1/r_2)$ is positive, the whole right side of Eq. 35-19 is positive, and all the signs are consistent.

Figure 35-23c shows a thin lens with concave outer surfaces. When rays that are parallel to the central axis of the lens are sent through this lens, they refract twice, as is shown enlarged in Fig. 35-23d; these rays *diverge*, never passing through any common point, and so this lens is a diverging lens. However, extensions of the rays do pass through a common point F_2 at a distance f from the center of the lens. Hence, the lens has a *virtual* focal point at F_2 . (If your eye intercepts some of the diverging rays, you perceive a bright spot to be at F_2 , as if it is the source of the light.) Another virtual focus exists on the opposite side of the lens at F_1 , symmetrically placed if the lens is thin. Because the focal points of a diverging lens are virtual, we take the focal length f to be negative. *Note:* For a thin lens, the two focal points are at the same distance from the lens on either side even if the curvatures of the two sides are not equal and opposite.

Images from Thin Lenses

We now consider the types of image formed by converging and diverging lenses. In thinking about the image formed of an object by a lens, it is important to keep in mind that the object scatters light falling on it in all directions. However, only those rays of light that fall on the lens are refracted and have their directions changed. Thus, all of the rays that are incident on the lens contribute to the image that forms.*

Figure 35-24a shows an object O outside the focal point F_1 of a converging lens. The two rays drawn in the figure show that the lens forms a real, inverted image I of the object on the side of the lens opposite the object.

A fire is being started by focusing sunlight onto newspaper by means of a converging lens made of clear ice. The lens was made by freezing water in the shallow vessel (which has a curved bottom).

* In Section 35-8, we use Eq. 35-12 to construct diagrams (Figs. 35-19 and 35-20) for spherical mirrors in which the center curvature of the mirror is replaced by its focal point. We can construct similar diagrams for thin lenses using Eq. 35-19 to determine the locations of F based on the value of f .

FIGURE 35-24 (a) A real, inverted image I is formed by a converging lens when the object O is outside the focal point F_1 . (b) The image I is virtual and has the same orientation as O when O is inside the focal point. (c) A diverging lens forms a virtual image I , with the same orientation as the object O , whether O is inside or outside the focal point of the lens.

When the object is placed inside the focal point F_1 , as in Fig. 35-24b, the lens forms a virtual image I on the same side of the lens as the object and with the same orientation but larger in size. In this situation, the lens acts as a magnifying glass. Hence, a converging lens can form either a real image or a virtual image, depending on whether the object is outside or inside the focal point, respectively.

Figure 35-24c shows an object O in front of a diverging lens. Regardless of the object distance (regardless of whether O is inside or outside the virtual focal point), this lens produces a virtual image that is on the same side of the lens as the object and has the same orientation.

As with mirrors, we take the image distance i to be positive when the image is real and negative when the image is virtual. However, the locations of real and virtual images from lenses are the reverse of those from mirrors:

Real images form on the side of a lens that is opposite the object, and virtual images form on the side where the object is.

The lateral magnification m produced by converging and diverging lenses is given by Eqs. 35-14 and 35-15, the same as for mirrors.

You have been asked to absorb a lot of information in this section, and you should organize it for yourself by filling in Table 35-3 for thin lenses. Under Image Location note whether the image is on the *same* side of the lens as the object or on the *opposite* side. Under Image Type note whether the image is *real* or *virtual*. Under Image Orientation note whether the image has the same orientation as the object or is inverted.

TABLE 35-3
Organizing Table for Lenses

Lens Type	Object Location	Image			Sign		
		Location	Type	Orientation	of f	of i	of m
Converging	Inside F						
	Outside F						
Diverging	Anywhere						

Locating Images of Extended Objects with Principal Rays

Converging Lens: Object Outside of F_1 Figure 35-25a shows an object O outside focal point F_1 of a converging lens. We can graphically locate the image of any off-axis point on such an object (such as the tip of the arrow in Fig. 35-25a) by drawing a ray diagram with any two of three easy-to-draw principal rays through the point. These principal rays are chosen for convenience from the infinite number of rays that pass through the lens to form the image:

FIGURE 35-25 ■ Three special rays allow us to locate an image formed by a thin lens whether the object O is (a) outside or (b) inside the focal point of a converging lens, or (c) anywhere in front of a diverging lens.

1. A ray (from outside the focal point) that is initially parallel to the central axis of a converging lens will pass through focal point F_2 (ray 1 in Fig. 35-25a).
2. A ray that initially passes through focal point F_1 will emerge from a converging lens parallel to the central axis (ray 2 in Fig. 35-25a).
3. A ray that is initially directed toward the center of a converging lens will emerge from the lens with no change in its direction (ray 3 in Fig. 35-25a) because the ray encounters the two sides of the lens where they are almost parallel.

The image of the point is located where the rays intersect on the far side of the converging lens. The image of the object is found by locating the images of two or more of its points.

Rules for Other Situations Figure 35-25b shows how the extensions of the three special rays can be used to locate the image of an object placed inside focal point F_1 of a converging lens. Notice that although ray 2 is determined by the focal point, no part of the ray goes through it. It is the reversal of ray 1—what ray 1 would do if it came from the other side of the lens. We suggest you develop rules like these three for Fig. 35-25a and 35-25b.

You need to modify the descriptions of rays 1 and 2 to use them to locate an image placed (anywhere) in front of a diverging lens. In Fig. 35-25c, for example, we find the intersection of ray 3 and the backward extensions of rays 1 and 2.

Two-Lens Systems

When an object O is placed in front of a system of two lenses whose central axes coincide, we can locate the final image of the system (that is, the image produced by the lens farther from the object) by working in steps. Let lens 1 be the nearer lens and lens 2 the farther lens.

Step 1. We let o_1 represent the distance of object O from lens 1. We then find the distance i_1 of the image produced by lens 1, by use of Eq. 35-18. The image could be real or virtual.

Step 2. Now, ignoring the presence of lens 1, we treat the image found in step 1 as the object for lens 2. If this new object is located beyond lens 2, the object distance o_2 for lens 2 is taken to be negative. (Note this exception to the rule that says the object distance is positive; the exception occurs because the object here is on the side opposite the source of light.) Otherwise, o_2 is taken to be positive as usual.

We then find the distance i_2 of the (final) image produced by lens 2 by use of Eq. 35-18.

A similar step-by-step solution can be used for any number of lenses or if a mirror is substituted for lens 2.

The overall lateral magnification M produced by a system of two lenses is the product of the lateral magnifications m_1 and m_2 produced by the two lenses:

$$M = m_1 m_2. \quad (35-20)$$

TOUCHSTONE EXAMPLE 35-5: Praying Mantis

A praying mantis preys along the central axis of a thin symmetric lens, 20 cm from the lens. The lateral magnification of the mantis provided by the lens is $m = -0.25$, and the index of refraction of the lens material is 1.65.

(a) Determine the type of image produced by the lens, the type of lens, whether the object (mantis) is inside or outside the focal point, on which side of the lens the image appears, and whether the image is inverted.

SOLUTION ■ The **Key Idea** here is that we can tell a lot about the lens and the image from the given value of m . From it and Eq. 35-16 ($m = -i/o$), we see that

$$i = -(m)(o) = 0.25o.$$

Even without finishing the calculation, we can answer the questions. Because o is positive, i here must be positive. That means we have a real image, which means we have a converging lens (the only lens that can by itself produce a real image). The object must be outside the focal point (the only way a real image can be produced). Also, the image is inverted and on the side of the lens opposite the object. (That is how a converging lens makes a real image.)

(b) What are the two radii of curvature of the lens?

SOLUTION ■ The **Key Ideas** here are these:

1. Because the lens is symmetric, r_1 (for the surface nearer the object) and r_2 have the same magnitude r .
2. Because the lens is a converging lens, the object faces a convex surface on the nearer side and so $r_1 = +r$. Similarly, it faces a concave surface on the farther side and so $r_2 = -r$.

3. We can relate these radii of curvature to the focal length f via the lens maker's equation, Eq. 35-19 (our only equation involving the radii of curvature of a lens).
4. We can relate f to the object distance o and image distance i via Eq. 35-18.

We know o but we do not know i . Thus, our starting point is to finish the calculation for i in part (a); we obtain

$$i = (0.25)(20 \text{ cm}) = 5.0 \text{ cm}.$$

Now Eq. 35-18 gives us

$$\frac{1}{f} = \frac{1}{o} + \frac{1}{i} = \frac{1}{20 \text{ cm}} + \frac{1}{5.0 \text{ cm}},$$

from which we find $f = 4.0 \text{ cm}$.

Equation 35-19 then gives us

$$\frac{1}{f} = (n - 1) \left(\frac{1}{r_1} - \frac{1}{r_2} \right) = (n - 1) \left(\frac{1}{+r} - \frac{1}{-r} \right)$$

or, with known values inserted,

$$\frac{1}{4.0 \text{ cm}} = (1.65 - 1) \frac{2}{r},$$

which yields

$$r = (0.65)(2)(4.0 \text{ cm}) = 5.2 \text{ cm}. \quad (\text{Answer})$$

TOUCHSTONE EXAMPLE 35-6: Jalapeño Seed

Figure 35-26a shows a jalapeño seed O_1 that is placed in front of two thin symmetrical coaxial lenses 1 and 2, with focal lengths $f_1 = +24 \text{ cm}$ and $f_2 = +9.0 \text{ cm}$, respectively, and with lens separation $L = 10 \text{ cm}$. The seed is 6.0 cm from lens 1. Where does the system of two lenses produce an image of the seed?

SOLUTION ■ We could locate the image produced by the system of lenses by tracing light rays from the seed through the two lenses. However, the **Key Idea** here is that we can, instead, calculate the location of that image by working through the system in steps, lens by lens. We begin with the lens closer to the

FIGURE 35-26 (a) Seed O_1 is distance o_1 from a two-lens system with lens separation L . We use the arrow to orient the seed. (b) The image I_1 produced by lens 1 alone. (c) Image I_1 acts as object O_2 for lens 2 alone, which produces the final image I_2 .

seed. The image we seek is the final one—that is, image I_2 produced by lens 2.

Lens 1. Ignoring lens 2, we locate the image I_1 produced by lens 1 by applying Eq. 35-18 to lens 1 alone:

$$\frac{1}{o_1} + \frac{1}{i_1} = \frac{1}{f_1}.$$

The object O_1 for lens 1 is the seed, which is 6.0 cm from the lens; thus, we substitute $o_1 = +6.0$ cm. Also substituting the given value of f_1 , we then have

$$\frac{1}{+6.0 \text{ cm}} + \frac{1}{i_1} = \frac{1}{+24 \text{ cm}},$$

which yields $i_1 = -8.0$ cm.

This tells us that image I_1 is 8.0 cm to the left of lens 1 and virtual. (We could have guessed that it is virtual by noting that the seed is inside the focal point of lens 1.) Since I_1 is virtual, it is on the same side of the lens as object O_1 and has the same orientation as the seed, as shown in Fig. 35-26b.

Lens 2. In the second step of our solution, the **Key Idea** is that we can treat image I_1 as an object O_2 for the second lens and now ignore lens 1. We first note that this object O_2 is outside the focal point of lens 2. So the image I_2 produced by lens 2 must be real, inverted, and on the side of the lens opposite O_2 . Let us see.

The distance o_2 between this object O_2 and lens 2 is, from Fig. 35-26c,

$$o_2 = L + |i_1| = 10 \text{ cm} + 8.0 \text{ cm} = 18 \text{ cm}.$$

Then Eq. 35-18, now written for lens 2, yields

$$\frac{1}{+18 \text{ cm}} + \frac{1}{i_2} = \frac{1}{+9.0 \text{ cm}}.$$

Hence, $i_2 = +18$ cm. (Answer)

The plus sign confirms our guess: Image I_2 produced by lens 2 is real, inverted, and on the side of lens 2 opposite O_2 , as shown in Fig. 35-26c.

35-11 Optical Instruments

The human eye is a remarkably effective organ, but its range can be extended in many ways by optical instruments such as eyeglasses, simple magnifying lenses, motion picture projectors, cameras (including TV cameras), microscopes, and telescopes. Many such devices extend the scope of our vision beyond the visible range; satellite-borne infrared cameras, x-ray microscopes, and radio telescopes are examples. Furthermore, electron microscopes and magnets in particle accelerators can focus electron and proton beams.

The mirror and thin-lens formulas can be applied only as approximations to most sophisticated optical instruments. The lenses in typical laboratory microscopes are by no means “thin.” In most optical instruments the lenses are compound lenses; that is, they are made of several components, the interfaces rarely being exactly spherical. A

more complex treatment is needed for these systems. Now we discuss three optical instruments, assuming for simplicity, that the thin-lens formulas apply.

Simple Magnifying Lens

The normal human eye can focus a sharp image of an object on the retina (at the rear of the eye) if the object is located anywhere from infinity to a certain point called the *near point* P_n . If you move the object closer to the eye than the near point, the perceived retinal image becomes fuzzy. The location of the near point normally varies with age. We have all heard about people who claim not to need glasses but read their newspapers at arm's length; their near points are receding. To find your own near point, remove your glasses or contacts if you wear any, close one eye, and then bring this page closer to your open eye until it becomes indistinct. In what follows, we take the near point to be 25 cm from the eye, a bit more than the typical value for 20-year-olds.

Figure 35-27a shows an object O placed at the near point P_n of an eye. The size of the image of the object produced on the retina depends on the angle θ that the object occupies in the field of view from that eye. By moving the object closer to the eye, as in Fig. 35-27b, you can increase the angle and, hence, the possibility of distinguishing details of the object. However, because the object is then closer than the near point, it is no longer in focus; that is, the image is no longer clear.

You can restore the clarity by looking at O through a converging lens, placed so that O is just inside the focal point F_1 of the lens, which is at focal length f (Fig. 35-27c). What you then see is the virtual image of O produced by the lens. That image is farther away than the near point; thus, the eye can see it clearly.

Moreover, the angle θ' occupied by the virtual image is larger than the largest angle θ that the object alone can occupy and still be seen clearly. The *angular magnification* m_θ (not to be confused with lateral magnification m) of what is seen is

$$m_\theta = \theta'/\theta.$$

In words, the angular magnification of a simple magnifying lens is a comparison of the angle occupied by the image the lens produces with the angle occupied by the object when the object is moved to the near point of the viewer.

From Fig. 35-27, assuming that O is at the focal point of the lens, and approximating $\tan \theta$ as θ and $\tan \theta'$ as θ' for small angles, we have

$$\theta \approx h/25 \text{ cm} \quad \text{and} \quad \theta' \approx h/f.$$

FIGURE 35-27 (a) An object O of height h , placed at the near point of a human eye, occupies angle θ in the eye's view. (b) The object is moved closer to increase the angle, but now the observer cannot bring the object into focus. (c) A converging lens is placed between the object and the eye, with the object just inside the focal point F_1 of the lens. The image produced by the lens is then far enough away to be focused by the eye, and the image occupies a larger angle θ' than object O does in (a).

We then find that

$$m_{\theta} \approx \frac{25 \text{ cm}}{f} \quad (\text{maximum magnification}). \quad (35-21)$$

Note that this is an equation for a person with a near point of 25 cm. It is an example of how the study of optics depends on the observer. That is, the value of the magnification depends not only on the lens but also on the person using the lens.

Compound Microscope

Figure 35-28 shows a thin-lens version of a compound microscope. The instrument consists of an *objective* (the front lens) of focal length f_{obj} and an *eyepiece* (the lens near the eye) of focal length f_{eye} . It is used for viewing small objects that are very close to the objective.

The object O to be viewed is placed just outside the first focal point F_{obj} of the objective lens, close enough to F_{obj} that we can approximate its distance o from the lens as being f_{obj} . Combining this with a consideration of the thin-lens equation

$$\frac{1}{f} = \frac{1}{o} + \frac{1}{i} \quad (\text{Eq. 35-18})$$

when an object under a microscope is very close to the focal point, we see that object distance o is approximately equal to focal length of the objective lens f_{obj} , so $1/f_{\text{obj}} - 1/o$ is very close to zero. As a result, the image distance i is very sensitive to *exactly how close* the object is to the focal point.

The separation between the lenses is then adjusted so that the enlarged, inverted, real image I produced by the objective is located just inside the first focal point F'_1 of the eyepiece. The *tube length* s shown in Fig. 35-28 is actually large relative to f_{obj} , and we can approximate the distance i between the objective and the image I as being length s .

From Eq. 35-15, and using our approximations for o and i , we can write the lateral magnification produced by the objective as

$$m_{\text{obj}} = -\frac{i}{o} = -\frac{s}{f_{\text{obj}}}. \quad (35-22)$$

Since the image I is located just inside the focal point F'_1 of the eyepiece, the eyepiece acts as a simple magnifying lens, and an observer sees a final (virtual, inverted) image I' through it. The overall magnification of the instrument is the product of the lateral magnification m_{obj} produced by the objective (Eq. 35-22) and the angular magnification produced by the eyepiece $m_{\text{eye}} = m_{\theta}$ (Eq. 35-21) so that

$$M = m_{\text{obj}} m_{\text{eye}} = -\frac{s}{f_{\text{obj}}} \frac{25 \text{ cm}}{f_{\text{eye}}} \quad (\text{microscope magnification}). \quad (35-23)$$

FIGURE 35-28 ■ A thin-lens representation of a compound microscope (not to scale). The objective produces a real image I of object O just inside the focal point F'_1 of the eyepiece. Image I then acts as an object for the eyepiece, which produces a virtual final image I' that is seen by the observer. The objective has focal length f_{obj} ; the eyepiece has focal length f_{eye} ; and s is the tube length.

The microscope designer must also take into account the difference between real lenses and the ideal thin lenses we have discussed. A real lens with spherical surfaces does not form sharp images, a flaw called **spherical aberration**. Also, because refraction by the two surfaces of a real lens depends on wavelength, a real lens does not focus light of different wavelengths to the same point, a flaw called **chromatic aberration**.

Refracting Telescope

Telescopes come in a variety of forms. The form we describe here is the simple refracting telescope that consists of an objective and an eyepiece; both are represented in Fig. 35-29 with simple lenses, although in practice, as is also true for most microscopes, each lens is usually a compound-lens system to reduce distortions.

The lens arrangements for telescopes and for microscopes are similar, but telescopes are designed to view large objects, such as galaxies, stars, and planets, at large distances, whereas microscopes are designed for just the opposite purpose. This difference requires that in the telescope of Fig. 35-29 the second focal point of the objective F_2 coincide with the first focal point of the eyepiece F_1' , whereas in the microscope of Fig. 35-28 these points are separated by the tube length s .

In Fig. 35-29a, parallel rays from a distant object strike the objective, making an angle θ_{obj} with the telescope axis and forming a real, inverted image at the common focal point F_2, F_1' . This image I acts as an object for the eyepiece, through which an observer sees a distant (still inverted) virtual image I' . The rays defining the image make an angle θ_{eye} with the telescope axis.

The angular magnification m_θ of the telescope is $\theta_{\text{eye}}/\theta_{\text{obj}}$. From Fig. 35-29b, for rays close to the central axis, we can write $\theta_{\text{obj}} = h'/f_{\text{obj}}$ and $\theta_{\text{eye}} \approx h'/f_{\text{eye}}$, which gives us

$$m_\theta = -\frac{f_{\text{obj}}}{f_{\text{eye}}} \quad (\text{telescope}), \quad (35-24)$$

where the minus sign indicates that I' is inverted. In words, the angular magnification of a telescope is a comparison of the angle occupied by the image the telescope produces with the angle occupied by the distant object as seen without the telescope.

Magnification is only one of the design factors for an astronomical telescope and is indeed easily achieved. A good telescope needs light-gathering power, which determines how bright the image is. This is important for viewing faint objects such as distant galaxies and is accomplished by making the objective diameter as large as possible. A telescope also needs resolving power, which is the ability to distinguish

FIGURE 35-29 (a) A thin-lens representation of a refracting telescope. The objective produces a real image I of a distant source of light (the object), with approximately parallel light rays at the objective. (One end of the object is assumed to lie on the central axis.) Image I , formed at the common focal points F_2 and F_1' , acts as an object for the eyepiece, which produces a virtual final image I' at a great distance from the observer. The objective has focal length f_{obj} ; the eyepiece has focal length f_{eye} . (b) Image I has height h' and takes up angle θ_{obj} measured from the objective and angle θ_{eye} measured from the eyepiece.

between two distant objects (stars, say) whose angular separation is small. Field of view is another important design parameter. A telescope designed to look at galaxies (which occupy a tiny field of view) is much different from one designed to track meteors (which move over a wide field of view).

The telescope designer must also take into account the differences between real lenses and the ideal thin lenses we have discussed. Designers use compound lens systems to minimize spherical and chromatic aberrations.

This brief discussion by no means exhausts the design parameters of astronomical telescopes—many others are involved. We could make a similar listing for any other high-performance optical instrument.

35-12 Three Proofs

The Spherical Mirror Formula (Eq. 35-13)

Let us prove that Eq. 35-13, $1/i + 1/o = 1/f$ is true for a spherical mirror. Figure 35-30 shows a point object O placed on the central axis of a concave spherical mirror, outside its center of curvature C . Here, we use the reflection principle that comes from treating the mirror as approximately flat near where the ray hits. A ray from O that makes an angle α with the axis intersects the axis at I after reflection from the mirror at a . A ray that leaves O along the axis is reflected back along itself at c and also passes through I . Thus, I is the image of O ; it is a real image because light actually passes through it. Let us find the image distance i .

A trigonometry theorem that is useful here tells us that an exterior angle of a triangle is equal to the sum of the two opposite interior angles. Applying this to triangles OaC and OaI in Fig. 35-30 yields

$$\beta = \alpha + \theta \quad \text{and} \quad \gamma = \alpha + 2\theta.$$

If we eliminate θ between these two equations, we find

$$\alpha + \gamma = 2\beta. \quad (35-25)$$

We can write angles α , β , and γ , in radian measure, as

$$\alpha \approx \frac{\widehat{ac}}{cO} = \frac{\widehat{ac}}{o}, \quad \beta = \frac{\widehat{ac}}{cC} = \frac{\widehat{ac}}{r},$$

and

$$\gamma \approx \frac{\widehat{ac}}{cI} = \frac{\widehat{ac}}{i}. \quad (35-26)$$

Only the equation for β is exact, because the center of curvature of arc ac is at C . Here, \widehat{ac} is the arc extending from the point that the ray reflects from the mirror to the central axis. However, the equations for α and γ are approximately correct if these angles are small enough (that is, for rays close to the central axis). Substituting Eqs. 35-26 into Eq. 35-25, using Eq. 35-12 to replace r with $2f$, and canceling \widehat{ac} lead exactly to Eq. 35-13, the relation that we set out to prove.

The Refracting Surface Formula (Eq. 35-17)

Next we prove that when light from an object passes through a medium having an index of refraction n_1 and encounters a smooth spherical refracting surface of a

FIGURE 35-30 ■ A concave spherical mirror forms a real point image I by reflecting light rays from a point object O .

FIGURE 35-31 ■ A real point image I of a point object O is formed by refraction at a spherical convex surface between two media.

medium with an index of refraction n_2 , the image and object distances are related by Eq. 35-17,

$$\frac{n_1}{o} + \frac{n_2}{i} = \frac{n_2 - n_1}{r}.$$

Let's start by considering how an incident ray from point object O in Fig. 35-31 is refracted. According to Eq. 35-2, $n_1 \sin \theta_1 = n_2 \sin \theta_2$.

If α is small, θ_1 and θ_2 will also be small and we can replace the sines of these angles with the angles themselves. Thus, the equation above becomes

$$n_1 \theta_1 \approx n_2 \theta_2. \quad (35-27)$$

We again use the fact that an exterior angle of a triangle is equal to the sum of the two opposite interior angles. Applying this to triangles COa and ICa yields

$$\theta_1 = \alpha + \beta \quad \text{and} \quad \beta = \theta_2 + \gamma. \quad (35-28)$$

If we use Eqs. 35-28 to eliminate θ_1 and θ_2 from Eq. 35-27, we find

$$n_1 \alpha + n_2 \gamma = (n_2 - n_1) \beta. \quad (35-29)$$

In radian measure the angles α , β , and γ , are

$$\alpha \approx \frac{\widehat{ac}}{o}; \quad \beta = \frac{\widehat{ac}}{r}; \quad \gamma \approx \frac{\widehat{ac}}{i}. \quad (35-30)$$

Only the second of these equations is exact. The other two are approximate because I and O are not the centers of circles of which ac is a part. However, for α small enough (for rays close to the axis), the inaccuracies in Eqs. 35-30 are small. Substituting Eqs. 35-30 into Eq. 35-29 leads directly to Eq. 35-17, the relation we set out to prove.

The Thin-Lens Formulas (Eqs. 35-18 and 35-19)

Finally, we set out to show that for a thin lens, the object and image distances are related to the focal length of the lens by Eq. 35-18, $1/o + 1/i = 1/f$. Our plan is to consider each lens surface as a separate refracting surface, and to use the image formed by the first surface as the object for the second.

We start with the thick glass “lens” of length L in Fig. 35-32a whose left and right refracting surfaces are ground to radii r' and r'' . A point object O' is placed near the left surface as shown. A ray leaving O' along the central axis is not deflected on entering or leaving the lens.

A second ray leaving O' at an angle α with the central axis intersects the left surface at point a' , is refracted, and intersects the second (right) surface at point a'' . The ray is again refracted and crosses the axis at I'' , which, being the intersection of two rays from O' , is the image of point O' , formed after refraction at two surfaces.

Figure 35-32b shows that the first (left) surface also forms a virtual image of O' at I' . To locate I' , we use Eq. 35-17,

$$\frac{n_1}{o'} + \frac{n_2}{i'} = \frac{n_2 - n_1}{r'}.$$

Putting $n_1 = 1$ for air and $n_2 = n$ for lens glass and bearing in mind that the image distance is negative (that is, $i = -i'$ in Fig. 35-32b), we obtain

$$\frac{1}{o'} - \frac{n}{|i'|} = \frac{n - 1}{r'}. \quad (35-31)$$

FIGURE 35-32 (a) Two rays from point object O' form a real image I'' after refracting through two spherical surfaces of a “lens.” The object faces a convex surface at the left side of the lens and a concave surface at the right side. The ray traveling through points a' and a'' is actually close to the central axis through the lens. (b) The left side and (c) the right side of the “lens” in (a), shown separately.

Figure 35-32c shows the second surface again. Unless an observer at point a'' were aware of the existence of the first surface, the observer would think that the light striking that point originated at point I' in Fig. 35-32b and that the region to the left of the surface was filled with glass as indicated. Thus, the (virtual) image I' formed by the first surface serves as a real object O'' for the second surface. The distance of this object from the second surface is

$$o'' = |i'| + L. \quad (35-32)$$

To apply Eq. 35-17 to the second surface, we must insert $n_1 = n$ and $n_2 = 1$ because the object now is effectively imbedded in glass. If we substitute with Eq. 35-31, then Eq. 35-17 becomes

$$\frac{n}{|i'| + L} + \frac{1}{i''} = \frac{1 - n}{r''}. \quad (35-33)$$

Let us now assume that the thickness L of the “lens” in Fig. 35-32a is so small that we can neglect it in comparison with our other linear quantities (such as o' , i' , o'' , i'' , r' , and r''). In all that follows we make this *thin-lens approximation*. Putting $L = 0$ in Eq. 35-33 and rearranging the right side lead to

$$\frac{n}{i'} + \frac{1}{i''} = -\frac{n - 1}{r''}. \quad (35-34)$$

Adding Eqs. 35-31 and 35-34 leads to

$$\frac{1}{o'} + \frac{1}{i''} = (n - 1) \left(\frac{1}{r'} - \frac{1}{r''} \right).$$

Finally, calling the original object distance simply o and the final image distance simply i leads to

$$\frac{1}{o} + \frac{1}{i} = (n - 1) \left(\frac{1}{r'} - \frac{1}{r''} \right), \quad (35-35)$$

which, with $r' \equiv r_1$ and $r'' = r_2$, reduces to Eqs. 35-18 and 35-19, the relations we set out to prove.

Problems

SEC. 35-2 ■ REFLECTION AND REFRACTION

1. Light in a Vacuum Light in vacuum is incident on the surface of a glass slab. In the vacuum the beam makes an angle of 32.0° with the normal to the surface, while in the glass it makes an angle of 21.0° with the normal. What is the index of refraction of the glass?

2. Two Perpendicular Surfaces Figure 35-33 shows light reflecting from two perpendicular reflecting surfaces A and B . Find the angle between the incoming ray i and the outgoing ray r' .

FIGURE 35-33 ■ Problem 2.

3. Rectangular Metal Tank

When the rectangular metal tank in Fig. 35-34 is filled to the top with an unknown liquid, an observer with eyes level with the top of the tank can just see the corner E ; a ray that refracts toward the observer at the top surface of the liquid is shown. Find the index of refraction of the liquid.

FIGURE 35-34 ■ Problem 3.

4. Claudius Ptolemy In about A.D. 150, Claudius Ptolemy gave the following measured values for the angle of incidence θ_1 and the angle of refraction θ_2 for a light beam passing from air to water:

θ_1	θ_2	θ_1	θ_2
10°	$8^\circ 00'$	50°	$35^\circ 00'$
20°	$15^\circ 30'$	60°	$45^\circ 30'$
30°	$22^\circ 30'$	70°	$45^\circ 30'$
40°	$29^\circ 00'$	80°	$50^\circ 00'$

(a) Are these data consistent with the law of refraction? (b) If so, what index of refraction results? These data are interesting as perhaps the oldest recorded physical measurements.

5. Vertical Pole In Fig. 35-35, a 2.00-m-long vertical pole extends from the bottom of a swimming pool to a point 50.0 cm above the water. Sunlight is incident at 55.0° above the horizon. What is the length of the shadow of the pole on the level bottom of the pool?

FIGURE 35-35 ■ Problem 5.

6. Four Transparent Materials In Fig. 35-36, light is incident at angle $\theta_1 = 40.1^\circ$ on a boundary between two transparent materials. Some of the light then travels down through the next three layers

of transparent materials, while some of it reflects upward and then escapes into the air. What are the values of (a) θ_5 and (b) θ_4 ?

7. Sideways Displacement Prove that a ray of light incident on the surface of a sheet of plate glass of thickness t emerges from the opposite face parallel to its initial direction but displaced sideways, as in Fig. 35-37. Show that, for small angles of incidence θ , this displacement is given by

$$x = t\theta \frac{n-1}{n},$$

where n is the index of refraction of the glass and θ is measured in radians.

8. White Light A ray of white light makes an angle of incidence of 35° on one face of a prism of fused quartz; the prism's cross section is an equilateral triangle. Sketch the light as it passes through the prism, showing the paths traveled by rays representing (a) blue light, (b) yellow-green light, and (c) red light.

9. Triangular Prism

In Fig. 35-38, a ray is incident on one face of a triangular glass prism in air. The angle of incidence θ is chosen so

FIGURE 35-38 ■ Problems 9 and 18.

that the emerging ray also makes the same angle θ with the normal to the other face. Show that the index of refraction n of the glass prism is given by

$$n = \frac{\sin \frac{1}{2}(\psi + \phi)}{\sin \frac{1}{2}\phi},$$

where ϕ is the vertex angle of the prism and ψ is the *deviation angle*, the total angle through which the beam is turned in passing through the prism. (Under these conditions the deviation angle ψ has the smallest possible value, which is called the *angle of minimum deviation*.)

10. Perpendicular Mirrors In Fig. 35-39 two perpendicular mirrors form the sides of a vessel filled with

FIGURE 35-36 ■ Problem 6.

FIGURE 35-37 ■ Problem 7.

FIGURE 35-39 ■ Problem 10.

water. (a) A light ray is incident from above, normal to the water surface. Show that the emerging ray is parallel to the incident ray. Assume that there are reflections at both mirror surfaces. (b) Repeat the analysis for the case of oblique incidence with the incident ray in the plane of the figure.

SEC. 35-3 ■ TOTAL INTERNAL REFLECTION

11. Glass Slab In Fig. 35-40 a light ray enters a glass slab at point A and then undergoes total internal reflection at point B . What minimum value for the index of refraction of the glass can be inferred from this information?

FIGURE 35-40 ■ Problem 11.

12. Benzene The index of refraction of benzene is 1.8. What is the critical angle for a light ray traveling in benzene toward a plane layer of air above the benzene?

13. Perpendicular to Face In Fig. 35-41, a ray of light is perpendicular to the face ab of a glass prism ($n = 1.52$). Find the largest value of the angle ϕ so that the ray is totally reflected at face ac if the prism is immersed (a) in air and (b) in water.

FIGURE 35-41 ■ Problem 13.

14. Point Source A point source of light is 80.0 cm below the surface of a body of water. Find the diameter of the circle at the surface through which light emerges from the water.

15. Solid Glass Cube A solid glass cube, of edge length 10 mm and index of refraction 1.5, has a small spot at its center. (a) What parts of each cube face must be covered to prevent the spot from being seen, no matter what the direction of viewing? (Neglect light that reflects inside the cube and then refracts out into the air.) (b) What fraction of the cube surface must be so covered?

16. Fused Quartz A ray of white light travels through fused quartz that is surrounded by air. If all the color components of the light undergo total internal reflection at the surface, then the reflected light forms a reflected ray of white light. However, if the color component at one end of the visible range (either blue or red) partially refracts through the surface into the air, there is less of that component in the reflected light. Then the reflected light is not white but has the tint of the opposite end of the visible range. (If blue were partially lost to refraction, then the reflected beam would be reddish, and vice versa.) Is it possible for the reflected light to be (a) bluish or (b) reddish? (c) If so, what must be the angle of incidence of the original white light on the quartz surface? (See Fig. 35-31.)

17. 90° Prism In Fig. 35-42, light enters a 90° triangular prism at point P with incident angle θ and then some of it refracts at point Q with an angle of refraction of 90°. (a) What is the index of refraction of the prism in terms of θ ? (b) What,

FIGURE 35-42 ■ Problem 17.

numerically, is the maximum value that the index of refraction can have? Explain what happens to the light at Q if the incident angle at Q is (c) increased slightly and (d) decreased slightly.

18. Apex Angle Given Suppose the prism of Fig. 35-38 has apex angle $\phi = 60.0^\circ$ and index of refraction $n = 1.60$. (a) What is smallest angle of incidence θ for which a ray can enter the left face of the prism and exit the right face? (b) What angle of incidence θ is required for the ray to exit the prism with an identical angle θ for its refraction, as it does in Fig. 35-38? (See Problem 9.)

SEC. 35-4 ■ POLARIZATION BY REFLECTION

19. Light in Water Light traveling in water of refractive index 1.33 is incident on a plate of glass with index of refraction 1.53. At what angle of incidence is the reflected light fully polarized?

20. Completely Polarized (a) At what angle of incidence will the light reflected from water be completely polarized? (b) Does this angle depend on the wavelength of the light?

SEC. 35-6 ■ PLANE MIRRORS

21. Moth A moth at about eye level is 10 cm in front of a plane mirror; you are behind the moth, 30 cm from the mirror. What is the distance between your eyes and the apparent position of the moth's image in the mirror?

22. Hummingbird You look through a camera toward an image of a hummingbird in a plane mirror. The camera is 4.30 m in front of the mirror. The bird is at camera level, 5.00 m to your right and 3.30 m from the mirror. What is the distance between the camera and the apparent position of the bird's image in the mirror?

23. Two Vertical Mirrors Figure 35-43a is an overhead view of two vertical plane mirrors with an object O placed between them. If you look into the mirrors, you see multiple images of O . You can find them by drawing the reflection in each mirror of the angular region between the mirrors, as is done for the left-hand mirror in Fig. 35-43b. Then draw the reflection of the reflection. Continue this on the left and on the right until the reflections meet or overlap at the rear of the mirrors. Then you can count the number of images of O .

FIGURE 35-43 ■ Problems 23 and 24.

(a) If $\theta = 90^\circ$, how many images of O would you see? (b) Draw their locations and orientations (as in Fig. 35-43b).

24. Repeat Repeat Problem 23 for the mirror angle θ equal to (a) 45° , (b) 60° , and (c) 120° . (d) Explain why there are several possible answers for (c).

25. Prove That Prove that if a plane mirror is rotated through an angle α , the reflected beam is rotated through an angle 2α . Show that this result is reasonable for $\alpha = 45^\circ$.

26. Corridor Figure 35-44 shows an overhead view of a corridor with a plane mirror M mounted at one end. A burglar B sneaks

along the corridor directly toward the center of the mirror. If $d = 3.0$ m, how far from the mirror will she be when the security guard S can first see her in the mirror?

27. S and d You put a point source of light S a distance d in front of a screen A . How is the light intensity at the center of the screen changed if you put a completely reflecting mirror M a distance d behind the source, as in Fig. 35-45? (*Hint:* Use Eq. 34-25.)

28. Small Lightbulb Figure 35-46 shows a small lightbulb suspended above the surface of the water in a swimming pool. The bottom of the pool is a large mirror. How far below the mirror's surface is the image of the bulb? (*Hint:* Construct a diagram of two rays like that of Fig. 35-14, but take into account the bending of light rays by refraction. Assume that the rays are close to a vertical axis through the bulb, and use the small-angle approximation that $\sin \theta \approx \tan \theta$.)

SEC. 35-8 ■ IMAGES FROM SPHERICAL MIRRORS

29. Concave Shaving Mirror A concave shaving mirror has a radius of curvature of 35.0 cm. It is positioned so that the (upright) image of a man's face is 2.50 times the size of the face. How far is the mirror from the face?

30. Fill in Table Fill in Table 35-4, each row of which refers to a different combination of an object and either a plane mirror, a spherical convex mirror, or a spherical concave mirror. Distances are in centimeters. If a number lacks a sign, find the sign. Sketch each combination and draw in enough rays to locate the object and its image.

FIGURE 35-44 ■ Problem 26.

FIGURE 35-45 ■ Problem 27.

FIGURE 35-46 ■ Problem 28.

31. Short Straight Object A short straight object of length L lies along the central axis of a spherical mirror of focal length f , a distance o from the mirror. (a) Show that its image in the mirror has a length L' where

$$L' = L \left(\frac{f}{o - f} \right)^2.$$

(*Hint:* Locate the two ends of the object.) (b) Show that the longitudinal magnification $m' (= L'/L)$ is equal to m^2 , where m is the lateral magnification.

32. Luminous Point (a) A luminous point is moving at speed v_o toward a spherical mirror with radius of curvature r , along the central axis of the mirror. Show that the image of this point is moving at speed

$$v_i = - \left(\frac{r}{2o - r} \right)^2 v_o,$$

where o is the distance of the luminous point from the mirror at any given time. (*Hint:* Start with Eq. 35-13.) Now assume that the mirror is concave, with $r = 15$ cm, and let $v_o = 5.0$ cm/s. Find the speed of the image when (b) $o = 30$ cm (far outside the focal point), (c) $o = 8.0$ cm (just outside the focal point), and (d) $o = 10$ mm (very near the mirror).

SEC. 35-9 ■ SPHERICAL REFRACTING SURFACES

33. Parallel Light Rays A beam of parallel light rays from a laser is incident on a solid transparent sphere of index of refraction n (Fig. 35-47). (a) If a point image is produced at the back of the sphere, what is the index of refraction of the sphere? (b) What index of refraction, if any, will produce a point image at the center of the sphere?

FIGURE 35-47 ■ Problem 33.

34. Fill in Table Two Fill in Table 35-5, each row of which refers to a different combination of a point object and a spherical refracting surface separating two media with different indexes of refraction. Distances are in centimeters. If a number lacks a sign, find the sign. Sketch each combination and draw in enough rays to locate the object and image.

35. Coin in a Pool You look downward at a coin that lies at the bottom of a pool of liquid with depth d and index of refraction n (Fig. 35-48). Because you view with two eyes, which intercept different rays of light from the coin, you perceive the coin to be where extensions of the intercepted rays cross, at depth d_a instead of d . Assuming that the intercepted rays in Fig. 35-48 are close to a vertical axis through the coin, show that $d_a = d/n$. (*Hint:* Use the small-angle approximation that $\sin \theta \approx \tan \theta \approx \theta$.)

FIGURE 35-48 Problem 35.

36. Carbon Tetrachloride A 20-mm-thick layer of water ($n = 1.33$) floats on a 40-mm-thick layer of carbon tetrachloride ($n = 1.46$) in a tank. A coin lies at the bottom of the tank. At what depth below the top water surface do you perceive the coin? (*Hint:* Use the result and assumptions of Problem 35 and work with a ray diagram of the situation.)

SEC. 35-10 ■ THIN LENSES

37. Thin Diverging Lens An object is 20 cm to the left of a thin diverging lens having a 30 cm focal length. What is the image distance i ? Find the image position with a ray diagram.

38. Image of Sun You produce an image of the Sun on a screen, using a thin lens whose focal length is 20.0 cm. What is the diameter of the image? (See Appendix C for needed data on the Sun.)

39. Double-Convex A double-convex lens is to be made of glass with an index of refraction of 1.5. One surface is to have twice the radius of curvature of the other and the focal length is to be 60 mm. What are the radii?

40. One Side Is Flat A lens is made of glass having an index of refraction of 1.5. One side of the lens is flat, and the other is convex with a radius of curvature of 20 cm. (a) Find the focal length of the lens. (b) If an object is placed 40 cm in front of the lens, where will the image be located?

41. Newtonian Form The formula

$$\frac{1}{o} + \frac{1}{i} = \frac{1}{f}$$

is called the *Gaussian* form of the thin-lens formula. Another form of this formula, the *Newtonian* form, is obtained by considering the distance x from the object to the first focal point and the distance x' from the second focal point to the image. Show that

$$xx' = f^2$$

is the Newtonian form of the thin-lens formula.

42. Movie Camera A movie camera with a (single) lens of focal length 75 mm takes a picture of a 180-cm-high person standing 27 m away. What is the height of the image of the person on the film?

43. Illuminated Slide An illuminated slide is held 44 cm from a screen. How far from the slide must a lens of focal length 11 cm be placed to form an image of the slide's picture on the screen?

44. Fill in Table Three To the extent possible, fill in Table 35-6, each row of which refers to a different combination of an object and a thin lens. Distances are in centimeters. For the type of lens, use C for converging and D for diverging. If a number (except for the index of refraction) lacks a sign, find the sign. Sketch each combination and draw in enough rays to locate the object and image.

TABLE 35-6

Problem 44: Thin Lenses

	Type	f	r_1	r_2	i	o	n	m	Real Image?	Inverted Image?
(a)	C	10				+20				
(b)		+10				+5.0				
(c)		10				+5.0		> 1.0		
(d)		10				+5.0		< 1.0		
(e)			+30	-30	+10	1.5				
(f)			-30	+30	+10	1.5				
(g)			-30	-60	+10	1.5				
(h)					+10			0.50		No
(i)					+10			-0.50		

45. Show That Show that the distance between an object and its real image formed by a thin converging lens is always greater than or equal to four times the focal length of the lens.

46. Diverging and Converging A diverging lens with a focal length of -15 cm and a converging lens with a focal length of 12 cm have a common central axis. Their separation is 12 cm. An object of height 1.0 cm is 10 cm in front of the diverging lens, on the common central axis. (a) Where does the lens combination produce the final image of the object (the one produced by the second, converging lens)? (b) What is the height of that image? (c) Is the image real or virtual? (d) Does the image have the same orientation as the object or is it inverted?

47. Final Image A converging lens with a focal length of $+20$ cm is located 10 cm to the left of a diverging lens having a focal length of -15 cm. If an object is located 40 cm to the left of the converging lens, locate and describe completely the final image formed by the diverging lens.

48. Location and Size An object is 20 cm to the left of a lens with a focal length of $+10$ cm. A second lens of focal length $+12.5$ cm is 30 cm to the right of the first lens. (a) Find the location and relative size of the final image. (b) Verify your conclusions by drawing the lens system to scale and constructing a ray diagram. (c) Is the final image real or virtual? (d) Is it inverted?

49. Two Thin Lenses Two thin lenses of focal lengths f_1 and f_2 are in contact. Show that they are equivalent to a single thin lens with

$$f = \frac{f_1 f_2}{f_1 + f_2}$$

as its focal length.

50. Real Inverted In Fig. 35-49, a real inverted image I of an object O is formed by a certain lens (not shown); the object–image separation is $d = 40.0$ cm, measured along the central axis of the lens. The image is just half the size of the object. (a) What kind of lens must be used to produce this image? (b) How far from the object must the lens be placed? (c) What is the focal length of the lens?

FIGURE 35-49 ■ Problem 50.

51. Object–Screen Distance A luminous object and a screen are a fixed distance D apart. (a) Show that a converging lens of focal length f , placed between object and screen, will form a real image on the screen for two lens positions that are separated by a distance

$$d = \sqrt{D(D - 4f)}.$$

(b) Show that

$$\left(\frac{D - d}{D + d}\right)^2$$

gives the ratio of the two image sizes for these two positions of the lens.

SEC. 35-11 ■ OPTICAL INSTRUMENTS

52. Astronomical Telescope If an angular magnification of an astronomical telescope is 36 and the diameter of the objective is 75 mm, what is the minimum diameter of the eyepiece required to collect all the light entering the objective from a distant point source on the telescope axis?

53. Microscope In a microscope of the type shown in Fig. 35-28, the focal length of the objective is 4.00 cm, and that of the eyepiece is 8.00 cm. The distance between the lenses is 25.0 cm. (a) What is the tube length s ? (b) If image I in Fig. 35-28 is to be just inside focal point F'_1 , how far from the objective should the object be? What then are (c) the lateral magnification m of the objective, (d) the angular magnification m_θ of the eyepiece, and (e) the overall magnification M of the microscope?

54. Magnifying Lens A simple magnifying lens of focal length f is placed near the eye of someone whose near point P_n is 25 cm from the eye. An object is positioned so that its image in the magnifying lens appears at P_n . (a) What is the lens's angular magnification? (b) What is the angular magnification if the object is moved so that its image appears at infinity? (c) Evaluate the angular magnifications of (a) and (b) for $f = 10$ cm. (Viewing an image at P_n requires effort by muscles in the eye, whereas for many people viewing an image at infinity requires no effort.)

55. Human Eye Figure 35-50a shows the basic structure of a human eye. Light refracts into the eye through the cornea and is then further redirected by a lens whose shape (and thus ability to focus the light) is controlled by muscles. We can treat the cornea and eye lens as a single effective thin lens (Fig. 35-50b). A “normal” eye can focus parallel light rays from a distant object O to a point on the retina at the back of the eye, where processing of the visual information begins. As an object is brought close to the eye, however, the muscles must change the shape of the lens so that rays form an inverted real image on the retina (Fig. 35-50c). (a) Suppose that for the parallel rays of Figs. 35-50a and b, the focal length f of the effective thin lens of the eye is 2.50 cm. For an object at distance $o = 40.0$ cm, what focal length f' of the effective lens is required for it to be seen clearly? (b) Must the eye muscles increase or decrease the radii of curvature of the eye lens to give focal length f' ?

FIGURE 35-50 ■ Problem 55.

56. Compound Microscope An object is 10.0 mm from the objective of a certain compound microscope. The lenses are 300 mm apart and the intermediate image is 50.0 mm from the eyepiece. What overall magnification is produced by the instrument?

57. Camera Figure 35-51a shows the basic structure of a camera. A lens can be moved forward or back to produce an image on film at the back of the camera. For a certain camera, with the distance i between the lens and the film set at $f = 5.0$ cm, parallel light rays from a very distant object O converge to a point image on the film, as shown. The object is now brought closer, to a distance of $o = 100$ cm, and the lens–film distance is adjusted so that an inverted real image forms on the film (Fig. 35-51b). (a) What is the lens–film distance i now? (b) By how much was i changed?

FIGURE 35-51 ■ Problem 57.

Additional Problems

58. Bizarre Behavior with Light You may have observed people with cameras behaving strangely:

(a) At a conference in North Carolina, one of the physics graduate students (who should have known better!) tried to take a picture of

the overheads projected on a white screen. Since the room was darkened, he used a flash. Explain why this is a bad idea and what his pictures are likely to show.

(b) Someone mentioned to the student that he probably should not be using his flash, so he turned it off. He then proceeded to try and take pictures of the participants in the darkened room! Explain why this is a bad idea and what his pictures are likely to show.

(c) A woman on an airplane at night with a camera was impressed with the view of the city lights in the dark as the plane flew over Washington, D.C. She stood back in the aisle with her camera and tried to take a picture through the window using her flash. Explain why this is a bad idea and what her pictures are likely to show.

59. Closer Than They May Appear When a *T. rex* pursues a jeep in the movie *Jurassic Park*, we see a reflected image of the (very large) *T. rex* via a side-view mirror, on which is printed the (then darkly humorous) warning: "Objects in mirror are closer than they appear." Is the mirror flat, convex, or concave? Why do you think so?

60. Where Can You See the Bulb? In Fig. 35-52, M is a plane mirror; B is a very small bright lightbulb that can be treated as a point source of light; and H is an opaque housing that does not transmit light. An observer can stand anywhere along a line O to try to see the image of the lightbulb in the mirror.

FIGURE 35-52 ■ Problem 60.

By using relevant rays of light, determine those locations along the line O from which the image of B is visible and those locations from which it is not visible. Mark the regions along line O accordingly, and explain the reasoning you used in drawing the rays. (Arons, Arnold, *A Guide to Introductory Physics Teaching*, John Wiley and Sons, New York, 1990.)

61. Who Sees What? Figure 35-53 shows a small object (represented by an arrow) in front of a curved mirror. At the tip of the arrow is a black dot. The mirror is a piece of a sphere. The center of the sphere is marked in the picture with an x . Eyes corresponding to three different observers are shown. For each question, explain how you got your result. Be sure to include a ray diagram as part of your explanation.

(a) How many black dots will the observer at position A see? Where will the dots appear to be? Specify quantitatively how far

FIGURE 35-53 ■ Problem 61.

from the mirror the dots will appear to be and how far off the axis they will be.

(b) How many black dots will the observer at position B see? Explain how you know.

(c) How many black dots will the observer at position C see? Explain how you know.

62. The Camera and the Slide Projector Address each part of this question in two ways: (1) by drawing and interpreting appropriate geometrical diagrams and (2) by appealing to the lens equation and the expression for lateral magnification and demonstrating your result mathematically. If your two approaches do not agree, explain which one is correct and why the other is wrong.

(a) Suppose you are using a camera and wish to have a larger image of a distant object than you are obtaining with the lens currently in use. Would you change to a lens with a longer or a shorter focal length? Explain your reasoning. (*Hint*: Note that the object distance is essentially fixed.)

(b) Suppose you are using a slide projector and wish to obtain a larger image on the screen. You cannot achieve this by moving the screen farther from the projector because you are already using the entire length of the room. Would you change to a lens with a longer or a shorter focal length than the one you are using? Explain your reasoning. (*Hint*: Note that the image distance is essentially fixed.)

63. Mirrors and Lenses Each of the parts of this problem has a description of an object and an optical device (lens or mirror). A sketch is shown in Fig. 35-54. For each case, specify whether

FIGURE 35-54 ■ Problem 63.

- The image is real (R), virtual (V), or no image is formed (N).
- The image is on the same side of the device as the object (S) or the opposite side (O). If there is no image put a null mark (\emptyset).
- If an image is formed, on which side of the system must the observer be in order to see it, left (−) or right (+)?

For each problem you should therefore give three answers (for example, VO +). For the mirrors, the center is shown. For the lenses, the focal points are shown. The radius of curvature of the mirrors is R , and the focal length of the lenses is f .

(a) An object on the right side of a spherical mirror, a distance $s > R$ from the mirror. The mirror is concave toward the object.

(b) An object on the right side of a spherical mirror, a distance $s < R/2$ from the mirror. The mirror is convex toward the object.

- (c) An object on the left side of a spherical mirror, a distance $R > s > R/2$ from the mirror. The mirror is concave toward the object.
- (d) An object on the right side of a convex lens, a distance $s > f$ from the lens.
- (e) An object on the left side of a convex lens, a distance $s < f$ from the lens.

64. The Diverging Lens In Fig. 35-55, point A (marked by a circle) is the top of a small object (indicated as an arrow). Near it is a concave lens, as shown. The focal points of the lens are marked with black dots.

FIGURE 35-55 ■ Problem 64.

- (a) Using a ray diagram, show where an image of point A would be formed.
- (b) If the focal length of the lens is 8 cm and the object is 6 cm from the lens, where will the image be?
- (c) If the object is 1 cm tall, how tall will the image be?
- (d) Will the image created by the lens be real or virtual?
- (e) Where will you have to be to see the image?

65. The Half Lens A projector has an arrangement of lenses as shown in Fig. 35-56. A bulb illuminates an object (a slide) and the light then passes through a lens that creates an image on a distant screen as shown.

FIGURE 35-56 ■ Problem 65.

When a sheet of a cardboard is brought up to cover the lower half of the lens, what happens to the image on the screen?

- (a) The top half of the image disappears.
- (b) The bottom half of the image disappears.
- (c) The image remains but is weaker (not as bright).
- (d) The image remains unchanged.
- (e) The bottom half of the image becomes weaker, the top is unchanged.
- (f) The top half of the image becomes weaker, the bottom is unchanged.
- (g) Something else happens. (Tell what it is.)

Explain your reasoning, drawing whatever rays are needed to make your point clear.

66. Alice and the Looking Glass Alice faces a looking glass (mirror) and is standing at a level so that her eyes appear to her to be right at the top of the mirror as shown in Fig. 35-57. At the position she is standing, she can just see her hands at the bottom of the mirror. If she steps back far enough,

FIGURE 35-57 ■ Problem 66.

- (a) She will eventually be able to see all of herself in the mirror at the same time.
- (b) There will be no change in how much of herself she can see.
- (c) She will see less of herself as she steps back.
- (d) Some other result (explain).

Choose the letter of the choice that completes the sentence correctly and explain why you think so with a few sentences and some rays on the diagram.

67. A Bigger Lens Point O in Fig. 35-58 is a source of light. Two rays from O are shown passing through a thin converging lens and crossing each other at the point marked C .

FIGURE 35-58 ■ Problem 67.

- (a) On a copy of the figure on your answer sheet, find the two principal foci of the lens by drawing appropriate rays. Label the foci F_1 and F_2 . Explain your reasoning.
- (b) Suppose the lens is replaced by another lens having the same focal length but a larger diameter. Indicate whether each of the following partial sentences is correctly completed by the phrase greater than ($>$), less than ($<$), or the same as ($=$).

- The distance of the image from the principal axis is _____ it was with the smaller lens.
- The brightness of the image with the large lens is _____ it was with the smaller lens.

68. Where's the Image? Figure 35-59 shows a thin lens (indicated by a gray rectangle) and a coordinate system. The x axis passes

FIGURE 35-59 ■ Problem 68.

through the center of the lens and runs along its axis of symmetry, with the positive x direction indicated by the arrowhead. The lens may be treated as being of negligible thickness and has a focal length f . The points $(x, y) = (f, 0)$ and $(-f, 0)$ are marked by black dots.

A small object is placed at the position $(x, 0)$. For each of the four cases (i)–(iv) below, indicate whether the location of the image formed ($= x'$) is on the positive or negative side of the axis, and closer to the lens than the focal point or farther away.

i. $-f < x < 0$

iii. $x < f < 0$

ii. $f < 0 < x$

iv. $0 < f < x$

Hint: Your answer should take a form such as $(x' > f > 0)$ to indicate that the image is on the positive side of the axis and farther away than the focal point or $(0 > x' > f)$ to indicate that the image is on the negative side of the axis between the lens and the focal point. Note that in some cases the focal length specified is negative and in some cases it is positive.

36

Interference

At first glance, the top surface of the *Morpho* butterfly's wing is simply a beautiful blue-green. There is something strange about the color, however, for it almost glimmers, unlike the colors of most objects—and if you change your perspective, or if the wing moves, the tint of the color changes. The wing is said to be iridescent, and the blue-green we see hides the wing's "true" dull brown color that appears on the bottom surface.

What is so different about the top surface that gives us this arresting display?

The answer is in this chapter.

36-1 Interference

Sunlight, as the rainbow shows us, is a composite of all the colors of the visible spectrum. The colors reveal themselves in the rainbow because the incident wavelengths refract and so are bent through different angles as they pass through raindrops that produce the bow. However, soap bubbles and oil slicks can also show striking colors produced not by refraction but by constructive and destructive **interference** of light waves. The interfering waves combine either to enhance or to suppress certain colors in the spectrum of the incident sunlight. Interference of light waves is thus a superposition phenomenon. Hence, this chapter is a significant point of connection between much of what we have just learned in Chapters 34 and 35 about electromagnetic waves in general and light in particular and what we learned earlier regarding the interference of waves on a string and sound waves in Chapters 17 and 18.

Interference, which can lead to the selective enhancement or suppression of wavelengths, has many applications. When light encounters an ordinary glass surface, for example, about 4% of the incident energy is reflected, thus weakening the transmitted beam by that amount. This unwanted loss of light can be a real problem in optical systems with many components. A thin, transparent “interference film,” deposited on the glass surface, can reduce the amount of reflected light (and thus enhance the transmitted light) by destructive interference. The bluish cast of a camera lens reveals the presence of such a coating. Interference coatings can also be used to enhance—rather than reduce—the ability of a surface to reflect light.

To understand interference, we must go beyond the restrictions of geometrical optics and employ the full power of wave optics. In fact, as you will see, the existence of interference phenomena is perhaps our most convincing evidence that light is a wave—because interference cannot be explained other than with waves.

36-2 Light as a Wave

The first person to advance a convincing wave theory for light was Dutch physicist Christian Huygens, in 1678. Although much less comprehensive than the later electromagnetic theory of Maxwell, Huygens’ theory was simpler mathematically and remains useful today. Its great advantages are that it accounts for the laws of reflection and refraction in terms of waves and gives physical meaning to the index of refraction.

Huygens’ wave theory is based on a geometrical construction that allows us to tell where a given wavefront will be at any time in the future if we know its present position. This construction is based on **Huygens’ principle**, which is:

All points on a wavefront serve as point sources of spherical secondary wavelets. After a time Δt , the new position of the wavefront will be that of a surface tangent to these secondary wavelets.*

Here is a simple example. At the left in Fig. 36-1, the present location of a wavefront of a plane wave traveling to the right in vacuum is represented by plane ab , perpendicular to the page. Where will the wavefront be at time Δt later? We let several points on plane ab (the dots) serve as sources of spherical secondary wavelets that are emitted at $t = 0$. At time Δt , the radius of all these spherical wavelets will have grown to

FIGURE 36-1 ■ The propagation of a plane wave in vacuum, as portrayed by Huygens’ principle.

* When using this principle in calculations, there is a factor which gives a greater wave amplitude in the direction of propagation of the original wavefront. This prevents the back wavelets from combining to create a backwards wavefront.

$c\Delta t$, where c is the speed of light in vacuum. We draw plane de tangent to these wavelets at time Δt . This plane represents the wavefront of the plane wave at time Δt ; it is parallel to plane ab and a perpendicular distance $c\Delta t$ from it.

The Law of Refraction

We now use Huygens' principle to derive the law of refraction or Snell's law, $n_1 \sin\theta_1 = n_2 \sin\theta_2$ (Eq. 35-2). Recall that here n_1 is the index of refraction in the medium from which the light is incident, n_2 is the index of refraction in the refracting medium, and θ_1 and θ_2 are the angles of incidence and refraction, respectively. There are two key ideas behind this derivation:

1. The oscillating electromagnetic wave (with its oscillating E - and B -fields) hitting the surface of a material drives the electrons in the surface to oscillate and hence to reradiate. As a result, the outgoing wave the electrons produce will have the same frequency as the incoming wave.
2. The wavelength is determined by how far the wave propagates into the media while the electrons at the surface are undergoing one full oscillation. Since the relationship between wavelength λ , period T , and speed of the wave v is $v = \lambda/T$, and the wave speed in a denser medium is slower, the wavelength is smaller in a denser medium.

FIGURE 36-2 ■ The refraction of a plane wave at an air–glass interface, as portrayed by Huygens' principle. The wavelength in glass is smaller than that in air. For simplicity, the reflected wave is not shown. Parts (a) through (c) represent three successive stages of the refraction.

Figure 36-2 shows three stages in the refraction of several wavefronts at a plane interface between air (medium 1) and glass (medium 2). By convention, we choose the wavefronts in the incident beam to be separated by λ_1 , the wavelength in medium 1. Let the speed of light in air be v_1 and that in glass be v_2 . We assume that $v_2 < v_1$, which happens to be true. (Since in this chapter we do not use vector components, we run no risk of confusing the magnitude of a velocity vector with its components. Therefore, we will simplify notation and write the speed as simply v , rather than $|\vec{v}|$.)

Angle θ_1 in Fig. 36-2a is the angle between the wavefront and the interface; it has the same value as the angle between the *normal* to the wavefront (that is, the incident ray) and the *normal* to the interface. Thus, θ_1 is the angle of incidence.

As the incident light wave moves into the glass, a wavefront at point e will travel a distance of λ_1 to point c . The time period required for the wave to travel this distance is the distance divided by the speed of the wavelet, or λ_1/v_1 . In this same time period, a Huygens wavelet (a new wave created by the oscillating electrons in the material) at point h will travel to point g , at the reduced speed v_2 and with wavelength λ_2 . Thus, this time period must also be equal to λ_2/v_2 . By equating these times, we obtain the relation

$$\frac{\lambda_1}{\lambda_2} = \frac{v_1}{v_2}, \quad (36-1)$$

which shows that the wavelengths of light in two media are proportional to the speeds of light in those media.

By Huygens' principle, the refracted wavefront must be tangent to an arc of radius λ_2 centered on h , say, at point g . The refracted wavefront must also be tangent to an arc of radius λ_1 centered on e , say, at c . Then the refracted wavefront must be oriented as shown. Note that θ_2 , the angle between the refracted wavefront and the interface, is actually the angle of refraction.

For the right triangles hce and hcg in Fig. 36-2b we may write

$$\sin\theta_1 = \frac{\lambda_1}{hc} \quad (\text{for triangle } hce)$$

and
$$\sin\theta_2 = \frac{\lambda_2}{hc} \quad (\text{for triangle } hcg).$$

Dividing the first of these two equations by the second and using Eq. 36-1, we find

$$\frac{\sin\theta_1}{\sin\theta_2} = \frac{\lambda_1}{\lambda_2} = \frac{v_1}{v_2}. \quad (36-2)$$

We can define an **index of refraction** n for each medium as the ratio of the speed of light in vacuum to the speed of light v in the medium. Thus,

$$n \equiv \frac{c}{v} \quad (\text{definition of index of refraction}). \quad (36-3)$$

In particular, for our two media, we have

$$n_1 = \frac{c}{v_1} \quad \text{and} \quad n_2 = \frac{c}{v_2}. \quad (36-4)$$

If we combine Eqs. 36-2 and 36-4 we find

$$\frac{\sin\theta_1}{\sin\theta_2} = \frac{c/n_1}{c/n_2} = \frac{n_2}{n_1}, \quad (36-5)$$

$$\text{or} \quad n_1 \sin\theta_1 = n_2 \sin\theta_2 \quad (\text{law of refraction}), \quad (36-6)$$

as introduced in Chapter 34. This result demonstrates that Huygen's Principle is a construct that can be used to explain the law of refraction.

Wavelength and Index of Refraction

We have now seen that the wavelength of light changes when the speed of the light changes, as happens when light crosses an interface from one medium into another. Further, the speed of light in any medium depends on the index of refraction of the medium, according to Eq. 36-3. Thus, the wavelength of light in any medium depends on the index of refraction of the medium. Let a certain monochromatic light have wavelength λ and speed c in vacuum and wavelength λ_n and speed v in a medium with an index of refraction n . Now we can rewrite Eq. 36-1 as

$$\lambda_n = \lambda \frac{v}{c}. \quad (36-7)$$

Using Eq. 36-3 to substitute $1/n$ for v/c then yields

$$\lambda_n = \frac{\lambda}{n}. \quad (36-8)$$

This equation relates the wavelength of light in any medium to its wavelength in vacuum. It tells us that the greater the index of refraction of a medium, the smaller is the wavelength of light in that medium.

What about the frequency of the light? Let f_n represent the frequency of the light in a medium with index of refraction n . Then from the general relation of Eq. 17-12 ($v = \lambda f$), we can write

$$f_n = \frac{v}{\lambda_n}.$$

Substituting Eqs. 36-3 and 36-8 then gives us

$$f_n = \frac{c/n}{\lambda/n} = \frac{c}{\lambda} = f,$$

where f is the frequency of the light in vacuum. Thus, although the speed and wavelength of light are different in the medium than in vacuum, the frequency of the light in the medium is the same as it is in vacuum. Since we started this discussion with the assumption that the periods of the waves were the same, this result indicates that our equations are consistent.

The fact that the wavelength of light depends on the index of refraction via Eq. 36-8 is important in certain situations involving the interference of light waves. For example, in Fig. 36-3, the *waves of the rays* (that is, the waves associated with the rays) have identical wavelengths λ and are initially in phase in air ($n \approx 1$). One of the waves travels through medium 1 of index of refraction n_1 and length L . The other travels through medium 2 of index of refraction n_2 and the same length L . Each ray acquires a different wavelength when traveling through its medium. When the waves leave the two media, they will have the same wavelength once again—their wavelength λ in air. However, because their wavelengths differed in the two media, the two waves may no longer be in phase.

FIGURE 36-3 Two light rays with the same initial wavelength λ in air travel through two media having different indexes of refraction. During that time, $\lambda_1 \neq \lambda_2$.

The phase difference between two light waves can change if the waves travel through different materials having different indexes of refraction.

As we shall discuss soon, this phase difference change can determine how the light waves will interfere if they reach some common point.

To find their new phase difference in terms of wavelengths, we first count the number N_1 of wavelengths there are in the length L of medium 1. From Eq. 36-8, the wavelength in medium 1 is $\lambda_{n_1} = \lambda/n_1$, so

$$N_1 = \frac{L}{\lambda_{n_1}} = \frac{Ln_1}{\lambda}. \quad (36-9)$$

In general, the term Ln is known as the **optical path difference**. Similarly, we count the number N_2 of wavelengths there are in the length L of medium 2, where the wavelength is $\lambda_{n_2} = \lambda/n_2$:

$$N_2 = \frac{L}{\lambda_{n_2}} = \frac{Ln_2}{\lambda}. \quad (36-10)$$

To find the new phase difference between the waves, we subtract the smaller of N_1 and N_2 from the larger. Assuming $n_2 > n_1$, we obtain

$$N_2 - N_1 = \frac{Ln_2}{\lambda} - \frac{Ln_1}{\lambda} = \frac{L}{\lambda}(n_2 - n_1). \quad (36-11)$$

Thus the phase difference is simply the optical path length difference divided by the wavelength of the light in a vacuum.

Suppose Eq. 36-11 tells us that the waves now have a phase difference of 45.6 wavelengths. That is equivalent to taking the initially in-phase waves and shifting one of them by 45.6 wavelengths. However, a shift of an integer number of wavelengths (such as 45) would put the waves back in phase, so it is only the decimal fraction (here, 0.6) that is important. A phase difference of 45.6 wavelengths is equivalent to an *effective phase difference* of 0.6 wavelength.

A phase difference of 0.5 wavelength puts two waves exactly out of phase. If the waves had equal amplitudes and were to reach some common point, they would then undergo fully destructive interference, producing darkness at that point. With an effective phase difference of 0.0 wavelength, they would, instead, undergo fully constructive interference, resulting in brightness at the common point. Our effective phase difference of 0.6 wavelength is an intermediate situation, but closer to destructive interference, and the waves would produce a dimly illuminated common point.

We can also express phase difference in terms of radians and degrees, as we have done already.

A phase difference of one wavelength is equivalent to phase differences of 2π rad or 360° .

READING EXERCISE 36-1: The figure shows a monochromatic ray of light traveling across parallel interfaces, from an original material *a*, through layers of material *b* and *c*, and then back into material *a*. Rank the materials according to the speed of light in them, greatest first.

TOUCHSTONE EXAMPLE 36-1: Phase Difference and Interference

In Fig. 36-3, the two light waves that are represented by the rays have wavelength 550.0 nm before entering media 1 and 2. They also have equal amplitudes and are in phase. Medium 1 is now just air, and medium 2 is a transparent plastic layer of index of refraction 1.600 and thickness 2.600 μm .

(a) What is the phase difference of the emerging waves in wavelengths, radians, and degrees? What is their effective phase difference (in wavelengths)?

SOLUTION ■ One **Key Idea** here is that the phase difference of two light waves can change if they travel through different media, with different indexes of refraction. The reason is that their wavelengths are different in the different media. We can calculate the change in phase difference by counting the number of wavelengths that fits into each medium and then subtracting those numbers. When the path lengths of the waves in the two media are identical, Eq. 36-11 gives the result. Here we have $n_1 = 1.000$ (for the air), $n_2 = 1.600$, $L = 2.600 \mu\text{m}$, and $\lambda = 550.0 \text{ nm}$. Thus, Eq. 36-11 yields

$$\begin{aligned} N_2 - N_1 &= \frac{L}{\lambda}(n_2 - n_1) \\ &= \frac{2.600 \times 10^{-6} \text{ m}}{5.500 \times 10^{-7} \text{ m}}(1.600 - 1.000) \\ &= 2.84. \end{aligned} \quad (\text{Answer})$$

Thus, the phase difference of the emerging waves is 2.84 wavelengths. Because 1.0 wavelength is equivalent to 2π rad and 360° , you can show that this phase difference is equivalent to

$$\text{phase difference} = 17.8 \text{ rad} \approx 1020^\circ. \quad (\text{Answer})$$

A second **Key Idea** is that the effective phase difference is the decimal part of the actual phase difference *expressed in wavelengths*. Thus, we have

$$\text{effective phase difference} = 0.84 \text{ wavelength}. \quad (\text{Answer})$$

You can show that this is equivalent to 5.3 rad and about 300° . **Caution:** We do *not* find the effective phase difference by taking the decimal part of the actual phase difference as expressed in radians or degrees. For example, we do *not* take 0.8 rad from the actual phase difference of 17.8 rad.

(b) If the rays of the waves were angled slightly so that the waves reached the same point on a distant viewing screen, what type of interference would the waves produce at that point?

SOLUTION ■ The **Key Idea** here is to compare the effective phase difference of the waves with the phase differences that give the extreme types of interference. Here the effective phase

difference of 0.84 wavelength is between 0.5 wavelength (for fully destructive interference, or the darkest possible result) and 1.0 wavelength (for fully constructive interference, or the brightest possible

result), but closer to 1.0 wavelength. Thus, the waves would produce intermediate interference that is closer to fully constructive interference—they would produce a relatively bright spot.

FIGURE 36-4 ■ The diffraction of water waves in a ripple tank. The waves are produced by an oscillating paddle at the left. As they move from left to right, they flare out through an opening in a barrier along the water surface.

36-3 Diffraction

In the next section we shall discuss the experiment that first proved that light is a wave. To prepare for that discussion, we must introduce the idea of **diffraction** of waves, a phenomenon that we explore much more fully in Chapter 37. Its essence is this: If a wave encounters a barrier that has an opening of dimensions similar to the wavelength, the part of the wave that passes through the opening will flare (spread) out—will *diffract*—into the region beyond the barrier. The flaring out is consistent with the spreading of the wavelets in the Huygens construction of Fig. 36-1. Diffraction occurs for waves of all types, not just light waves. Figure 36-4 shows the diffraction of water waves traveling across the surface of water in a shallow tank.

Figure 36-5a shows the situation schematically for an incident plane wave of wavelength λ encountering a slit that has width $a = 6.0\lambda$ and extends into and out of the page. The wave flares out on the far side of the slit. Figures 36-5b (with $a = 3.0\lambda$) and 36-5c ($a = 1.5\lambda$) illustrate the main feature of diffraction: the narrower the slit, the greater the diffraction.

Diffraction limits geometrical optics, in which we represent an electromagnetic wave with a ray. If we actually try to form a ray by sending light through a narrow slit, or through a series of narrow slits, diffraction will always defeat our effort because it always causes the light to spread. Indeed, the narrower we make the slits (in the hope of producing a narrower beam), the greater the spreading is. Thus, geometrical optics holds only when slits or other apertures that might be located in the path of light have dimensions that are much larger than the wavelength of the light.

FIGURE 36-5 ■ Diffraction represented schematically. For a given wavelength λ , the diffraction is more pronounced the smaller the slit width a . The figures show the cases for (a) slit width $a = 6.0\lambda$, (b) slit width $a = 3.0\lambda$, and (c) slit width $a = 1.5\lambda$. In all three cases, the screen and the length of the slit extend well into and out of the page, perpendicular to it.

36-4 Young's Interference Experiment

In 1801, Thomas Young experimentally proved that light is a wave, contrary to what most other scientists then thought. He did so by demonstrating that light undergoes interference, as do water waves, sound waves, and waves of all other types. In addition, he was able to measure the average wavelength of sunlight; his value, 570 nm, is

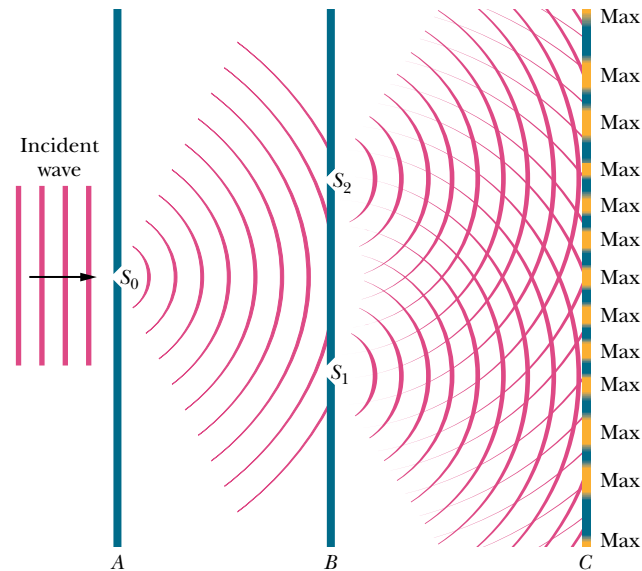

FIGURE 36-6 ■ In Young's interference experiment, incident monochromatic light is diffracted by slit S_0 , which then acts as a point source of light that emits semicircular wavefronts. As that light reaches screen B , it is diffracted by slits S_1 and S_2 , which then act as two point sources of light. The light waves traveling from slits S_1 and S_2 overlap and undergo interference, forming an interference pattern of maxima and minima on viewing screen C . This figure is a cross section; the screens, slits, and interference pattern extend into and out of the page. Between screens B and C , the semicircular wavefronts centered on S_2 depict the waves that would be there if only S_2 were open. Similarly, those centered on S_1 depict waves that would be there if only S_1 were open.

impressively close to the modern accepted value of 555 nm. We shall here examine Young's historic experiment as an example of the interference of light waves.

Figure 36-6 gives the basic arrangement of Young's experiment. Light from a distant monochromatic source illuminates slit S_0 in screen A . The emerging light then spreads via diffraction to illuminate two slits S_1 and S_2 in screen B . Diffraction of the light by these two slits sends overlapping circular waves into the region beyond screen B , where the waves from one slit interfere with the waves from the other slit.

The “snapshot” of Fig. 36-6 depicts the interference of the overlapping waves from very small slits. However, we cannot see evidence for the interference except where a viewing screen C intercepts the light. Where it does so, points of interference maxima form visible bright rows—called *bright bands*, *bright fringes*, or (loosely speaking) *maxima*—that extend across the screen (into and out of the page in Fig. 36-6). Dark regions—called *dark bands*, *dark fringes*, or (loosely speaking) *minima*—result from fully destructive interference and are visible between adjacent pairs of bright fringes. (*Maxima* and *minima* more properly refer to the center of a band.) The pattern of bright and dark fringes on the screen is called an **interference pattern**. Figure 36-7 is a photograph of part of the interference pattern as seen from the left in Fig. 36-6. The fringes that appear on a flat screen get further apart and dimmer as the distance from the center of the screen increases.

Note: These are very small slits, so we assume diffraction acts to spread out the waves passing through each slit. This explains why the waves from the two slits can overlap at a distant point. However, for now we ignore the fact that a diffracted wave has more intensity in the direction of the wavefront incident on the slit. In Chapter 37 we will analyze diffraction mathematically, which is the cause of the weakening intensity away from the center of the pattern seen in Fig. 36-7.

Locating the Fringes

Light waves produce fringes in a *Young's double-slit interference experiment*, as it is called, but what exactly determines the locations of the fringes? To answer, we shall use the arrangement in Fig. 36-8a. There, a plane wave of monochromatic light is incident on two slits S_1 and S_2 in screen B ; the light diffracts through the slits and produces an interference pattern on screen C . We draw a central axis from the point halfway between the slits to screen C as a reference. We then pick, for discussion, an arbitrary point P on the screen, at angle θ to the central axis. This point intercepts the wave of ray r_1 from the bottom slit and the wave of ray r_2 from the top slit.

FIGURE 36-7 ■ A photograph of the interference pattern produced by the arrangement shown in Fig. 36-6. (The photograph is a front view of part of screen C .) The alternating maxima and minima are called *interference fringes* (because they resemble the decorative fringe sometimes used on clothing and rugs).

(a)

(b)

FIGURE 36-8 (a) Waves from slits S_1 and S_2 (which extend into and out of the page) with spacing d combine at P , an arbitrary point on screen C at distance y from the central axis. The angle θ serves as a convenient locator for P . (b) For a slit screen distance of $D \gg d$, we can approximate rays r_1 and r_2 as being parallel, at angle θ to the central axis. *Note:* In a typical demonstration of these effects d might be on the order of 1 mm or some fraction thereof and D might be 1–2 meters or more.

These waves are in phase when they pass through the two slits because they are just portions of the same incident wave. However, once they have passed the slits, the two waves must travel different distances to reach P . We saw a similar situation in Section 18-4 with sound waves and concluded that

The phase difference between two waves can change if the waves travel paths of different lengths.

The change in phase difference is due to the *path length difference* ΔL in the paths taken by the waves. Consider two waves initially exactly in phase, traveling along paths with a path length difference ΔL , and then passing through some common point. When ΔL is zero or an integer number of wavelengths, the waves arrive at the common point exactly in phase and they interfere fully constructively there. If that is true for the waves of rays r_1 and r_2 in Fig. 36-8, then point P is part of a bright fringe. When, instead, ΔL is an odd multiple of half a wavelength, the waves arrive at the common point exactly out of phase and they interfere fully destructively there. If that is true for the waves of rays r_1 and r_2 , then point P is part of a dark fringe (and, of course, we can have intermediate situations of interference and thus intermediate illumination at P .) Thus,

What appears at each point on the viewing screen in a Young's double-slit interference experiment is determined by the path length difference ΔL of the rays reaching that point.

We can specify where each bright or dark fringe is located on the screen by giving the angle θ from the central axis to that fringe. To find θ , we must relate it to ΔL . We start with Fig. 36-8a by finding a point b along ray r_1 such that the path length from points b to P equals the path length from S_2 to P . Then the path length difference ΔL between the two rays is the distance from S_1 to b .

The relation between this S_1 -to- b distance and θ is complicated, but we can simplify it considerably if we arrange for the distance D from the slits to the screen to be much greater than the slit separation d . Then we can approximate rays r_1 and r_2 as being parallel to each other and at angle θ to the central axis (Fig. 36-8b). We can also approximate the triangle formed by S_1 , S_2 , and b as being a right triangle, and approximate the angle inside that triangle at S_2 as being θ . Then, for that triangle, $\sin \theta = \Delta L/d$ and thus

$$\Delta L = d \sin \theta \quad (\text{path length difference}). \quad (36-12)$$

For a bright fringe, we saw that ΔL must be zero or an integer number of wavelengths. Using Eq. 36-12, we can write this requirement as

$$\Delta L = d \sin \theta = (\text{integer})(\lambda), \quad (36-13)$$

$$\text{or as} \quad d \sin \theta = m\lambda, \quad \text{for } m = 0, 1, 2, \dots \quad (\text{maxima—bright fringes}). \quad (36-14)$$

For a dark fringe, ΔL must be an odd multiple of half a wavelength. Again using Eq. 36-12, we can write this requirement as

$$\Delta L = d \sin \theta = (\text{odd number})(\frac{1}{2}\lambda), \quad (36-15)$$

$$\text{or as} \quad d \sin \theta = (m + \frac{1}{2})\lambda, \quad \text{for } m = 0, 1, 2, \dots \quad (\text{minima—dark fringes}). \quad (36-16)$$

With Eqs. 36-14 and 36-16, we can find the angle θ to any fringe and thus locate that fringe; further, we can use the values of m to label the fringes. For $m = 0$, Eq. 36-14 tells us that a bright fringe is at $\theta = 0$ —that is, on the central axis. This *central maximum* is the point at which waves arriving from the two slits have a path length difference $\Delta L = 0$, hence zero phase difference.

For, say, $m = 2$, Eq. 36-14 tells us that *bright* fringes are at

$$\theta = \sin^{-1}\left(\frac{2\lambda}{d}\right)$$

above and below the central axis. Waves from the two slits arrive at these two fringes with $\Delta L = 2\lambda$ and with a phase difference of two wavelengths. These fringes are said to be the *second-order fringes* (meaning $m = 2$) or the *second side maxima* (the second maxima to the side of the central maximum), or they are described as being the second fringes from the central maximum.

For $m = 1$, Eq. 36-16 tells us that *dark* fringes are at

$$\theta = \sin^{-1}\left(\frac{1.5\lambda}{d}\right)$$

above and below the central axis. Waves from the two slits arrive at these two fringes with $\Delta L = 1.5\lambda$ and with a phase difference, in wavelengths, of 1.5. These fringes are called the *second dark fringes* or *second minima* because they are the second dark fringes from the central axis. (The first dark fringes, or first minima, are at locations for which $m = 0$ in Eq. 36-16.)

We derived Eqs. 36-14 and 36-16 for the situation $D \gg d$. However, they also apply if we place a converging lens between the slits and the viewing screen and then move the viewing screen closer to the slits, to the focal point of the lens. (The screen is then said to be in the *focal plane* of the lens; that is, it is in the plane perpendicular to the central axis at the focal point.) One property of a converging lens is that it focuses all rays that are parallel to one another to the same point on its focal plane. Thus, the rays that now arrive at any point on the screen (in the focal plane) were exactly parallel (rather than approximately) when they left the slits. They are like the initially parallel rays in Fig. 35-23a that are directed to a point (the focal point) by a lens.

READING EXERCISE 36-2: In Fig. 36-8, what are ΔL (as a multiple of the wavelength) and the phase difference (in wavelengths) for the two rays if point P is (a) a third side maximum and (b) a third minimum? ■

TOUCHSTONE EXAMPLE 36-2: Distance Between Adjacent Maxima

What is the distance on screen C in Fig. 36-8a between adjacent maxima near the center of the interference pattern? The wavelength λ of the light is 546 nm, the slit separation d is 0.12 mm, and the slit–screen separation D is 55 cm. Assume that θ in Fig. 36-8 is small enough to permit use of the approximations $\sin \theta \approx \tan \theta \approx \theta$, in which θ is expressed in radian measure.

SOLUTION ■ First, let us pick a maximum with a low value of m to ensure that it is near the center of the pattern. Then one **Key Idea** is that, from the geometry of Fig. 36-8a, the maximum's verti-

cal distance y_m from the center of the pattern is related to its angle θ from the central axis by

$$\tan \theta \approx \theta = \frac{y_m}{D}.$$

A second **Key Idea** is that, from Eq. 36-14, this angle θ for the m th maximum is given by

$$\sin \theta \approx \theta = \frac{m\lambda}{d}.$$

If we equate these two expressions for θ and solve for y_m , we find

$$y_m = \frac{m\lambda D}{d}. \quad (36-17)$$

For the next farther out maximum, we have

$$y_{m+1} = \frac{(m+1)\lambda D}{d}. \quad (36-18)$$

We find the distance between these adjacent maxima by subtracting Eq. 36-17 from Eq. 36-18:

$$\begin{aligned} \Delta y &= y_{m+1} - y_m = \frac{\lambda D}{d} \\ &= \frac{(546 \times 10^{-9} \text{ m})(55 \times 10^{-2} \text{ m})}{0.12 \times 10^{-3} \text{ m}} \\ &= 2.50 \times 10^{-3} \text{ m} \approx 2.5 \text{ mm}. \end{aligned} \quad (\text{Answer})$$

As long as d and θ in Fig. 36-8a are small, the separation of the interference fringes is independent of m ; that is, the fringes are evenly spaced.

36-5 Coherence

For the interference pattern to appear on viewing screen C in Fig. 36-6, the light waves reaching any point P on the screen must have a phase difference that does not vary in time. That is the case in Fig. 36-6, because the waves passing through slits S_1 and S_2 are portions of the single light wave that illuminates the slits. Because the phase difference remains constant, the light from slits S_1 and S_2 is said to be completely **coherent**.

Direct sunlight is partially coherent; that is, sunlight waves intercepted at two points have a constant phase difference only if the points are very close. If you look closely at your fingernail in bright sunlight, you can see a faint interference pattern called *speckle* that causes the nail to appear to be covered with specks. You see this effect because light waves scattering from very close points on the nail are sufficiently coherent to interfere with one another at your eye. The slits in a double-slit experiment, however, are not close enough, and in direct sunlight, the light at the slits would be **incoherent**. To get coherent light, we would have to send the sunlight through a single slit as in Fig. 36-6; because that single slit is small, light that passes through it is coherent. In addition, the smallness of the slit causes the coherent light to spread sufficiently via diffraction to illuminate both slits in the double-slit experiment.

If we replace the double slits with two similar but independent monochromatic light sources, such as two fine incandescent wires, the phase difference between the waves emitted by the sources varies rapidly and randomly. (This occurs because the light is emitted by vast numbers of atoms in the wires, acting randomly and independently for extremely short times—of the order of nanoseconds.) As a result, at any given point on the viewing screen, the interference between the waves from the two sources varies rapidly and randomly between fully constructive and fully destructive. The eye (and most common optical detectors) cannot follow such changes, and no interference pattern can be seen. The fringes disappear, and the screen is seen as being uniformly illuminated.

A *laser* differs from common light sources in that its atoms emit light in a cooperative manner, thereby making the light coherent. Moreover, the light is almost monochromatic, is emitted in a thin beam with little spreading, and can be focused to a width that almost matches the wavelength of the light.

36-6 Intensity in Double-Slit Interference

Equations 36-14 and 36-16 tell us how to locate the maxima and minima of the double-slit interference pattern on screen C of Fig. 36-8 as a function of the angle θ in that figure. Here we wish to derive an expression for the intensity I of the fringes as a function of θ .

The light leaving the slits is in phase. However, let us assume that the light waves from the two slits are not in phase when they arrive at point P . Instead, the electric field components of those waves at point P are not in phase and vary with time as

$$E_1 = E_0 \sin \omega t \quad (36-19)$$

and
$$E_2 = E_0 \sin(\omega t + \phi), \quad (36-20)$$

where ω is the angular frequency of the waves and ϕ is the phase constant of wave E_2 . Note that when θ is small the two waves have approximately the same amplitude E_0 and a phase difference of ϕ . Because that phase difference does not vary, the waves are coherent. We shall show that these two waves will combine at P to produce an illumination of intensity I given by

$$I = 4I_0 \cos^2 \frac{1}{2}\phi, \quad (36-21)$$

where

$$\phi = \frac{2\pi d}{\lambda} \sin \theta. \quad (36-22)$$

In Eq. 36-21, I_0 is the intensity of the light that arrives on the screen from one slit when the other slit is temporarily covered. We assume that the slits are so narrow in comparison to the wavelength that this single-slit intensity is essentially uniform over the central region of the screen in which we wish to examine the fringes.

Equations 36-21 and 36-22, which together tell us how the intensity I of the fringe pattern varies with the angle θ in Fig. 36-8, necessarily contain information about the location of the maxima and minima. Let us see if we can extract it.

Study of Eq. 36-21 shows that intensity maxima will occur when

$$\frac{1}{2}\phi = m\pi \quad \text{for } m = 0, 1, 2, \dots \quad (36-23)$$

If we put this result into Eq. 36-22, we find

$$2m\pi = \frac{2\pi d}{\lambda} \sin \theta \quad \text{for } m = 0, 1, 2, \dots,$$

or
$$\Delta L = d \sin \theta = m\lambda \quad \text{for } m = 0, 1, 2, \dots \quad (\text{maxima}), \quad (36-24)$$

which is exactly Eq. 36-14, the expression that we derived earlier for the locations of the maxima.

The minima in the fringe pattern occur when

$$\frac{1}{2}\phi = (m + \frac{1}{2})\pi \quad \text{for } m = 0, 1, 2, \dots$$

If we combine this relation with Eq. 36-22 we are led at once to

$$d \sin \theta = (m + \frac{1}{2})\lambda \quad \text{for } m = 0, 1, 2, \dots \quad (\text{minima}), \quad (36-25)$$

which is just Eq. 36-16, the expression we derived earlier for the locations of the fringe minima.

Figure 36-9, which is a plot of Eq. 36-21, shows the intensity of double-slit interference pattern fringes near the central maxima as a function of the phase difference ϕ

FIGURE 36-9 ■ A plot of Eq. 36-21, showing the intensity of a double-slit interference pattern as a function of the phase difference between the waves when they arrive from the two slits. I_0 is the (uniform) intensity that would appear on the screen if one slit were covered. The average intensity of the fringe pattern is $2I_0$, and the *maximum* intensity (for coherent light) is $4I_0$.

between the waves at the screen. The horizontal solid line is I_0 , the (uniform) intensity on the screen when one of the slits is covered up. Note in Eq. 36-21 and the graph that the intensity I (which is always positive) varies from zero at the fringe minima to $4I_0$ at the fringe maxima.

If the waves from the two sources (slits) were *incoherent*, so that no enduring phase relation existed between them, there would be no fringe pattern and the intensity would have the uniform value $2I_0$ for all points on the screen; the horizontal dashed line in Fig. 36-9 shows this uniform value.

Interference cannot create or destroy energy but merely redistributes it over the screen. Thus, the *average* intensity on the screen must be the same $2I_0$ regardless of whether the sources are coherent. This follows at once from Eq. 36-21; if we substitute $\frac{1}{2}$, the average value of the cosine-squared function, this equation reduces to $\langle I \rangle = 2I_0$.

Proof of Eqs. 36-21 and 36-22

We shall combine the electric field components E_1 and E_2 , given by Eqs. 36-19 and 36-20, respectively, by the method of phasors discussed in Section 17-12. In Fig. 36-10a, the waves with components E_1 and E_2 are represented by phasors of magnitude E_0 that rotate around the origin at angular speed ω . The values of E_1 and E_2 at any time are the projections of the corresponding phasors on the vertical axis. Figure 36-10a shows the phasors and their projections at an arbitrary time t . Consistent with Eqs. 36-19 and 36-20, the phasor for E_1 has a rotation angle ωt and the phasor for E_2 has a rotation angle $\omega t + \phi$.

To combine the field components E_1 and E_2 at any point P in Fig. 36-8, we add their phasors as if they were vectors (which they are not), as shown in Fig. 36-10b. The magnitude of the phasor sum is the amplitude E of the resultant wave at point P , and that wave has a certain phase constant β . To find the amplitude E in Fig. 36-10b, we first note that the two angles marked β are equal because they are opposite equal-length sides of a triangle. From the theorem (for triangles) that an exterior angle (ϕ) is equal to the sum of the two opposite interior angles ($\beta + \beta$), we see that $\beta = \frac{1}{2}\phi$. Thus, we have

$$\begin{aligned} E &= 2(E_0 \cos \beta) \\ &= 2E_0 \cos \frac{1}{2}\phi. \end{aligned} \quad (36-26)$$

If we square each side of this relation we obtain

$$E^2 = 4E_0^2 \cos^2 \frac{1}{2}\phi. \quad (36-27)$$

Now, from Eq. 34-24, we know that the intensity of an electromagnetic wave is proportional to the square of its amplitude. Therefore, the waves we are combining in Fig. 36-10b, whose amplitudes are E_0 , each have an intensity I_0 that is proportional to

(a)

(b)

FIGURE 36-10 ■ (a) Phasors representing, at time t , the electric field components given by Eqs. 36-19 and 36-20. Both phasors have magnitude E_0 and rotate with angular speed ω . Their phase difference is ϕ . (b) Addition of the two phasors gives the phasor representing the resultant wave, with amplitude E and phase constant β .

E_0^2 , and the resultant wave, with amplitude E , has an intensity I that is proportional to E^2 . Thus,

$$\frac{I}{I_0} = \frac{E^2}{E_0^2}.$$

Substituting Eq. 36-27 into this equation and rearranging then yield

$$I = 4I_0 \cos^2 \frac{1}{2} \phi,$$

which is Eq. 36-21, which we set out to prove.

It remains to prove Eq. 36-22, which relates the phase difference ϕ between the waves arriving at any point P on the screen of Fig. 36-8 to the angle θ that serves as a locator of that point.

The phase difference ϕ in Eq. 36-20 is associated with the path difference $\Delta L = S_1 b$ in Fig. 36-8*b*. If ΔL is $\frac{1}{2}\lambda$, then ϕ is π ; if ΔL is λ , then ϕ is 2π , and so on. This suggests

$$(\text{phase difference}) = \frac{2\pi}{\lambda} (\text{path length difference}). \quad (36-28)$$

The path difference ΔL in Fig. 36-8*b* is $d \sin \theta$, so Eq. 36-28 becomes

$$\phi = \frac{2\pi d}{\lambda} \sin \theta,$$

which is Eq. 36-22, the other equation that we set out to prove.

Combining More Than Two Waves

In a more general case, we might want to find the resultant of more than two sinusoidally varying waves at a point. The general procedure is this:

1. Construct a series of phasors representing the waves to be combined. Draw them end to end, maintaining the proper phase relations between adjacent phasors.
2. Construct the vector-like phasor sum of this array. The length of this sum gives the amplitude of the resultant phasor. The angle between the phasor sum and the first phasor is the phase of the resultant with respect to this first phasor. The projection of this resultant-sum phasor on the vertical axis gives the time variation of the resultant wave.

TOUCHSTONE EXAMPLE 36-3: Three Light Waves

Three light waves combine at a certain point where their electric field components are

$$\begin{aligned} E_1 &= E_0 \sin \omega t, \\ E_2 &= E_0 \sin(\omega t + 60^\circ), \\ E_3 &= E_0 \sin(\omega t - 30^\circ). \end{aligned}$$

Find their resultant component $E(t)$ at that point.

SOLUTION ■ The resultant wave is

$$E(t) = E_1(t) + E_2(t) + E_3(t).$$

The **Key Idea** here is two-fold: We can use the method of phasors to find this sum, and we are free to evaluate the phasors at any time t . To simplify the solution we choose $t = 0$, for which the phasors representing the three waves are shown in Fig. 36-11. We can add these three phasors either directly on a vector-capable calcula-

FIGURE 36-11 ■ Three phasors, representing waves with equal amplitudes E_0 and with phase constants 0° , 60° , and 230° , shown at time $t = 0$. The phasors combine to give a resultant phasor with magnitude E_R , at angle β .

tor or by components. For the component approach, we first write the sum of their horizontal components as

$$\sum E_h = E_0 \cos 0 + E_0 \cos 60^\circ + E_0 \cos(-30^\circ) = 2.37E_0.$$

The sum of their vertical components, which is the value of E at $t = 0$, is

$$\sum E_v = E_0 \sin 0 + E_0 \sin 60^\circ + E_0 \sin(-30^\circ) = 0.366E_0.$$

The resultant wave $E(t)$ thus has an amplitude E_R of

$$E_R = \sqrt{(2.37E_0)^2 + (0.366E_0)^2} = 2.4E_0,$$

and a phase angle β relative to the phasor representing E_1 of

$$\beta = \tan^{-1}\left(\frac{0.366E_0}{2.37E_0}\right) = 8.8^\circ.$$

We can now write, for the resultant wave $E(t)$,

$$\begin{aligned} E &= E_R \sin(\omega t + \beta) \\ &= 2.4 E_0 \sin(\omega t + 8.8^\circ). \end{aligned} \quad (\text{Answer})$$

Be careful to interpret the angle β correctly in Fig. 36-11: It is the constant angle between E_R and the phasor representing E_1 as the four phasors rotate as a single unit around the origin. The angle between E_R and the horizontal axis in Fig. 36-11 does not remain equal to β .

FIGURE 36-12 Light waves, represented with ray i , are incident on a thin film of thickness L and index of refraction n_2 . Rays r_1 and r_2 represent light waves that have been reflected by the front and back surfaces of the film, respectively. (All three rays are actually nearly perpendicular to the film.) The interference of the waves of r_1 and r_2 with each other depends on their phase difference. The index of refraction n_1 of the medium at the left can differ from the index of refraction n_3 of the medium at the right, but for now we assume that both media are air, with $n_1 = n_3 = 1.0$, which is less than n_2 .

36-7 Interference from Thin Films

The colors we see when sunlight illuminates a soap bubble or an oil slick are caused by the interference of light waves reflected from the front and back surfaces of a thin transparent film. The thickness of the soap or oil film is typically of the order of magnitude of the wavelength of the (visible) light involved. (We shall not consider greater thicknesses, which spoil the coherence of the light needed to produce colors by interference; we shall discuss lesser thicknesses shortly.)

Figure 36-12 shows a thin transparent film of uniform thickness L and index of refraction n_2 , illuminated by bright light of wavelength λ from a distant point source. For now, we assume that air lies on both sides of the film and thus that $n_1 = n_3$ in Fig. 36-12. For simplicity, we also assume that the light rays are almost perpendicular to the film ($\theta \approx 0$). We are interested in whether the film is bright or dark to an observer viewing it almost perpendicularly. (Since the film is brightly illuminated, how could it possibly be dark? You will see.)

The incident light, represented by ray i , hits the front (left) surface of the film at point a and undergoes both reflection and refraction there. The reflected ray r_1 enters the observer's eye. The refracted light crosses the film to point b on the back surface, where it undergoes both reflection and refraction. The light reflected at b crosses back through the film to point c , where it undergoes both reflection and refraction. The light refracted at c , represented by ray r_2 , also enters the observer's eye.

If the light waves of rays r_1 and r_2 are exactly in phase at the eye, they produce an interference maximum, and region ac on the film is bright to the observer. If they are exactly out of phase, they produce an interference minimum, and region ac is dark to the observer, *even though it is illuminated*. If there is some intermediate phase difference, there are intermediate interference and intermediate brightness.

Thus, the key to what the observer sees is the phase difference between the waves of rays r_1 and r_2 . Both rays are derived from the same ray i , but the path involved in producing r_2 involves light traveling twice across the film (a to b , and then b to c), whereas the path involved in producing r_1 involves no travel through the film. Because θ is close to zero, we approximate the path length difference between the waves of r_1 and r_2 as $2L$. However, to find the phase difference between the waves, we cannot just find the number of wavelengths λ that is equivalent to a path length difference of $2L$. This simple approach is impossible for two reasons: (1) the path length difference occurs in a medium other than air, and (2) the reflections involved can change the phase.

The phase difference between two waves can change if one or both are reflected.

Before we continue our discussion of interference from thin films, we must discuss changes in phase that are caused by reflections.

Reflection Phase Shifts

Refraction at an interface never causes a phase change—but reflection can, depending on the indices of refraction on the two sides of the interface. Figure 36-13 shows what happens when reflection of light waves causes a phase change, using as an example mechanical wave pulses on a denser string (along which pulse travel is relatively slow) and a lighter string (along which pulse travel is relatively fast). This effect is just like the one we discussed in Section 17-10. Recall that a pulse traveling down a string will reflect differently from an end of the string that is tied to a post (a fixed end) than from an end that is tied to a ring that can slide on the post (an open end) (see Fig. 17-25). Reflecting off a heavy string is like reflecting off a fixed end. Reflecting off a light string is like reflecting off an open end.

When a pulse traveling relatively slowly along the denser string in Fig. 36-13a reaches the interface with the lighter string, the pulse is partially transmitted and partially reflected, with no change in orientation. For light, this situation corresponds to the incident wave traveling in the medium of greater index of refraction n (recall that greater n means slower speed). In that case, the wave that is reflected at the interface does not undergo a change in phase; that is, the *reflection phase shift* is zero.

When a pulse traveling more quickly along the lighter string in Fig. 36-13b reaches the interface with the denser string, the pulse is again partially transmitted and partially reflected. The transmitted pulse again has the same orientation as the incident pulse, but now the reflected pulse is inverted. For a sinusoidal wave, such an inversion involves a phase change of π rad, or half a wavelength. For light, this situation corresponds to the incident wave traveling in the medium of lesser index of refraction (with greater speed). In that case, the wave that is reflected at the interface undergoes a phase shift of π rad, or half a wavelength.

We can summarize these results for light in terms of the index of refraction of the medium off which (or from which) the light reflects:

Reflection	Reflection phase shift	Phase change (rad)
Off lower index	0.0λ	0
Off higher index	0.5λ	π

An aid to remembering this is “reflection off high, phase change is pi.”

Equations for Thin-Film Interference

In this chapter we have now seen three ways in which the phase difference between two light waves can change:

1. by reflection,
2. by the waves traveling along paths of different lengths,
3. by the waves traveling through media of different indexes of refraction.

When light reflects from a thin film, producing the waves of rays r_1 and r_2 in Fig. 36-12, all three ways are involved. Let us consider them one by one.

We first reexamine the two reflections in Fig. 36-12. At point a on the front interface, the incident wave (in air) reflects from the medium having the higher of the two indexes of refraction, so the wave of reflected ray r_1 has its phase shifted by 0.5 wavelength. At point b on the back interface, the incident wave reflects from the medium

FIGURE 36-13 ■ Phase changes when a pulse is reflected at the interface between two stretched strings of different linear densities. The wave speed is greater in the lighter string. (a) The incident pulse is in the denser string. (b) The incident pulse is in the lighter string. Only here is there a phase change, and only in the reflected wave.

TABLE 36-1

An Organizing Table for Thin-Film Interference in Air^a

Reflection phase shifts	r_1	r_2
	0.5	0
	wavelength	
Path length difference	$2L$	
Index in which path length difference occurs	n_2	

^aValid for $n_2 > n_1$ and $n_2 > n_3$

(air) having the lower of the two indexes of refraction, so the wave reflected there is not shifted in phase by the reflection, and thus neither is the portion of it that exits the film as ray r_2 . We can organize this information with the first line in Table 36-1. It tells us that, so far, as a result of the reflection phase shifts, the waves of r_1 and r_2 have a phase difference of 0.5 wavelength and thus are exactly out of phase.

Based on the information presented in Table 36-1, we have the following rules for predicting constructive interference (in phase) and destructive interference (out of phase):

For a film thickness L , two waves of wavelength λ traveling through a film with index of refraction n_2 will:

constructively interfere (in phase) if $2L = \frac{\text{odd number}}{2} \times \frac{\lambda}{n_2}$,

destructively interfere (out of phase) if $2L = \text{integer} \times \frac{\lambda}{n_2}$.

These equations are valid for $n_2 > n_1$ and $n_2 > n_3$.

Now we must consider the path length difference $2L$ that occurs because the wave of ray r_2 crosses the film twice. (This difference $2L$ is shown in the expressions above. If the waves of r_1 and r_2 are to be exactly in phase so that they produce fully constructive interference, the path length $2L$ must cause an additional phase difference of 0.5, 1.5, 2.5, . . . wavelengths. Only then will the net phase difference be an integer number of wavelengths. Thus, for a bright film, we must have

$$2L = \frac{\text{odd number}}{2} \times \text{wavelength} \quad (\text{in-phase waves}). \quad (36-29)$$

The wavelength we need here is the wavelength λ_{n_2} of the light in the medium containing path length $2L$ —that is, in the medium with index of refraction n_2 . Thus, we can rewrite Eq. 36-29 as

$$2L = \frac{\text{odd number}}{2} \times \lambda_{n_2} \quad (\text{in-phase waves}). \quad (36-30)$$

If, instead, the waves are to be exactly out of phase so that there is fully destructive interference, the path length $2L$ must cause either no additional phase difference or a phase difference of 1, 2, 3, . . . , wavelengths. Only then will the net phase difference be an odd number of half-wavelengths. For a dark film, we must have

$$2L = \text{integer} \times \text{wavelength}, \quad (36-31)$$

where, again, the wavelength is the wavelength λ_{n_2} in the medium containing $2L$. Thus, this time we have

$$2L = \text{integer} \times \lambda_{n_2} \quad (\text{out-of-phase waves}). \quad (36-32)$$

Now we can use Eq. 36-8 ($\lambda_n = \lambda/n$) to write the wavelength of the wave of ray r_2 inside the film as

$$\lambda_{n_2} = \frac{\lambda}{n_2}, \quad (36-33)$$

where λ is the wavelength of the incident light in vacuum (and approximately also in air). Substituting Eq. 36-33 into Eq. 36-30 and replacing “odd number/2” with $(m + \frac{1}{2})$ give us

$$2L = (m + \frac{1}{2}) \frac{\lambda}{n_2} \quad \text{for } m = 0, 1, 2, \dots \quad (\text{maxima—bright film in air}). \quad (36-34)$$

Similarly, with m replacing “integer,” Eq. 36-32 yields

$$2L = m \frac{\lambda}{n_2} \quad \text{for } m = 0, 1, 2, \dots \quad (\text{minima—dark film in air}). \quad (36-35)$$

For a given film thickness L , Eqs. 36-34 and 36-35 tell us the wavelengths of light for which the film appears bright and dark, respectively, one wavelength for each value of m . Intermediate wavelengths give intermediate brightnesses. For a given wavelength λ , Eqs. 36-34 and 36-35 tell us the thicknesses of the films that appear bright and dark in that light, respectively, one thickness for each value of m . Intermediate thicknesses give intermediate brightnesses.

A special situation arises when a film is so thin that L is much less than λ , say, $L < 0.1\lambda$. Then the path length difference $2L$ can be neglected, and the phase difference between r_1 and r_2 is due *only* to reflection phase shifts. If the film of Fig. 36-12, where the reflections cause a phase difference of 0.5 wavelength, has thickness $L < 0.1\lambda$, then r_1 and r_2 are exactly out of phase, and thus the film is dark, regardless of the wavelength and even the intensity of the light that illuminates it. This special situation corresponds to $m = 0$ in Eq. 36-35. We shall count any thickness $L < 0.1\lambda$ as being the least thickness specified by Eq. 36-35 to make the film of Fig. 36-12 dark. (Every such thickness will correspond to $m = 0$.) The next greater thickness that will make the film dark is that corresponding to $m = 1$.

Figure 36-14 shows a vertical soap film whose thickness increases from top to bottom because the weight of the film has caused it to slump. Bright white light illuminates the film. However, the top portion is so thin that it is dark. In the (somewhat thicker) middle we see fringes, or bands, whose color depends primarily on the wavelength at which reflected light undergoes fully constructive interference for a particular thickness. Toward the (thickest) bottom of the film the fringes become progressively narrower and the colors begin to overlap and fade.

Iridescence of a *Morpho* Butterfly Wing

A surface that displays colors due to thin-film interference is said to be *iridescent* because the tints of the colors change as you change your view of the surface. The iridescence of the top surface of a *Morpho* butterfly wing is due to thin-film interference of light reflected by thin terraces of transparent cuticle-like material on the wing. These terraces are arranged like wide, flat branches on a tree-like structure that extends perpendicular to the wing.

FIGURE 36-14 ■ The reflection of light from a soapy water film spanning a vertical loop. The top portion is so thin that the light reflected there undergoes destructive interference, making that portion dark. Colored interference fringes, or bands, decorate the rest of the film but are marred by circulation of liquid within the film as the liquid is gradually pulled downward by gravitation.

Suppose you look directly down on these terraces as white light shines directly down on the wing. Then the light reflected back up to you from the terraces undergoes fully constructive interference in the blue-green region of the visible spectrum. Light in the yellow and red regions, at the opposite end of the spectrum, is weaker because it undergoes only intermediate interference. Thus, the top surface of the wing looks blue-green to you.

If you intercept light that reflects from the wing in some other direction, the light has traveled along a slanted path through the terraces. Then the wavelength at which there is fully constructive interference is somewhat different from that for light reflected directly upward. Thus, if the wing moves in your view so that the angle at which you view it changes, the color at which the wing is brightest changes somewhat, producing the iridescence or brilliant rainbow-like colors of the wing.

TOUCHSTONE EXAMPLE 36-4: Brightest Reflected Light

White light, with a uniform intensity across the visible wavelength range of 400 to 690 nm, is perpendicularly incident on a water film, of index of refraction $n_2 = 1.33$ and thickness $L = 320$ nm, that is suspended in air. At what wavelength λ is the light reflected by the film brightest to an observer?

SOLUTION ■ The **Key Idea** here is that the reflected light from the film is brightest at the wavelengths λ for which the reflected rays are in phase with one another. The equation relating these wavelengths λ to the given film thickness L and film index of refraction n_2 is either Eq. 36-34 or Eq. 36-35, depending on the reflection phase shifts for this particular film.

To determine which equation is needed, we should fill out an organizing table like Table 36-1. However, because there is air on both sides of the water film, the situation here is exactly like that in Fig. 36-12, and thus the table would be exactly like Table 36-1. Then from Table 36-1, we see that the reflected rays are in phase (and thus the film is brightest) when

$$2L = \frac{\text{odd number}}{2} \times \frac{\lambda}{n_2},$$

which leads to Eq. 36-34:

$$2L = \left(m + \frac{1}{2}\right) \frac{\lambda}{n_2}.$$

Solving for λ and substituting for L and n_2 , we find

$$\lambda = \frac{2n_2L}{m + \frac{1}{2}} = \frac{(2)(1.33)(320 \text{ nm})}{m + \frac{1}{2}} = \frac{851 \text{ nm}}{m + \frac{1}{2}}.$$

For $m = 0$, this gives us $\lambda = 1700$ nm, which is in the infrared region. For $m = 1$, we find $\lambda = 567$ nm, which is yellow-green light, near the middle of the visible spectrum. For $m = 2$, $\lambda = 340$ nm, which is in the ultraviolet region. Thus, the wavelength at which the light seen by the observer is brightest is

$$\lambda = 567 \text{ nm.} \quad (\text{Answer})$$

TOUCHSTONE EXAMPLE 36-5: Magnesium Fluoride Film

In Fig. 36-15, a glass lens is coated on one side with a thin film of magnesium fluoride (MgF_2) to reduce reflection from the lens surface. The index of refraction of MgF_2 is 1.38; that of the glass is 1.50. What is the least coating thickness that eliminates (via interference) the reflections at the middle of the visible spectrum ($\lambda = 550$ nm)? Assume that the light is approximately perpendicular to the lens surface.

SOLUTION ■ The **Key Idea** here is that reflection is eliminated if the film thickness L is such that light waves reflected from the two film interfaces are exactly out of phase. The equation relating L to the given wavelength λ and the index of refraction n_2 of the thin film is either Eq. 36-34 or Eq. 36-35, depending on the reflection phase shifts at the interfaces.

FIGURE 36-15 ■ Unwanted reflections from glass can be suppressed (at a chosen wavelength) by coating the glass with a thin transparent film of magnesium fluoride of the properly chosen thickness.

To determine which equation is needed, we fill out an organizing table like Table 36-1. At the first interface, the incident light is in air, which has a lesser index of refraction than the MgF_2 (the thin film). Thus, we fill in 0.5 wavelength under r_1 in our organizing table (meaning that the waves of ray r_1 are shifted by 0.5λ at the first interface). At the second interface, the incident light is in the MgF_2 , which has a lesser index of refraction than the glass on the other side of the interface. Thus, we fill in 0.5 wavelength under r_2 in our table.

Because both reflections cause the same phase shift, they tend to put the waves of r_1 and r_2 in phase. Since we want those waves to be *out of phase*, their path length difference $2L$ must be an odd number of half-wavelengths:

$$2L = \frac{\text{odd number}}{2} \times \frac{\lambda}{n_2}.$$

This leads to Eq. 36-34. Solving that equation for L then gives us the film thicknesses that will eliminate reflection from the lens and coating:

$$L = (m + \frac{1}{2}) \frac{\lambda}{2n_2}, \quad \text{for } m = 0, 1, 2, \dots \quad (36-36)$$

We want the least thickness for the coating—that is, the least L . Thus, we choose $m = 0$, the least possible value of m . Substituting it and the given data in Eq. 36-36, we obtain

$$L = \frac{\lambda}{4n_2} = \frac{550 \text{ nm}}{(4)(1.38)} = 99.6 \text{ nm}. \quad (\text{Answer})$$

TOUCHSTONE EXAMPLE 36-6: Red Light

Figure 36-16a shows a transparent plastic block with a thin wedge of air at the right. (The wedge thickness is exaggerated in the figure.) A broad beam of red light, with wavelength $\lambda = 632.8 \text{ nm}$, is directed downward through the top of the block (at an incidence angle of 0°). Some of the light is reflected back up from the top and bottom surfaces of the wedge, which acts as a thin film (of air) with a thickness that varies uniformly and gradually from L_L at the left-hand end to L_R at the right-hand end. (The plastic layers above and below the wedge of air are too thick to act as thin films.) An observer looking down on the block sees an interference pattern consisting of six dark fringes and five bright red fringes along the wedge. What is the change in thickness $\Delta L = (L_R - L_L)$ along the wedge?

FIGURE 36-16 (a) Red light is incident on a thin, air-filled wedge in the side of a transparent plastic block. The thickness of the wedge is L_L at the left end and L_R at the right end. (b) The view from above the block: an interference pattern of six dark fringes and five bright red fringes lies over the region of the wedge. (c) A representation of the incident ray i , reflected rays r_1 and r_2 , and thickness L of the wedge anywhere along the length of the wedge.

SOLUTION ■ One **Key Idea** here is that the brightness at any point along the left–right length of the air wedge is due to the interference of the waves reflected at the top and bottom interfaces of the wedge. A second **Key Idea** is that the variation of brightness in the pattern of bright and dark fringes is due to the variation in the thickness of the wedge. In some regions, the thickness puts the reflected waves in phase and thus produces a bright reflection (a bright red fringe). In other regions, the thickness puts the reflected waves out of phase and thus produces no reflection (a dark fringe).

Because the observer sees more dark fringes than bright fringes, we can assume that a dark fringe is produced at both the left and right ends of the wedge. Thus, the interference pattern is that shown in Fig. 36-16b, which we can use to determine the change in thickness ΔL of the wedge.

Another **Key Idea** is that we can represent the reflection of light at the top and bottom interfaces of the wedge, at any point along its length, with Fig. 36-16c, in which L is the wedge thickness at that point. Let us apply this figure to the left end of the wedge, where the reflections give a dark fringe.

We know that, for a dark fringe, the waves of rays r_1 and r_2 in Fig. 36-16c must be out of phase. We also know that the equation relating the film thickness L to the light's wavelength λ and the film's index of refraction n_2 is either Eq. 36-34 or Eq. 36-35, depending on the reflection phase shifts. To determine which equation gives a dark fringe at the left end of the wedge, we should fill out an organizing table like Table 36-1.

At the top interface of the wedge, the incident light is in the plastic, which has a greater index of refraction than the air beneath that interface. Thus, we fill in 0 under r_1 in our organizing table. At the bottom interface of the wedge, the incident light is in air, which has a lesser index of refraction than the plastic beneath that interface. Thus, we fill in 0.5 wavelength under r_2 in our organizing table. Therefore, the reflections alone tend to put the waves of r_1 and r_2 out of phase.

Since the waves are, in fact, out of phase at the left end of the air wedge, the path length difference $2L$ at that end of the wedge must be given by

$$2L = \text{integer} \times \frac{\lambda}{n_2},$$

which leads to Eq. 36-35:

$$2L = m \frac{\lambda}{n_2}, \quad \text{for } m = 0, 1, 2, \dots \quad (36-37)$$

Here is another **Key Idea**: Eq. 36-37 holds not only for the left end of the wedge but also at any point along the wedge where a dark fringe is observed, including the right end—with a different integer value of m for each fringe. The least value of m is associated with the least thickness of the wedge where a dark fringe is observed. Progressively greater values of m are associated with progressively greater thicknesses of the wedge where a dark fringe is observed. Let m_L be the value at the left end. Then the value at the right end must be $m_L + 5$ because, from Fig. 36-16b, the right end is located at the fifth dark fringe from the left end.

We want the change ΔL in thickness, from the left end to the right end of the wedge. To find it we first solve Eq. 36-37 twice—

once for the thickness L_L at the left end and once for the thickness L_R at the right end:

$$L_L = (m_L) \frac{\lambda}{2n_2}, \quad L_R = (m_L + 5) \frac{\lambda}{2n_2}. \quad (36-38)$$

To find the change in thickness ΔL , we can now subtract L_L from L_R and substitute known data, including $n_2 = 1.00$ for the air within the wedge:

$$\begin{aligned} \Delta L &= L_R - L_L = \frac{(m_L + 5)\lambda}{2n_2} - \frac{m_L\lambda}{2n_2} = \frac{5}{2} \frac{\lambda}{n_2} \\ &= \frac{5}{2} \frac{632.8 \times 10^{-9} \text{ m}}{1.00} \\ &= 1.58 \times 10^{-6} \text{ m}. \end{aligned} \quad (\text{Answer})$$

36-8 Michelson's Interferometer

An **interferometer** is a device that can be used to measure lengths or changes in length with great accuracy by means of interference fringes. We describe the form originally devised and built by A. A. Michelson in 1881.

Consider light that leaves point P on extended source S in Fig. 36-17 and encounters *beam splitter* M . A beam splitter is a mirror that transmits half the incident light and reflects the other half. In the figure we have assumed, for convenience, that this mirror possesses negligible thickness. At M the light thus divides into two waves. One proceeds by transmission toward mirror M_1 ; the other proceeds by reflection toward mirror M_2 . The waves are entirely reflected at these mirrors and are sent back along their directions of incidence, each wave eventually entering telescope T . What the observer sees is a pattern of curved or approximately straight interference fringes; in the latter case the fringes resemble the stripes on a zebra.

The path length difference for the two waves when they recombine at the telescope is $2d_2 - 2d_1$, and anything that changes this path length difference will cause a change in the phase difference between these two waves at the eye. As an example, if mirror M_2 is moved by a distance $\frac{1}{2}\lambda$, the path length difference is changed by λ and the fringe pattern is shifted by one fringe (as if each dark stripe on a zebra had moved to where the adjacent dark stripe had been). Similarly, moving mirror M_2 by $\frac{1}{4}\lambda$ causes a shift by half a fringe (each dark zebra stripe shifts to where the adjacent white stripe was).

A shift in the fringe pattern can also be caused by the insertion of a thin transparent material into the optical path of one of the mirrors—say, M_1 . If the material has thickness L and index of refraction n , then the number of wavelengths along the light's to-and-fro path through the material is, from Eq. 36-9,

$$N_m = \frac{2L}{\lambda_n} = \frac{2Ln}{\lambda}. \quad (36-39)$$

The number of wavelengths in the same thickness $2L$ of air before the insertion of the material is

$$N_a = \frac{2L}{\lambda}. \quad (36-40)$$

FIGURE 36-17 ■ Michelson's interferometer, showing the path of light originating at point P of an extended source S . Mirror M splits the light into two beams, which reflect from mirrors M_1 and M_2 back to M and then to telescope T . In the telescope an observer sees a pattern of interference fringes.

When the material is inserted, the light returned by mirror M_1 undergoes a phase change (in terms of wavelengths) of

$$N_m - N_a = \frac{2Ln}{\lambda} - \frac{2L}{\lambda} = \frac{2L}{\lambda}(n - 1). \quad (36-41)$$

For each phase change of one wavelength, the fringe pattern is shifted by one fringe. Thus, by counting the number of fringes through which the material causes the pattern to shift, and substituting that number for $N_m - N_a$ in Eq. 36-41, you can determine the thickness L of the material in terms of λ .

By such techniques the lengths of objects can be expressed in terms of the wavelengths of light. In Michelson's day, the standard of length—the meter—was chosen by international agreement to be the distance between two fine scratches on a certain metal bar preserved at Sèvres, near Paris. Michelson was able to show, using his interferometer, that the standard meter was equivalent to 1 553 163.5 wavelengths of a certain monochromatic red light emitted from a light source containing cadmium. For this careful measurement, Michelson received the 1907 Nobel Prize in physics. His work laid the foundation for the eventual abandonment (in 1961) of the meter bar as a standard of length and for the redefinition of the meter in terms of the wavelength of light. By 1983, as we have seen, even this wavelength standard was not precise enough to meet the growing requirements of science and technology, and it was replaced with a new standard based on a defined value for the speed of light as discussed in Section 1-6.

Problems

SEC. 36-2 ■ LIGHT AS A WAVE

1. Yellow Sodium Light The wavelength of yellow sodium light in air is 589 nm. (a) What is its frequency? (b) What is its wavelength in glass whose index of refraction is 1.52? (c) From the results of (a) and (b) find its speed in this glass.

2. Sapphire vs. Diamond How much faster, in meters per second, does light travel in sapphire than in diamond? See Table 35-1.

3. Yellow Light The speed of yellow light (from a sodium lamp) in a certain liquid is measured to be 1.92×10^8 m/s. What is the index of refraction of this liquid for the light at this wavelength?

4. Fused Quartz What is the speed in fused quartz of light of wavelength 550 nm? (See Fig. 35-3.)

5. Ocean Wave Ocean waves moving at a speed of 4.0 m/s are approaching a beach at an angle of 30° to the normal, as shown from above in Fig. 36-18. Suppose the water depth changes abruptly at a certain distance from the beach and the wave speed there drops to 3.0 m/s. Close to the beach, what is the angle θ between the direction of wave motion and the normal? (Assume the same law of refraction as for light.) Explain why most waves come in normal to a shore even though at large distances they approach at a variety of angles.

FIGURE 36-18 ■ Problem 5.

6. Two Pulses In Fig. 36-19. Two pulses of light are sent through layers of plastic with the indexes of refraction indicated and with thicknesses of either L or $2L$ as shown. (a) Which pulse travels through the plastic in less time? (b) In terms of L/c , what is the difference in the traversal times of the pulses?

FIGURE 36-19 ■ Problem 6.

7. Two Waves In Fig. 36-3, assume that two waves of light in air, of wave length 400 nm, are initially in phase. One travels through a glass layer of index of refraction $n_1 = 1.60$ and thickness L . The other travels through an equally thick plastic layer of index of refraction $n_2 = 1.50$. (a) What is the least value L should have if the waves are to end up with a phase difference of 5.65 rad? (b) If the waves arrive at some common point after emerging, what type of interference do they undergo?

8. Two Media Suppose that the two waves in Fig. 36-3 have wavelength 500 nm in air. In wavelengths, what is their phase difference after traversing media 1 and 2 if (a) $n_1 = 1.50$, $n_2 = 1.60$, and $L = 8.50 \mu\text{m}$; (b) $n_1 = 1.62$, $n_2 = 1.72$, and $L = 8.50 \mu\text{m}$; and (c) $n_1 = 1.59$, $n_2 = 1.79$, and $L = 3.25 \mu\text{m}$? (d) Suppose that in each of these three situations the waves arrive at a common point after emerging. Rank the situations according to the brightness the waves produce at the common point.

9. Initially in Phase Two waves of light in air, of wavelength 600.0 nm, are initially in phase. They then travel through plastic layers as shown in Fig. 36-20, with $L_1 = 4.00 \mu\text{m}$, $L_2 = 3.50 \mu\text{m}$,

$n_1 = 1.40$, and $n_2 = 1.60$. (a) In wavelengths, what is their phase difference after they both have emerged from the layers? (b) If the waves later arrive at some common point, what type of interference do they undergo?

10. Two Light Waves In Fig. 36-3, assume that the two light waves, of wavelength 620 nm in air, are initially out of phase by π rad. The indexes of refraction of the media are $n_1 = 1.45$ and $n_2 = 1.65$. (a) What is the least thickness L that will put the waves exactly in phase once they pass through the two media? (b) What is the next greater L that will do this?

FIGURE 36-20 ■ Problem 9.

SEC. 36-4 ■ YOUNG'S INTERFERENCE EXPERIMENT

11. Green Light Monochromatic green light, of wavelength 550 nm, illuminates two parallel narrow slits $7.70 \mu\text{m}$ apart. Calculate the angular deviation (θ in Fig. 36-8) of the third-order (for $m = 3$) bright fringe (a) in radians and (b) in degrees.

12. Phase Difference What is the phase difference of the waves from the two slits when they arrive at the m th dark fringe in a Young's double-slit experiment?

13. Blue-Green Light Suppose that Young's experiment is performed with blue-green light of wavelength 500 nm. The slits are 1.20 mm apart, and the viewing screen is 5.40 m from the slits. How far apart are the bright fringes.

14. Angular Separation In a double-slit arrangement the slits are separated by a distance equal to 100 times the wavelength of the light passing through the slits. (a) What is the angular separation in radians between the central maximum and an adjacent maximum? (b) What is the distance between these maxima on a screen 50.0 cm from the slits?

15. Interference Fringes A double-slit arrangement produces interference fringes for sodium light ($\lambda = 589 \text{ nm}$) that have an angular separation of 3.50×10^{-3} rad. For what wavelength would the angular separation be 10.0% greater?

16. Immersed in Water A double-slit arrangement produces interference fringes for sodium light ($\lambda = 589 \text{ nm}$) that are 0.20° apart. What is the angular fringe separation if the entire arrangement is immersed in water ($n = 1.33$)?

17. Radio Frequency Sources Two radio-frequency point sources separated by 2.0 m are radiating in phase with $\lambda = 0.50 \text{ m}$. A detector moves in a circular path around the two sources in a plane containing them. Without written calculation, find how many maxima it detects.

18. Long-Range Radio Waves Sources A and B emit long-range radio waves of wavelength 400 m, with the phase of the emission from A ahead of that from source B by 90° . The distance r_A from A to a detector is greater than the corresponding distance r_B by 100 m. What is the phase difference at the detector?

19. Two Interference Patterns In a double-slit experiment the distance between slits is 5.0 nm and the slits are 1.0 m from the screen. Two interference patterns can be seen on the screen: one due to light with wavelength 480 nm, and the other due to light with wave-

length 600 nm. What is the separation on the screen between the third-order ($m = 3$) bright fringes of the two interference patterns?

20. Identical Radiators In Fig. 36-21, S_1 and S_2 are identical radiators of waves that are in phase and of the same wavelength λ . The radiators are separated by distance $d = 3.00\lambda$. Find the greatest distance from S_1 , along the x axis, for which fully destructive interference occurs. Express this distance in wavelengths.

FIGURE 36-21 ■ Problems 20 and 27.

21. Mica Flake A thin flake of mica ($n = 1.58$) is used to cover one slit of a double-slit interference arrangement. The central point on the viewing screen is now occupied by what had been the seventh bright side fringe ($m = 7$) before the mica was used. If $\lambda = 550 \text{ nm}$, what is the thickness of the mica? (*Hint:* Consider the wavelength of the light within the mica.)

22. Laser Light Laser light of wavelength 632.8 nm passes through a double-slit arrangement at the front of a lecture room, reflects off a mirror 20.0 m away at the back of the room, and then produces an interference pattern on a screen at the front of the room. The distance between adjacent bright fringes is 10.0 cm. (a) What is the slit separation? (b) What happens to the pattern when the lecturer places a thin cellophane sheet over one slit, thereby increasing by 2.50 the number of wavelengths along the path that includes the cellophane?

SEC. 36-6 ■ INTENSITY IN DOUBLE-SLIT INTERFERENCE

23. Same Frequency Two waves of the same frequency have amplitudes 1.00 and 2.00. They interfere at a point where their phase difference is 60.0° . What is the resultant amplitude?

24. Find Sum Find the sum y of the following quantities:

$$y_1 = 0 \sin \omega t \quad \text{and} \quad y_2 = 8.0 \sin(\omega t + 30^\circ).$$

25. Use Phasors Add the quantities

$$y_1 = 10 \sin \omega t$$

$$y_2 = 15 \sin(\omega t + 30^\circ)$$

$$y_3 = 5.0 \sin(\omega t - 45^\circ)$$

using the phasor method.

26. Sketch Intensity Light of wavelength 600 nm is incident normally on two parallel narrow slits separated by 0.60 mm. Sketch the intensity pattern observed on a distant screen as a function of angle θ from the pattern's center for the range of values $0 \leq \theta \leq 0.0040$ rad.

27. Electromagnetic Waves S_1 and S_2 in Fig. 36-21 are point sources of electromagnetic waves of wavelength 1.00 m. They are in phase and separated by $d = 4.00 \text{ m}$, and they emit at the same power. (a) If a detector is moved to the right along the x axis from source S_1 , at what distances from S_1 are the first three interference maxima detected? (b) Is the intensity of the nearest minimum exactly zero? (*Hint:* Does the intensity of a wave from a point source remain constant with an increase in distance from the source?).

28. Horizontal Arrow The double horizontal arrow in Fig. 36-9 marks the points on the intensity curve where the intensity of the central fringe is half the maximum intensity. Show that the angular separation $\Delta\theta$ between the corresponding points on the viewing screen is

$$\Delta\theta = \frac{\lambda}{2d}$$

if θ in Fig. 36-8 is small enough so that $\sin \theta \approx \theta$.

29. Wider Slit Suppose that one of the slits of a double-slit interference experiment is wider than the other, so the amplitude of the light reaching the central part of the screen from one slit, acting alone, is twice that from the other slit, acting alone. Derive an expression for the light intensity I at the screen as a function of θ , corresponding to Eqs. 36-21 and 36-22.

SEC. 36-7 ■ INTERFERENCE FROM THIN FILMS

30. Reflections In Fig. 36-22, light wave W_1 reflects once from a reflecting surface while light wave W_2 reflects twice from that surface and once from a reflecting sliver at distance L from the mirror. The waves are initially in phase and have a wavelength of 620 nm. Neglect the slight tilt of the rays. (a) For what least value of L are the reflected waves exactly out of phase? (b) How far must the sliver be moved to put the waves exactly out of phase again?

FIGURE 36-22 ■ Problems 30 and 32.

31. Bright Light Bright light of wavelength 585 nm is incident perpendicularly on a soap film ($n = 1.33$) of thickness $1.21 \mu\text{m}$, suspended in air. Is the light reflected by the two surfaces of the film closer to interfering fully destructively or fully constructively?

32. Exactly Out of Phase Suppose the light waves of Problem 30 are initially exactly out of phase. Find an expression for the values of L (in terms of the wavelength λ) that put the reflected waves exactly in phase.

33. Soap Film Light of wavelength 624 nm is incident perpendicularly on a soap film (with $n = 1.33$) suspended in air. What are the least two thicknesses of the film for which the reflections from the film undergo fully constructive interference?

34. Camera Lens A camera lens with index of refraction greater than 1.30 is coated with a thin transparent film of index of refraction 1.25 to eliminate by interference the reflection of light at wavelength λ that is incident perpendicularly on the lens. In terms of λ , what minimum film thickness is needed?

35. Rhinestones The rhinestones in costume jewelry are glass with index of refraction 1.50. To make them more reflective, they are often coated with a layer of silicon monoxide of index of refraction 2.00. What is the minimum coating thickness needed to ensure that light of wavelength 560 nm and of perpendicular incidence will be reflected from the two surfaces of the coating with fully constructive interference?

36. Five Sections In Fig. 36-23, light of wavelength 600 nm is incident perpendicularly on five sections of a transparent structure suspended in air. The structure has index of refraction 1.50. The thickness of each section is given in terms of $L = 4.00 \mu\text{m}$. For

which sections will the light that is reflected from the top and bottom surfaces of that section undergo fully constructive interference?

37. Coat Glass We wish to coat flat glass ($n = 1.50$) with a transparent material ($n = 1.25$) so that reflection of light at wavelength 600 nm is eliminated by interference. What minimum thickness can the coating have to do this?

38. Four Thin Layers In Fig. 36-24, light is incident perpendicularly on four thin layers of thickness L . The indexes of refraction of the thin layers and of the media above and below these layers are given. Let λ represent the wavelength of the light in air and n_2 represent the index of refraction of the thin layer in each situation. Consider only the transmission of light that undergoes no reflection or two reflections, as in Fig. 36-24a. For which of the situations does the expression

$$\lambda = \frac{2Ln_2}{m}, \quad \text{for } m = 1, 2, 3, \dots,$$

give the wavelengths of the transmitted light that undergoes fully constructive interference?

FIGURE 36-24 ■ Problems 38 and 39.

39. Leaking Tanker A disabled tanker leaks kerosene ($n = 1.20$) into the Persian Gulf creating a large slick on top of the water ($n = 1.30$). (a) If you are looking straight down from an airplane, while the Sun is overhead, at a region of the slick where its thickness is 460 nm, for which wavelength(s) of visible light is the reflection brightest because of constructive interference? (b) If you are scuba diving directly under this same region of the slick, for which wavelength(s) of visible light is the transmitted intensity strongest? (Hint: Use Fig. 36-24a with appropriate indexes of refraction.)

40. Plane Wave A plane wave of monochromatic light is incident normally on a uniform thin film of oil that covers a glass plate. The wavelength of the source can be varied continuously. Fully destructive interference of the reflected light is observed for wavelengths of 500 and 700 nm and for no wavelengths in between. If the index of refraction of the oil is 1.30 and that of the glass is 1.50, find the thickness of the oil film.

41. Monochromatic Light A plane monochromatic light wave in air is incident perpendicularly on a thin film of oil that covers a glass plate. The wavelength of the source may be varied continuously. Fully destructive interference of the reflected light is

FIGURE 36-23 ■ Problem 36.

observed for wavelengths of 500 and 700 nm and for no wavelength in between. The index of refraction of the glass is 1.50. Show that the index of refraction of the oil must be less than 1.50.

42. Soap Film Two The reflection of perpendicularly incident white light by a soap film in air has an interference maximum at 600 nm and a minimum at 450 nm, with no minimum in between. If $n = 1.33$ for the film, what is the film thickness, assumed uniform?

43. Glass Plates In Fig. 36-25, a broad beam of light of wavelength 683 nm is sent directly downward through the top plate of a pair of glass plates. The plates are 120 mm long, touch at the left end, and are separated by a wire of diameter 0.048 mm at the right end. The air between the plates acts as a thin film. How many bright fringes will be seen by an observer looking down through the top plate?

FIGURE 36-25 Problems 43 and 44.

44. Directly Downward In Fig. 36-25, white light is sent directly downward through the top plate of a pair of glass plates. The plates touch at the left end and are separated by a wire of diameter 0.048 mm at the right end; the air between the plates acts as a thin film. An observer looking down through the top plate sees bright and dark fringes due to that film. (a) Is a dark fringe or a bright fringe seen at the left end? (b) To the right of that end, fully destructive interference occurs at different locations for different wavelengths of the light. Does it occur first for the red end or the blue end of the visible spectrum?

45. Wedge-Shaped A broad beam of light of wavelength 630 nm is incident at 90° on a thin, wedge-shaped film with index of refraction 1.50. An observer intercepting the light transmitted by the film sees 10 bright and 9 dark fringes along the length of the film. By how much does the film thickness change over this length?

46. Acetone A thin film of acetone ($n = 1.25$) coats a thick glass plate ($n = 1.50$). White light is incident normal to the film. In the reflections, fully destructive interference occurs at 600 nm and fully constructive interference at 700 nm. Calculate the thickness of the acetone film.

47. Two Glass Plates Two glass plates are held together at one end to form a wedge of air that acts as a thin film. A broad beam of light of wavelength 480 nm is directed through the plates, perpendicular to the first plate. An observer intercepting light reflected from the plates sees on the plates an interference pattern that is due to the wedge of air. How much thicker is the wedge at the sixteenth bright fringe than it is at the sixth bright fringe, counting from where the plates touch?

48. Broad Beam A broad beam of monochromatic light is directed perpendicularly through two glass plates that are held together at one end to create a wedge of air between them. An observer intercepting light reflected from the wedge of air, which acts as a thin film, sees 4001 dark fringes along the length of the wedge. When the air between the plates is evacuated, only 4000 dark fringes are seen. Calculate the index of refraction of air from these data.

49. Radius of Curvature Figure 36-26a shows a lens with radius of curvature R lying on plane glass plate and illuminated from above by light with wavelength λ . Figure 36-26b (a photograph taken from above the lens) shows that circular interference fringes (called

Newton's rings) appear, associated with the variable thickness d of the air film between the lens and the plate. Find the radii r of the interference maxima assuming $r/R \ll 1$.

50. Newton's Rings One In a Newton's rings experiment (see Problem 49), the radius of curvature R of the lens is 5.0 m and the lens diameter is 20 mm. (a) How many bright rings are produced? Assume that $\lambda = 589$ nm. (b) How many bright rings would be produced if the arrangement were immersed in water ($n = 1.33$)?

51. Newton's Rings Two A Newton's rings apparatus is to be used to determine the radius of curvature of a lens (see Fig. 36-26 and Problem 49). The radii of the n th and $(n + 20)$ th bright rings are measured and found to be 0.162 and 0.368 cm, respectively, in light of wavelength 546 nm. Calculate the radius of curvature of the lower surface of the lens.

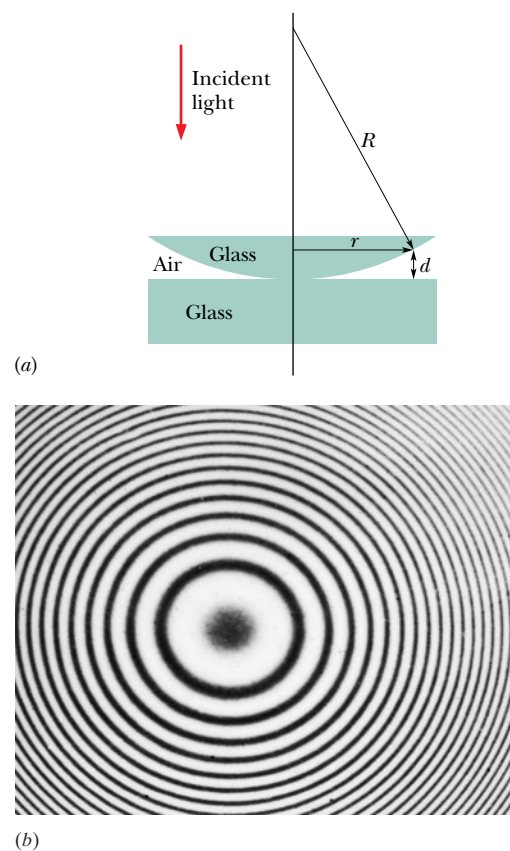

FIGURE 36-26 Problems 49 through 52.

52. Newton's Rings Three (a) Use the result of Problem 49 to show that, in a Newton's rings experiment, the difference in radius between adjacent bright rings (maxima) is given by

$$\Delta r = r_{m+1} - r_m \approx \frac{1}{2}\sqrt{\lambda R/m},$$

assuming $m \gg 1$. (b) Now show that the *area* between adjacent bright rings is given by

$$A = \pi\lambda R,$$

assuming $m \gg 1$. Note that this area is independent of m .

53. Microwave Transmitter In Fig. 36-27, a microwave transmitter at height a above the water level of a wide lake transmits microwaves of wavelength λ toward a receiver on the opposite shore, a distance x above the water level. The microwaves reflecting from the water interfere with the microwaves arriving directly from the transmitter. Assuming that the lake width D is much greater than a and x , and that $\lambda \geq a$, at what values of x is the signal at the receiver maximum? (*Hint: Does the reflection cause a phase change?*)

FIGURE 36-27 ■ Problem 53.

SEC. 36-8 ■ MICHELSON'S INTERFEROMETER

54. Thin Film A thin film with index of refraction $n = 1.40$ is placed in one arm of a Michelson interferometer, perpendicular to the optical path. If this causes a shift of 7.0 fringes of the pattern produced by light of wavelength 589 nm, what is the film thickness?

55. Move the Mirror If mirror M_2 in a Michelson interferometer (Fig. 36-17) is moved through 0.233 mm, a shift of 792 fringes occurs. What is the wavelength of the light producing the fringe pattern?

56. Light at Two Wavelengths The element sodium can emit light at two wavelengths, $\lambda_1 = 589.10$ nm and $\lambda_2 = 589.59$ nm. Light from sodium is being used in a Michelson interferometer (Fig. 36-17).

Through what distance must mirror M_2 be moved to shift the fringe pattern for one wavelength by 1.00 fringe more than the fringe pattern for the other wavelength?

57. Airtight Chamber In Fig. 36-28, an airtight chamber 5.0 cm long with glass windows is placed in one arm of a Michelson interferometer. Light of wavelength $\lambda = 500$ nm is used. Evacuating the air from the chamber causes a shift of 60 fringes. From these data, find the index of refraction of air at atmospheric pressure.

FIGURE 36-28 ■ Problem 57.

58. Observed Intensity Write an expression for the intensity observed in a Michelson interferometer (Fig. 36-17) as a function of the position of the moveable mirror. Measure the position of the mirror from the point at which $d_2 = d_1$.

Additional Problems

59. Arranging the Patio Speakers You have set up two stereo speakers on your patio as shown in the top view diagram in Fig. 36-29. You are worried that at certain positions you will lose frequencies as a result of interference. The coordinate grid on the edge of the picture has its large tick marks separated by 1 m. For ease of calculation, make the following assumptions:

FIGURE 36-29 ■ Problem 59.

- Assume that the relevant objects lie on integer or half-integer grid points of the coordinate system.
 - Take the speed of sound to be 343 m/s.
 - Ignore the reflection of sound from the house, trees, etc.
 - Assume that the speakers are in phase.
- (a) What will happen if you are sitting in the middle of the bench?
 (b) If you are sitting in the lawn chair on the left, what will be the lowest frequency you will lose to destructive interference?
 (c) Can you restore the frequency lost in part (b) by switching the leads to one of the speakers, thereby reversing the phase of that source?
 (d) With the leads reversed, what will happen to the sound for a person sitting at the center of the bench?

60. What Happens If a Double Slit Winks?

When a laser beam is incident on a double slit, a closeup of the center of the pattern looks like that shown in Fig. 36-30. If one of the slits is covered (the left one) but the other slit remains open, what will the pattern look like? Explain how you know.

FIGURE 36-30 ■ Problem 60.

37

Diffraction

Georges Seurat painted *Sunday Afternoon on the Island of La Grande Jatte* using not brush strokes in the usual sense, but rather a myriad of small colored dots, in a style of painting now known as pointillism. You can see the dots if you stand close enough to the painting, but as you move away from it, they eventually blend and cannot be distinguished. Moreover, the color that you see at any given place on the painting changes as you move away—which is why Seurat painted with the dots.

What causes this change in color?

The answer is in this chapter.

FIGURE 37-1 ■ This diffraction pattern appeared on a viewing screen when light that had passed through a narrow but tall vertical slit reached the screen. Diffraction causes light to flare out perpendicular to the long sides of the slit. That produces an interference pattern consisting of a broad central maximum less intense and narrower secondary (or side) maxima, with minima between them.

FIGURE 37-2 ■ The diffraction pattern produced by a razor blade in monochromatic light. Note the lines of alternating maximum and minimum intensity.

37-1 Diffraction and the Wave Theory of Light

In Chapter 36 we defined diffraction rather loosely as the flaring of light as it emerges from a narrow slit. More than just flaring occurs, however, because the light produces an interference pattern called a **diffraction pattern**. For example, when monochromatic light from a distant source (or a laser) passes through a narrow slit and is then intercepted by a viewing screen, the light produces on the screen a diffraction pattern like that in Fig. 37-1. This pattern consists of a broad and intense (very bright) central maximum and a number of narrower and less intense maxima (called **secondary** or **side** maxima) to both sides. In between the maxima are minima.

Such a pattern would be totally unexpected in geometrical optics: If light traveled in straight lines as rays, then the slit would allow some of those rays through and they would form a sharp, bright rendition of the slit on the viewing screen. As in Chapter 36, we again must conclude that geometrical optics is only an approximation.

Diffraction of light is not limited to situations of light passing through a narrow opening (such as a slit or pinhole). It also occurs when light passes an edge, such as the edges of the razor blade whose diffraction pattern is shown in Fig. 37-2. Note the lines of maxima and minima that run approximately parallel to the edges, at both the inside edges of the blade and the outside edges. As the light passes, say, the vertical edge at the left, it flares left and right and undergoes interference, producing the pattern along the left edge. The rightmost portion of that pattern actually lies within what would have been the shadow of the blade if geometrical optics prevailed.

You encounter a common example of diffraction when you look at a clear blue sky and see tiny specks and hair-like structures floating in your view. These *floaters*, as they are called, are produced when light passes the edges of tiny deposits in the vitreous humor, the transparent material filling most of your eyeball. What you are seeing when a floater is in your field of vision is the diffraction pattern produced on the retina by one of these deposits. If you sight through a pinhole in an otherwise opaque sheet so as to make the light entering your eye approximately a plane wave, you can distinguish individual maxima and minima in the patterns.

The Fresnel Bright Spot

Diffraction finds a ready explanation in the wave theory of light. However, this theory, originally advanced in the late 1600s by Huygens and used 123 years later by Young to explain double-slit interference, was very slow in being adopted, largely because it ran counter to Newton's theory that light was a stream of particles.

Newton's view was the prevailing view in French scientific circles of the early 19th century, when Augustin Fresnel was a young military engineer. Fresnel, who believed in the wave theory of light, submitted a paper to the French Academy of Sciences describing his experiments with light and his wave-theory explanations of them.

In 1819, the Academy, dominated by supporters of Newton and thinking to challenge the wave point of view, organized a prize competition for an essay on the subject of diffraction. Fresnel won. The Newtonians, however, were neither converted nor silenced. One of them, S. D. Poisson, pointed out the "strange result" that if Fresnel's theories were correct, then light waves should flare into the shadow region of a sphere as they pass the edge of the sphere, producing a bright spot at the center of the shadow. The prize committee arranged to have Dominique Argo test the famous mathematician's prediction. He discovered (see Fig. 37-3) that the predicted *Fresnel bright spot*, as we call it today, was indeed there!* Nothing builds confidence in a

* Since Poisson predicted the spot and Argo discovered it, an alternate name is the Poisson-Argo bright spot.

FIGURE 37-3 ■ A photograph of the diffraction pattern of a disk. Note the concentric diffraction rings and the Fresnel bright spot at the center of the pattern. This experiment is essentially identical to that arranged by the committee testing Fresnel's theories, because both the sphere they used and the disk used here have a cross section with a circular edge.

theory so much as having one of its unexpected and counterintuitive predictions verified by experiment.

37-2 Diffraction by a Single Slit: Locating the Minima

Let us now examine the diffraction pattern of plane waves of light of wavelength λ that are diffracted by a single, long, narrow slit of width a in an otherwise opaque screen B , as shown in cross section in Fig. 37-4a. (In that figure, the slit's length extends into and out of the page, and the incoming wavefronts are parallel to screen B .) When the diffracted light reaches viewing screen C , waves from different points within the slit undergo interference and produce a diffraction pattern of bright and dark fringes (interference maxima and minima) on the screen. To locate the fringes, we shall use a procedure somewhat similar to the one we used to locate the fringes in a two-slit interference pattern. However, diffraction is more mathematically challenging, and here we shall be able to find equations for only the dark fringes.

Before we do that, however, we can justify the central bright fringe seen in Fig. 37-1 by noting that the Huygens wavelets from all points in the slit travel about the same distance to reach the center of the pattern and thus are in phase there. As for the other bright fringes, we can say only that they are approximately halfway between adjacent dark fringes.

To find the dark fringes, we shall use a clever (and simplifying) strategy that involves pairing up all the rays coming through the slit and then finding what conditions cause the wavelets of the rays in each pair to cancel each other. Figure 37-4a shows how we apply this strategy to locate the first dark fringe, at point P_1 . First, we mentally divide the slit into two zones of equal widths $a/2$. Then we extend to P_1 a light ray r_1 from the top point of the top zone and a light ray r_2 from the top point of the bottom zone. A central axis is drawn from the center of the slit to screen C , and P_1 is located at an angle θ to that axis.

The wavelets of the pair of rays r_1 and r_2 are in phase within the slit because they originate from the same wavefront passing through the slit, along the width of the slit. However, to produce the first dark fringe they must be out of phase by $\lambda/2$ when they reach P_1 ; this phase difference is due to their path length difference, with the wavelet of r_2 traveling a longer path to reach P_1 than the wavelet of r_1 . To display this path length difference, we find a point b on ray r_2 such that the path length from b to P_1 matches the path length of ray r_1 . Then the path length difference between the two rays is the distance from the center of the slit to b .

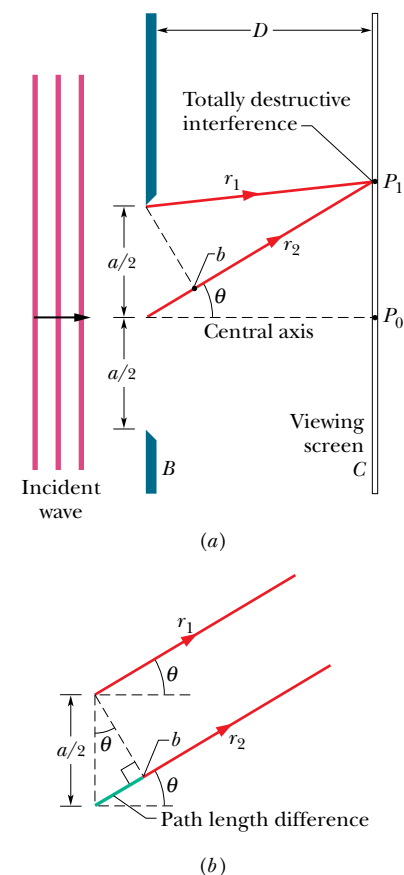

FIGURE 37-4 ■ (a) Waves from the top points of two zones of width $a/2$ undergo totally destructive interference at point P_1 on viewing screen C . (b) For $D \gg a$, we can approximate rays r_1 and r_2 as being parallel, at angle θ to the central axis.

FIGURE 37-5 (a) Waves from the top points of four zones of width $a/4$ undergo totally destructive interference at point P_2 . (b) For $D \gg a$, we can approximate rays r_1 , r_2 , r_3 , and r_4 as being parallel, at angle θ to the central axis.

When viewing screen C is near screen B , as in Fig. 37-4a, the diffraction pattern on C is difficult to describe mathematically. However, we can simplify the mathematics considerably if we arrange for the distance between the slit and screen D to be much larger than the slit width a . Then we can approximate rays r_1 and r_2 as being parallel, at angle θ to the central axis (Fig. 37-4b). We can also approximate the triangle formed by point b , the top point of the slit, and the center point of the slit as being a right triangle, and one of the angles inside that triangle as being θ . The path length difference between rays r_1 and r_2 (which is still the distance from the center of the slit to point b) is then equal to $(a/2) \sin \theta$.

We can repeat this analysis for any other pair of rays originating at corresponding points in the two zones (say, at the midpoints of the zones) and extending to point P_1 . Each such pair of rays has the same path length difference $(a/2) \sin \theta$. Setting this common path length difference equal to $\lambda/2$ (our condition for the first dark fringe), we have

$$\frac{a}{2} \sin \theta = \frac{\lambda}{2},$$

which gives us

$$a \sin \theta = \lambda \quad (\text{first minimum for } D \gg a). \quad (37-1)$$

Given slit width a and wavelength λ , Eq. 37-1 tells us the angle θ of the first dark fringe above and (by symmetry) below the central axis.

Note that if we begin with $a > \lambda$ and then narrow the slit while holding the wavelength constant, we increase the angle at which the first dark fringes appear; that is, the extent of the diffraction (the extent of the flaring and the width of the pattern) is *greater* for a *narrower* slit. When we have reduced the slit width to the wavelength (that is, $a = \lambda$), the angle of the first dark fringes is 90° . Since the first dark fringes mark the two edges of the central bright fringe, that bright fringe must then cover the entire viewing screen.

We find the second dark fringes above and below the central axis as we found the first dark fringes, except that we now divide the slit into *four* zones of equal widths $a/4$, as shown in Fig. 37-5a. We then extend rays r_1 , r_2 , r_3 , and r_4 from the top points of the zones to point P_2 , the location of the second dark fringe above the central axis. To produce that fringe, the path length difference between r_1 and r_2 , that between r_2 and r_3 , and that between r_3 and r_4 must all be equal to $\lambda/2$.

For $D \gg a$, we can approximate these four rays as being parallel, at angle θ to the central axis. To display their path length differences, we extend a perpendicular line through each adjacent pair of rays, as shown in Fig. 37-5b, to form a series of right triangles, each of which has a path length difference as one side. We see from the top triangle that the path length difference between r_1 and r_2 is $(a/4) \sin \theta$. Similarly, from the bottom triangle, the path length difference between r_3 and r_4 is also $(a/4) \sin \theta$. In fact, the path length difference for any two rays that originate at corresponding points in two adjacent zones is $(a/4) \sin \theta$. Since in each such case the path length difference is equal to $\lambda/2$, we have

$$\frac{a}{4} \sin \theta = \frac{\lambda}{2},$$

which gives us

$$a \sin \theta = 2\lambda \quad (\text{second minimum for } D \gg a). \quad (37-2)$$

We could now continue to locate dark fringes in the diffraction pattern by splitting up the slit into more zones of equal width. We would always choose an even num-

ber of zones so that the zones (and their waves) could be paired as we have been doing. We would find that the dark fringes above and below the central axis can be located with the following general equation:

$$a \sin \theta = m\lambda, \quad \text{for } m = 1, 2, 3, \dots \quad (\text{single slit minima—dark fringes}). \quad (37-3)$$

You can remember this result in the following way. Draw a triangle like the one in Fig. 37-4b, but for the full slit width a , and note that the path length difference between the top and bottom rays from the slit equals $a \sin \theta$. Thus, Eq. 37-3 says:

In a single-slit diffraction experiment, dark fringes are produced where the path length differences ($a \sin \theta$) between the top and bottom rays are equal to $\lambda, 2\lambda, 3\lambda, \dots$

This may seem to be wrong, because the waves of those two particular rays will be exactly in phase with each other when their path length difference is an integer number of wavelengths. However, they each will still be part of a pair of waves that are exactly out of phase with each other; thus, *each* will be canceled by some other wave.

READING EXERCISE 37-1: We produce a diffraction pattern on a viewing screen by means of a long narrow slit illuminated by blue light. Does the pattern expand away from the bright center (the maxima and minima shift away from the center) or contract toward it if we (a) switch to yellow light or (b) decrease the slit width? ■

TOUCHSTONE EXAMPLE 37-1: White Light, Red Light

A slit of width a is illuminated by white light (which consists of all the wavelengths in the visible range).

(a) For what value of a will the first minimum for red light of wavelength $\lambda = 650 \text{ nm}$ appear at $\theta = 15^\circ$?

SOLUTION ■ The **Key Idea** here is that diffraction occurs separately for each wavelength in the range of wavelengths passing through the slit, with the locations of the minima for each wavelength given by Eq. 37-3 ($a \sin \theta = m\lambda$). When we set $m = 1$ (for the first minimum) and substitute the given values of θ and λ , Eq. 37-3 yields

$$\begin{aligned} a &= \frac{m\lambda}{\sin \theta} = \frac{(1)(650 \text{ nm})}{\sin 15^\circ} \\ &= 2511 \text{ nm} \approx 2.5 \mu\text{m}. \end{aligned} \quad (\text{Answer})$$

For the incident light to flare out that much ($\pm 15^\circ$ to the first minima) the slit has to be very fine indeed—about four times the wavelength. For comparison, note that a fine human hair may be about $100 \mu\text{m}$ in diameter.

(b) What is the wavelength λ' of the light whose first side diffraction maximum is at 15° , thus coinciding with the first minimum for the red light?

SOLUTION ■ The **Key Idea** here is that the first side maximum for any wavelength is about halfway between the first and second minima for that wavelength. Those first and second minima can be located with Eq. 37-3 by setting $m = 1$ and $m = 2$, respectively. Thus, the first side maximum can be located *approximately* by setting $m = 1.5$. Then Eq. 37-3 becomes

$$a \sin \theta = 1.5\lambda'.$$

Solving for λ' and substituting known data yield

$$\begin{aligned} \lambda' &= \frac{a \sin \theta}{1.5} = \frac{(2511 \text{ nm})(\sin 15^\circ)}{1.5} \\ &= 430 \text{ nm}. \end{aligned} \quad (\text{Answer})$$

Light of this wavelength is violet. The first side maximum for light of wavelength 430 nm will always coincide with the first minimum for light of wavelength 650 nm , no matter what the slit width is. If the slit is relatively narrow, the angle θ at which this overlap occurs will be relatively large, and conversely for a wide slit the angle is small.

37-3 Intensity in Single-Slit Diffraction, Qualitatively

In Section 37-2 we saw how to find the positions of the minima and the maxima in a single-slit diffraction pattern. Now we turn to a more general problem: Find an expression for the intensity I of the pattern as a function of θ , the angular position of a point on a viewing screen.

To do this, we divide the slit of Fig. 37-4a into N zones of equal widths Δx small enough that we can assume each zone acts as a source of Huygens wavelets. We wish to superimpose the wavelets arriving at an arbitrary point P on the viewing screen, at angle θ to the central axis, so that we can determine the amplitude E_θ of the magnitude of the electric field of the resultant wave at P . The intensity of the light at P is then proportional to the square of that amplitude.

To find E_θ , we need the phase relationships among the arriving wavelets. The phase difference between wavelets from adjacent zones is given by

$$(\text{phase difference}) = \left(\frac{2\pi}{\lambda}\right)(\text{path length difference}).$$

For point P at angle θ , the path length difference between wavelets from adjacent zones is $\Delta x \sin\theta$, so the phase difference $\Delta\phi$ between wavelets from adjacent zones is

$$\Delta\phi = \left(\frac{2\pi}{\lambda}\right)(\Delta x \sin\theta). \quad (37-4)$$

We assume that the wavelets arriving at P all have the same amplitude ΔE . To find the amplitude E_θ of the resultant wave at P , we add the amplitudes ΔE via phasors. To do this, we construct a diagram of N phasors, one corresponding to the wavelet from each zone in the slit.

For point P_0 at $\theta = 0$ on the central axis of Fig. 37-4a, Eq. 37-4 tells us that the phase difference $\Delta\phi$ between the wavelets is zero; that is, the wavelets all arrive in phase. Figure 37-6a is the corresponding phasor diagram; adjacent phasors represent wavelets from adjacent zones and are arranged head to tail. Because there is zero phase difference between the wavelets, there is zero angle between each pair of adjacent phasors. The amplitude E_θ of the net wave at P_0 is the vector-like sum of these phasors. This arrangement of the phasors turns out to be the one that gives the greatest value for the amplitude E_θ . We call this value E^{\max} ; that is, E^{\max} is the value of E_θ for $\theta = 0$.

We next consider a point P that is at a small angle θ to the central axis. Equation 37-4 now tells us that the phase difference $\Delta\phi$ between wavelets from adjacent zones is no longer zero. Figure 37-6b shows the corresponding phasor diagram; as before,

FIGURE 37-6 ■ Phasor diagrams for $N = 18$ phasors, corresponding to the division of a single slit into 18 zones. Resultant amplitudes E_θ are shown for (a) the central maximum at $\theta = 0$, (b) a point on the screen lying at a small angle θ to the central axis, (c) the first minimum, and (d) the first side maximum.

the phasors are arranged head to tail, but now there is an angle $\Delta\phi$ between adjacent phasors. The amplitude E_θ at this new point is still the vector sum of the phasors, but it is smaller than the amplitude in Fig. 37-6a, which means that the intensity of the light is less at this new point P than at P_θ .

If we continue to increase θ , the angle $\Delta\phi$ between adjacent phasors increases, and eventually the chain of phasors curls completely around so that the head of the last phasor just reaches the tail of the first phasor (Fig. 37-6c). The amplitude E_θ is now zero, which means that the intensity of the light is also zero. We have reached the first minimum, or dark fringe, in the diffraction pattern. The first and last phasors now have a phase difference of 2π rad, which means that the path length difference between the top and bottom rays through the slit equals one wavelength. Recall that this is the condition we determined for the first diffraction minimum.

As we continue to increase θ , the angle $\Delta\phi$ between adjacent phasors continues to increase, the chain of phasors begins to wrap back on itself, and the resulting coil begins to shrink. Amplitude E_θ now increases until it reaches a maximum value in the arrangement shown in Fig. 37-6d. This arrangement corresponds to the first side maximum in the diffraction pattern.

If we increase θ a bit more, the resulting shrinkage of the coil decreases E_θ , which means that the intensity also decreases. When θ is increased enough, the head of the last phasor again meets the tail of the first phasor. We have then reached the second minimum.

We could continue this qualitative method of determining the maxima and minima of the diffraction pattern but, instead, we shall now turn to a quantitative method.

READING EXERCISE 37-2: The figures represent, in smoother form (with more phasors) than Fig. 37-6, the phasor diagrams for two points of a diffraction pattern that are on opposite sides of a certain diffraction maximum. (a) Which maximum is it? (b) What is the approximate value of m (in Eq. 37-3) that corresponds to this maximum?

37-4 Intensity in Single-Slit Diffraction, Quantitatively

Equation 37-3 tells us how to locate the minima of the single-slit diffraction pattern on screen C of Fig. 37-4a as a function of the angle θ in that figure. Here we wish to derive an expression for the intensity I_θ of the pattern as a function of θ . We state, and shall prove below, that the intensity is given by

$$I_\theta = I^{\max} \left(\frac{\sin \alpha}{\alpha} \right)^2, \quad (37-5)$$

where

$$\alpha = \frac{1}{2} \Delta\phi = \frac{\pi a}{\lambda} \sin \theta. \quad (37-6)$$

The symbol α is just a convenient connection between the angle θ that locates a point on the viewing screen and the light intensity I_θ at that point. I^{\max} is the greatest value of the intensity I_θ in the pattern and occurs at the central maximum (where $\theta = 0$), and $\Delta\phi$ is the phase difference (in radians) between the top and bottom rays from the slit width a .

Study of Eq. 37-5 shows that intensity minima will occur where

$$\alpha = m\pi, \quad \text{for } m = 1, 2, 3, \dots \quad (37-7)$$

FIGURE 37-7 ■ The relative intensity in single-slit diffraction for three values of the ratio a/λ . The wider the slit is, the narrower is the central diffraction maximum.

FIGURE 37-8 ■ A construction used to calculate the intensity in single-slit diffraction. The situation shown corresponds to that of Fig. 37-6b.

If we put this result into Eq. 37-6 we find

$$m\pi = \frac{\pi a}{\lambda} \sin\theta, \quad \text{for } m = 1, 2, 3, \dots,$$

$$\text{or} \quad a \sin\theta = m\lambda, \quad \text{for } m = 1, 2, 3, \dots \quad (\text{minima—dark fringes}), \quad (37-8)$$

which is exactly Eq. 37-3, the expression that we derived earlier for the location of the minima.

Figure 37-7 shows plots of the intensity of a single-slit diffraction pattern, calculated with Eqs. 37-5 and 37-6 for three slit widths: $a = \lambda$, $a = 5\lambda$, and $a = 10\lambda$. Note that as the slit width increases (relative to the wavelength), the width of the *central diffraction maximum* (the central hill-like region of the graphs) decreases; that is, the light undergoes less flaring by the slit. The secondary maxima also decrease in width (and become weaker). In the limit of slit width a being much greater than wavelength λ , the secondary maxima due to the slit disappear; we then no longer have single-slit diffraction (but we still have diffraction due to the edges of the wide slit, like that produced by the edges of the razor blade in Fig. 37-2).

Proof of Eqs. 37-5 and 37-6

The arc of phasors in Fig. 37-8 represents the wavelets that reach an arbitrary point P on the viewing screen of Fig. 37-4, corresponding to a particular small angle θ . The amplitude E_θ of the resultant wave at P is the vector sum of these phasors. If we divide the slit of Fig. 37-4 into infinitesimal zones of width Δx , the arc of phasors in Fig. 37-8 approaches the arc of a circle; we call its radius R as indicated in that figure. The length of the arc must be E^{\max} , the amplitude at the center of the diffraction pattern, because if we straightened out the arc we would have the phasor arrangement of Fig. 37-6a (shown lightly in Fig. 37-8).

The angle $\Delta\phi$ in the lower part of Fig. 37-8 is the difference in phase between the infinitesimal vectors at the left and right ends of arc E^{\max} . From the geometry, $\Delta\phi$ is also the angle between the two radii marked R in Fig. 37-8. The dashed line in that figure, which bisects $\Delta\phi$, then forms two congruent right triangles. From either triangle we can write

$$\sin \frac{1}{2} \Delta\phi = \frac{E_\theta}{2R}. \quad (37-9)$$

In radian measure, $\Delta\phi$ is (with E^{\max} considered to be a circular arc)

$$\Delta\phi = \frac{E^{\max}}{R}.$$

Solving this equation for R , substituting the result into Eq. 37-9 and re-arranging terms yields

$$E_\theta = \frac{E^{\max}}{\frac{1}{2} \Delta\phi} \sin \frac{1}{2} \Delta\phi. \quad (37-10)$$

In Section 34-4 we saw that the intensity of an electromagnetic wave is proportional to the square of the amplitude of its electric field. Here, this means that the maximum intensity I^{\max} (which occurs at the center of the diffraction pattern) is proportional to $(E^{\max})^2$ and the intensity I_θ at angle θ is proportional to E_θ^2 . Thus, we may write

$$\frac{I_\theta}{I_{\max}} = \frac{E_\theta^2}{(E_{\max})^2}. \quad (37-11)$$

Substituting for E_θ with Eq. 37-10 and then substituting $\alpha = \frac{1}{2}\Delta\phi$, we are led to the following expression for the intensity as a function of θ :

$$I_\theta = I_{\max} \left(\frac{\sin\alpha}{\alpha} \right)^2.$$

This is exactly Eq. 37-5, one of the two equations we set out to prove.

The second equation we wish to prove relates α to θ : The phase difference $\Delta\phi$ between the rays from the top and bottom of the entire slit may be related to a path length difference with Eq. 37-4; it tells us that

$$\Delta\phi = \left(\frac{2\pi}{\lambda} \right) (a \sin\theta),$$

where a is the sum of the widths Δx of the infinitesimal zones. However, $\Delta\phi = 2\alpha$, so this equation reduces to Eq. 37-6.

READING EXERCISE 37-3:

Two wavelengths, 650 and 430 nm, are used separately in a single-slit diffraction experiment. The figure shows the results as graphs of intensity I versus angle θ for the two diffraction patterns. If both wavelengths are then used simultaneously, what color will be seen in the combined diffraction pattern at (a) angle A and (b) angle B ?

TOUCHSTONE EXAMPLE 37-2: Maxima Intensities

Find the intensities of the first three secondary maxima (side maxima) in the single-slit diffraction pattern of Fig. 37-1, measured relative to the intensity of the central maximum.

SOLUTION ■ One **Key Idea** here is that the secondary maxima lie approximately halfway between the minima, whose angular locations are given by Eq. 37-7 ($\alpha = m\pi$). The locations of the secondary maxima are then given (approximately) by

$$\alpha = \left(m + \frac{1}{2}\right)\pi, \quad \text{for } m = 1, 2, 3, \dots,$$

with α in radian measure.

A second **Key Idea** is that we can relate the intensity I at any point in the diffraction pattern to the intensity I_{\max} of the central maximum via Eq. 37-5. Thus, we can substitute the approximate values of α for the secondary maxima into Eq. 37-5 to obtain the relative intensities at those maxima. We get

$$\frac{I}{I_{\max}} = \left(\frac{\sin\alpha}{\alpha} \right)^2 = \left(\frac{\sin\left(m + \frac{1}{2}\right)\pi}{\left(m + \frac{1}{2}\right)\pi} \right)^2, \quad \text{for } m = 1, 2, 3, \dots$$

The first of the secondary maxima occurs for $m = 1$, and its relative intensity is

$$\begin{aligned} \frac{I_1}{I_{\max}} &= \left(\frac{\sin\left(1 + \frac{1}{2}\right)\pi}{\left(1 + \frac{1}{2}\right)\pi} \right)^2 = \left(\frac{\sin 1.5\pi}{1.5\pi} \right)^2 \\ &= 4.50 \times 10^{-2} \approx 4.5\%. \end{aligned} \quad (\text{Answer})$$

For $m = 2$ and $m = 3$ we find that

$$\frac{I_2}{I_{\max}} = 1.6\% \quad \text{and} \quad \frac{I_3}{I_{\max}} = 0.83\%. \quad (\text{Answer})$$

Successive secondary maxima decrease rapidly in intensity. Figure 37-1 was deliberately overexposed to reveal them.

FIGURE 37-9 ■ The diffraction pattern of a circular aperture. Note the central maximum and the circular secondary maxima. The figure has been overexposed to bring out these secondary maxima, which are much less intense than the central maximum.

37-5 Diffraction by a Circular Aperture

Here we consider diffraction by a circular aperture—that is, a circular opening such as a circular lens, through which light can pass. Figure 37-9 shows the image of a distant point source of light (a star, for instance) formed on photographic film placed in the focal plane of a converging lens. This image is not a point, as geometrical optics would suggest, but a circular disk surrounded by several progressively fainter secondary rings. Comparison with Fig. 37-1 leaves little doubt that we are dealing with a diffraction phenomenon. Here, however, the aperture is a circle of diameter d rather than a rectangular slit.

The analysis of such patterns is complex. It shows, however, that the first minimum for the diffraction pattern of a circular aperture of diameter d is located by

$$\sin \theta = 1.22 \frac{\lambda}{d} \quad (\text{first minimum—circular aperture}). \quad (37-12)$$

The angle θ here is the angle from the central axis to any point on that (circular) minimum. Compare this with Eq. 37-1,

$$\sin \theta = \frac{\lambda}{a} \quad (\text{first minimum—single slit}), \quad (37-13)$$

which locates the first minimum for a long narrow slit of width a . The main difference is the factor 1.22, which enters because of the circular shape of the aperture.

Resolvability

The fact that lens images are diffraction patterns is important when we wish to *resolve* (distinguish) two distant point objects whose angular separation is small. Figure 37-10 shows, in three different cases, the visual appearance and corresponding intensity pattern for two distant point objects (stars, say) with small angular separation. In Figure 37-10*a*, the objects are not resolved because of diffraction; that is, their diffraction patterns (mainly their central maxima) overlap so much that the two objects cannot be distinguished from a single point object. In Fig. 37-10*b* the objects are barely resolved, and in Fig. 37-10*c* they are fully resolved.

FIGURE 37-10 ■ At the top, the images of two point sources (stars), formed by a converging lens. At the bottom, representations of the image intensities. In (a) the angular separation of the sources is too small for them to be distinguished; in (b) they can be marginally distinguished, and in (c) they are clearly distinguished. Rayleigh's criterion is just satisfied in (b), with the central maximum of one diffraction pattern coinciding with the first minimum of the other.

In Fig. 37-10*b* the angular separation of the two point sources is such that the central maximum of the diffraction pattern of one source is centered on the first minimum of the diffraction pattern of the other, a condition called **Rayleigh's criterion** for resolvability. From Eq. 37-12, two objects that are barely resolvable by this criterion must have an angular separation θ_R of

$$\theta_R = \sin^{-1} \frac{1.22\lambda}{d}.$$

Since the angles involved are small, we can replace $\sin \theta_R$ with θ_R expressed in radians:

$$\theta_R = 1.22 \frac{\lambda}{d} \quad (\text{Rayleigh's criterion—circular aperture}). \quad (37-14)$$

Rayleigh's criterion for resolvability is only an approximation, because resolvability depends on many factors, such as the relative brightness of the sources and their surroundings, turbulence in the air between the sources and the observer, and the functioning of the observer's visual system. Experimental results show that the least angular separation that can actually be resolved by a person is generally somewhat greater than the value given by Eq. 37-14. However, for the sake of calculations here, we shall take Eq. 37-14 as being a precise criterion: If the angular separation θ between the sources is greater than θ_R , we can resolve the sources; if it is less, we cannot.

Rayleigh's criterion can explain the colors in Seurat's *Sunday Afternoon on the Island of La Grande Jatte* (or any other pointillistic painting). When you stand close enough to the painting, the angular separations θ of adjacent dots are greater than θ_R and thus the dots can be seen individually. Their colors are the colors of the paints Seurat used. However, when you stand far enough from the painting, the angular separations θ are less than θ_R and the dots cannot be seen individually. The resulting blend of colors coming into your eye from any group of dots can then cause your brain to “make up” a color for that group—a color that may not actually exist in the group. In this way, Seurat uses your visual system to create the colors of his art.

When we wish to use a lens instead of our visual system to resolve objects of small angular separation, it is desirable to make the diffraction pattern as small as possible. According to Eq. 37-14, this can be done either by increasing the lens diameter or by using light of a shorter wavelength.

For this reason ultraviolet light is often used with microscopes; because of its shorter wavelength, it permits finer detail to be examined than would be possible for the same microscope operated with visible light. It turns out that under certain circumstances, a beam of electrons behaves like a wave. In an *electron microscope* such beams may have an effective wavelength that is 10^{-5} of the wavelength of visible light. They permit the detailed examination of tiny structures, like that in Fig. 37-11, that would be blurred by diffraction if viewed with an optical microscope.

READING EXERCISE 37-4: Suppose you can barely resolve two red dots, due to diffraction by the pupil of your eye. If we increase the general illumination around you so that the pupil decreases in diameter, does the resolvability of the dots improve or diminish? Consider only diffraction. (You might experiment to check your answer.) ■

FIGURE 37-11 ■ A false-color scanning electron micrograph of red blood cells traveling through an arterial branch.

TOUCHSTONE EXAMPLE 37-3: Circular Converging Lens

A circular converging lens, with diameter $d = 32$ mm and focal length $f = 24$ cm, forms images of distant point objects in the focal plane of the lens. Light of wavelength $\lambda = 550$ nm is used.

(a) Considering diffraction by the lens, what angular separation must two distant point objects have to satisfy Rayleigh's criterion?

SOLUTION ■ Figure 37-12 shows two distant point objects P_1 and P_2 , the lens, and a viewing screen in the focal plane of the lens. It also shows, on the right, plots of light intensity I versus position on the screen for the central maxima of the images formed by the lens. Note that the angular separation θ_o of the objects equals the angular separation θ_i of the images. Thus, the **Key Idea** here is that if the images are to satisfy Rayleigh's criterion for resolvability, the angular separations on both sides of the lens must be given by Eq. 37-14 (assuming small angles). Substituting the given data, we obtain from Eq. 37-14

$$\begin{aligned}\theta_o = \theta_i = \theta_R &= 1.22 \frac{\lambda}{d} \\ &= \frac{(1.22)(550 \times 10^{-9} \text{ m})}{32 \times 10^{-3} \text{ m}} = 2.1 \times 10^{-5} \text{ rad. (Answer)}\end{aligned}$$

At this angular separation, each central maximum in the two intensity curves of Fig. 37-12 is centered on the first minimum of the other curve.

FIGURE 37-12 ■ Light from two distant point objects P_1 and P_2 passes through a converging lens and forms images on a viewing screen in the focal plane of the lens. Only one representative ray from each object is shown. The images are not points but diffraction patterns, with intensities approximately as plotted at the right. The angular separation of the objects is θ_o and that of the images is θ_i ; the central maxima of the images have a separation Δx .

(b) What is the separation Δx of the centers of the *images* in the focal plane? (That is, what is the separation of the *central* peaks in the two curves?)

SOLUTION ■ The **Key Idea** here is to relate the separation Δx to the angle θ_i , which we now know. From either triangle between the lens and the screen in Fig. 37-12, we see that $\tan \theta_i/2 = \Delta x/2f$. Rearranging this and making the approximation $\tan \theta < \theta$, we find

$$\Delta x = f\theta_i, \quad (37-15)$$

where θ_i is in radian measure. Substituting known data then yields

$$\Delta x = (0.24 \text{ m})(2.1 \times 10^{-5} \text{ rad}) = 5.0 \mu\text{m. (Answer)}$$

37-6 Diffraction by a Double Slit

In the double-slit experiments of Chapter 36, we implicitly assumed that the slits were narrow compared to the wavelength of the light illuminating them; that is, $a \ll \lambda$. For such narrow slits, the central maximum of the diffraction pattern of either slit covers the entire viewing screen. Moreover, the interference of light from the two slits produces bright fringes that all have approximately the same intensity (Fig. 36-9).

In practice with visible light, however, the condition $a \ll \lambda$ is rarely met. For relatively wide slits, the interference of light from two slits produces bright fringes that do not all have the same intensity. That is, the intensities of the fringes produced by double-slit interference (as discussed in Chapter 36) are modified by diffraction of the light passing through each slit (as discussed in this chapter).

As an example, the intensity plot of Fig. 37-13a (like that in Fig. 36-9) suggests the double-slit interference pattern that would occur if the slits were infinitely narrow (for $a \ll \lambda$); all the bright interference fringes would have the same intensity. The intensity plot of Fig. 37-13b is that for diffraction by a single actual slit; the diffraction pattern has a broad central maximum and weaker secondary maxima at $\pm 1.7^\circ$. The plot of Fig. 37-13c suggests the interference pattern for two actual slits. That plot was constructed by using the curve of Fig. 37-13b as an *envelope* on the intensity plot in Fig. 37-13a. The positions of the fringes are not changed; only the intensities are affected.

Figure 37-14a shows an actual pattern in which both double-slit interference and diffraction are evident. If one slit is covered, the single-slit diffraction pattern of Fig. 37-14b results. Note the correspondence between Figs. 37-14a and 37-13c and between Figs. 37-14b and 37-13b. In comparing these figures, bear in mind that 37-14 has been deliberately overexposed to bring out the faint secondary maxima and that two secondary maxima (rather than one) are shown.

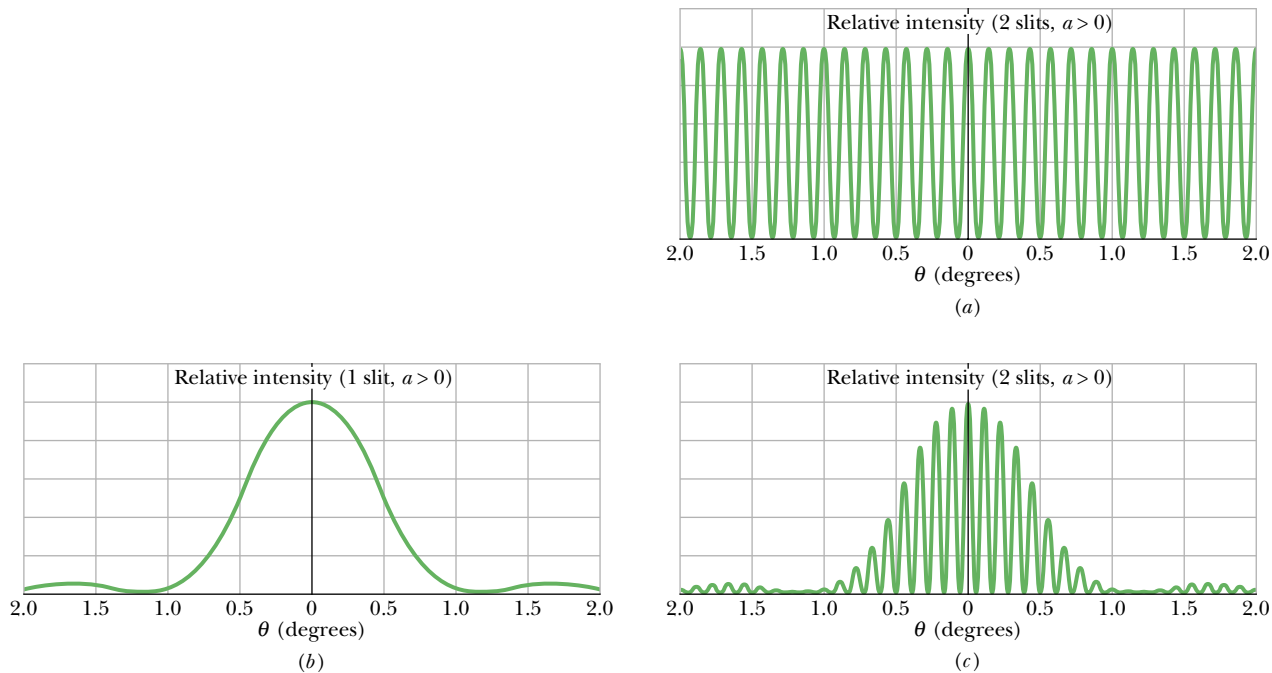

FIGURE 37-13 (a) The intensity plot to be expected in a double-slit interference experiment with vanishingly narrow slits (here the distance between the center of the slits is $d = 25$ mm and the incident light is reddish-orange with $\lambda = 623$ nm). (b) The intensity plot for diffraction by a typical slit of width $a = 0.031$ mm (not vanishingly narrow). (c) The intensity plot to be expected for two slits of width $a = 0.031$ mm. The curve of (b) acts as an envelope, limiting the intensity of the double-slit fringes in (a). Note that the first minima of the diffraction pattern of (b) eliminate the double-slit fringes that would occur near 1.2° in (c).

With diffraction effects taken into account, the intensity of a double-slit interference pattern is given by

$$I(\theta) = I^{\max}(\cos^2 \beta) \left(\frac{\sin \alpha}{\alpha} \right)^2 \quad (\text{double slit}), \quad (37-16)$$

in which
$$\beta = \frac{\pi d}{\lambda} \sin \theta \quad (37-17)$$

and
$$\alpha = \frac{\pi a}{\lambda} \sin \theta. \quad (37-18)$$

Here d is the distance between the centers of the slits, and a is the slit width. Note carefully that the right side of Eq. 37-16 is the product of I^{\max} and two factors. (1) The

FIGURE 37-14 (a) Interference fringes for an actual double-slit system; compare with Fig. 37-13c. (b) The diffraction pattern of a single slit; compare with Fig. 37-13b.

interference factor $\cos^2 \beta$ is due to the interference between two slits with slit separation d (as given by Eqs. 36-17 and 36-18). (2) The *diffraction factor* $[(\sin \alpha)/\alpha]^2$ is due to diffraction by a single slit of width a (as given by Eqs. 37-5 and 37-6).

Let us check these factors. If we let $a \rightarrow 0$ in Eq. 37-18, for example, then $\alpha \rightarrow 0$ and using L'Hopital's rule, we find that $(\sin \alpha)/\alpha \rightarrow 1$. Equation 37-16 then reduces, as it must, to an equation describing the interference pattern for a pair of vanishingly narrow slits with slit separation d . Similarly, putting $d = 0$ in Eq. 37-17 is equivalent physically to causing the two slits to merge into a single slit of width a . Then Eq. 37-17 yields $\beta = 0$ and $\cos^2 \beta = 1$. In this case Eq. 37-16 reduces, as it must, to an equation describing the diffraction pattern for a single slit of width a .

The double-slit pattern described by Eq. 37-16 and displayed in Fig. 37-14a combines interference and diffraction in an intimate way. Both are superposition effects, in that they result from the combining of waves with different phases at a given point. If the combining waves originate from a small number of elementary coherent sources—as in a double-slit experiment with $a \ll \lambda$ —we call the process *interference*. If the combining waves originate in a single wavefront—as in a single-slit experiment—we call the process *diffraction*. This distinction between interference and diffraction (which is somewhat arbitrary and not always adhered to) is a convenient one, but we should not forget that both are superposition effects and usually both are present simultaneously (as in Fig. 37-14a).

TOUCHSTONE EXAMPLE 37-4: Bright Fringes

Let's consider a double slit with an unusually small spacing. Suppose the wavelength λ of the light source is 405 nm, the slit separation d is 19.44 μm , and the slit width a is 4.050 μm . Consider the interference of the light from the two slits and also the diffraction of the light through each slit.

(a) How many bright interference fringes are within the central peak of the diffraction envelope?

SOLUTION ■ Let us first analyze the two basic mechanisms responsible for the optical pattern produced in the experiment:

Single-slit diffraction: The **Key Idea** here is that the limits of the central peak are the first minima in the diffraction pattern due to either slit, individually. (See Fig. 37-13.) The angular locations of those minima are given by Eq. 37-3 ($a \sin \theta = m\lambda$). Let us write this equation as $a \sin \theta = m_1\lambda$, with the subscript 1 referring to the one-slit diffraction. For the first minima in the diffraction pattern, we substitute $m_1 = 1$, obtaining

$$a \sin \theta = \lambda. \quad (37-19)$$

Double-slit interference: The **Key Idea** here is that the angular locations of the bright fringes of the double-slit interference pattern are given by Eq. 36-14, which we can write as

$$d \sin \theta = m_2\lambda, \quad \text{for } m_2 = 1, 2, 3, \dots \quad (37-20)$$

Here the subscript 2 refers to the double-slit interference.

We can locate the first diffraction minimum within the double-slit fringe pattern by dividing Eq. 37-20 by Eq. 37-19 and solving for m_2 . By doing so and then substituting the given data, we obtain

$$m_2 = \frac{d}{a} = \frac{19.44 \mu\text{m}}{4.050 \mu\text{m}} = 4.8.$$

This tells us that the bright interference fringe for $m_2 = 4$ fits into the central peak of the one-slit diffraction pattern, but the fringe for

FIGURE 37-15 ■ One side of the intensity plot for a two-slit interference experiment; the diffraction envelope is indicated by the dotted curve. The smaller inset shows (vertically expanded) the intensity plot within the first and second side peaks of the diffraction envelope.

$m_2 = 5$ does not fit. Within the central diffraction peak we have the central bright fringe ($m_2 = 0$), and four bright fringes (up to $m_2 = 4$) on each side of it. Thus, a total of nine bright fringes of the double-slit interference pattern are within the central peak of the diffraction envelope. The bright fringes to one side of the central bright fringe are shown in Fig. 37-15.

(b) How many bright fringes are within either of the first side peaks of the diffraction envelope?

SOLUTION ■ The **Key Idea** here is that the outer limits of the first side diffraction peaks are the second diffraction minima, each of which is at the angle θ given by a $\sin \theta = m_1 \lambda$ with $m_1 = 2$:

$$a \sin \theta = 2\lambda \quad (37-21)$$

Dividing Eq. 37-20 by Eq. 37-21, we find

$$m_2 = \frac{2d}{a} = \frac{(2)(19.44 \mu\text{m})}{4.050 \mu\text{m}} = 9.6.$$

This tells us that the second diffraction minimum occurs just before the bright interference fringe for $m_2 = 10$ in Eq. 37-20. Within either first side diffraction peak we have the fringes from $m_2 = 5$ to $m_2 = 9$ for a total of five bright fringes of the double-slit interference pattern (shown in the inset of Fig. 37-15). However, if the $m_2 = 5$ bright fringe, which is almost eliminated by the first diffraction minimum, is considered too dim to count, then only four bright fringes are in the first side diffraction peak.

37-7 Diffraction Gratings

One of the most useful tools in the study of light and of objects that emit and absorb light is the **diffraction grating**. A diffraction grating is a device that uses **interference** phenomena to separate a beam of light by wavelength. A diffraction grating is a more elaborate form of the double-slit arrangement of Fig. 36-8. This device has a much greater number N of slits, often called *rulings*, perhaps as many as several thousand per millimeter. An idealized grating consisting of only five slits is represented in Fig. 37-16. When monochromatic light is sent through the slits, it forms narrow interference fringes that can be analyzed to determine the wavelength of the light. (Diffraction gratings can also be opaque surfaces with narrow parallel grooves arranged like the slits in Fig. 37-16. Light then scatters back from the grooves to form interference fringes rather than being transmitted through open slits.)

With monochromatic light incident on a diffraction grating, if we gradually increase the number of slits from two to a large number N , the intensity plot changes from the typical double-slit plot of Fig. 37-13c to a much more complicated one and then eventually to a simple graph like that shown in Fig. 37-17a. The pattern you would see on a viewing screen using monochromatic red light from, say, a helium-neon laser, is shown in Fig. 37-17b. The maxima are now very narrow (and so are called *lines*); they are separated by relatively wide dark regions.

We use a familiar procedure to find the locations of the bright lines on the viewing screen. We first assume that the screen is far enough from the grating so that the rays reaching a particular point P on the screen are approximately parallel when they leave the grating (Fig. 37-18). Then we apply to each pair of adjacent rulings the same reasoning we used for double-slit interference. The separation d between rulings is called the *grating spacing*. (If N rulings occupy a total width w , then $d = w/N$.) The path length difference between adjacent rays is again $d \sin \theta$ (Fig. 37-18), where θ is the angle from the central axis of the grating (and of the diffraction pattern) to point P . A line will be located at P if the path length difference between adjacent rays is an integer number of wavelengths—that is, if

$$d \sin \theta = m\lambda, \quad \text{for } m = 0, 1, 2, \dots \quad (\text{maxima—lines}), \quad (37-22)$$

where λ is the wavelength of the light. Each integer m represents a different line; hence these integers can be used to label the lines, as in Fig. 37-17. The integers are then called the *order numbers*, and the lines are called the *zeroth-order line* (the central line, with $m = 0$), the *first-order line*, the *second-order line*, and so on.

FIGURE 37-16 ■ An idealized diffraction grating, consisting of only five rulings, that produces an interference pattern on a distant viewing screen C .

FIGURE 37-17 ■ A diffraction grating illuminated with a single wavelength of light. (a) The intensity plot produced by a diffraction grating with a great many rulings consists of narrow peaks, here labeled with their order numbers m . (b) The corresponding bright fringes seen on the screen are called lines and are here also labeled with order numbers m . Lines of the zeroth, first, second, and third orders are shown.

FIGURE 37-18 ■ The rays from the rulings in a diffraction grating to a distant point P are approximately parallel. The path length difference between each two adjacent rays is $d \sin \theta$, where θ is measured as shown. (The rulings extend into and out of the page.)

FIGURE 37-19 ■ The half-width $\Delta\theta_{\text{hw}}$ of the central line is measured from the center of that line to the adjacent minimum on a plot of I versus θ like Fig. 37-17a.

FIGURE 37-20 ■ The top and bottom rulings of a diffraction grating of N rulings are separated by distance Nd . The top and bottom rays passing through these rulings have a path length difference of $Nd \sin \Delta\theta_{\text{hw}}$, where $\Delta\theta_{\text{hw}}$ is the angle to the first minimum. (The angle is here greatly exaggerated for clarity.)

If we rewrite Eq. 37-22 as $\theta = \sin^{-1}(m\lambda/d)$ we see that, for a given diffraction grating, the angle from the central axis to any line (say, the third-order line) depends on the wavelength of the light being used. Thus, when light of an unknown wavelength is sent through a diffraction grating, measurements of the angles to the higher-order lines can be used in Eq. 37-22 to determine the wavelength. Even light of several unknown wavelengths can be distinguished and identified in this way. We cannot do that with the double-slit arrangement of Section 36-4, even though the same equation and wavelength dependence apply there. In double-slit interference, the bright fringes due to different wavelengths overlap too much to be distinguished.

Width of the Lines

A grating's ability to resolve (separate) lines of different wavelengths depends on the width of the lines. We shall here derive an expression for the *half-width* of the central line (the line for which $m = 0$) and then state an expression for the half-widths of the higher-order lines. We measure the half-width of the central line as the angle $\Delta\theta_{\text{hw}}$ from the center of the line at $\theta = 0$ outward to where the line effectively ends and darkness effectively begins with the first minimum (Fig. 37-19). At such a minimum, the N rays from the N slits of the grating cancel one another. (The actual width of the central line is, of course $2(\Delta\theta_{\text{hw}})$, but line widths are usually compared via half-widths.)

In Section 37-2 we were also concerned with the cancellation of a great many rays, there due to diffraction through a single slit. We obtained Eq. 37-3, which, because of the similarity of the two situations, we can use to find the first minimum here. It tells us that the first minimum occurs where the path length difference between the top and bottom rays equals λ . For single-slit diffraction, this difference is $a \sin \theta$. For a grating of N rulings, each separated from the next by distance d , the distance between the top and bottom rulings is Nd (Fig. 37-20), so the path length difference between the top and bottom rays here is $Nd \sin \Delta\theta_{\text{hw}}$. Thus, the first minimum occurs where

$$Nd \sin \Delta\theta_{\text{hw}} = \lambda. \quad (37-23)$$

Because $\Delta\theta_{\text{hw}}$ is small, $\sin \Delta\theta_{\text{hw}} \approx \Delta\theta_{\text{hw}}$ (in radian measure). Substituting this in Eq. 37-23 gives the half-width of the central line as

$$\Delta\theta_{\text{hw}} = \frac{\lambda}{Nd} \quad (\text{half-width of central line}). \quad (37-24)$$

We state without proof that the half-width of any other line depends on its location relative to the central axis and is

$$\Delta\theta_{\text{hw}} = \frac{\lambda}{Nd \cos \theta} \quad (\text{half-width of line at } \theta). \quad (37-25)$$

Note that for light of a given wavelength λ and a given ruling separation d , the widths of the lines decrease with an increase in the number N of rulings. Thus, of two diffraction gratings, the grating with the larger value of N is better able to distinguish between wavelengths because its diffraction lines are narrower and so produce less overlap. But the line width of a monochromatic light beam is determined by the number of slits that the beam encounters. In a diffraction grating spectrometer, a collimating telescope can be used to illuminate all N slits of the grating.

The Diffraction Grating Spectrometer

Diffraction gratings are widely used to determine the wavelengths that are emitted by sources of light ranging from lamps to stars. Figure 37-21 shows a simple *grating spectroscope* in which a grating is used for this purpose. Light from source S is focused by lens L_1 on a vertical slit S_1 placed in the focal plane of lens L_2 . The light emerging from tube C (called a *collimator*) is a plane wave and is incident perpendicularly on grating G , where it is diffracted into a diffraction pattern, with the $m = 0$ order diffracted at angle $\theta = 0$ along the central axis of the grating.

We can view the diffraction pattern that would appear on a viewing screen at any angle θ simply by orienting telescope T in Fig. 37-21 to that angle. Lens L_3 of the telescope then focuses the light diffracted at angle θ (and at slightly smaller and larger angles) onto a focal plane FF' within the telescope. When we look through eyepiece E , we see a magnified view of this focused image.

By changing the angle θ of the telescope, we can examine the entire diffraction pattern. For any order number other than $m = 0$, the original light is spread out according to wavelength (or color) so that we can determine, with Eq. 37-22, just what wavelengths are being emitted by the source. If the source emits a number of discrete wavelengths, what we see as we rotate the telescope horizontally through the angles corresponding to an order m is a vertical line of color for each wavelength, with the shorter-wavelength line at a smaller angle $m = 0$ than the longer-wavelength line.

For example, the light emitted by a hydrogen lamp, which contains hydrogen gas, has four discrete wavelengths in the visible range. If our eyes intercept this light directly, it appears to be white. If, instead, we view it through a grating spectroscope, we can distinguish, in several orders, the lines of the four colors corresponding to these visible wavelengths. (Such lines are called *emission lines*.) Four orders are represented in Fig. 37-22. In the central order ($m = 0$), the lines corresponding to all four wavelengths are superimposed, giving a single white line at $\theta = 0$. The colors are separated in the higher orders.

The third order is not shown in Fig. 37-22 for the sake of clarity; it actually overlaps the second and fourth orders. The fourth-order red line is missing because it is not formed by the grating used here. That is, when we attempt to solve Eq. 37-22 for

FIGURE 37-21 ■ A simple type of grating spectroscope used to analyze the wavelengths of light emitted by source S .

FIGURE 37-22 ■ The zeroth, first, second, and fourth orders of the visible emission lines from hydrogen. Note that the lines are farther apart at greater angles. (The lines are also dimmer and wider, although that is not shown here. Also, the third order line is eliminated for clarity.)

the angle θ for the red wavelength when $m = 4$, we find that $\sin \theta$ is greater than unity, which is not possible. The fourth order is then said to be *incomplete* for this grating; it might not be incomplete for a grating with greater spacing d , which will spread the lines less than in Fig. 37-22. Figure 37-23 is a photograph of the visible emission lines produced by cadmium.

FIGURE 37-23 ■ The visible emission lines of cadmium, as seen through a grating spectroscope.

READING EXERCISE 37-5: The figure shows lines of different orders produced by a diffraction grating in monochromatic red light. (a) Is the center of the pattern to the left or right? (b) If we switch to monochromatic green light, will the half-widths of the lines then produced in the same orders be greater than, less than, or the same as the half-widths of the lines shown? ■

37-8 Gratings: Dispersion and Resolving Power

The fine rulings, each $0.5 \mu\text{m}$ wide, on a compact disc function as a diffraction grating. When a small source of white light illuminates a disc, the diffracted light forms colored “lanes” that are the composite of the diffraction patterns from the rulings.

There are two characteristics that are important in the design of a diffraction grating spectrometer. First, the different wavelengths of light in a beam should be spread out. This characteristic is called **dispersion**. The second characteristic is the **resolving power** of the spectrometer. It should have a narrow line width for each wavelength so the lines are sharp.

Dispersion

To be useful in distinguishing wavelengths that are close to each other (as in a grating spectroscopy), a grating must spread apart the diffraction lines associated with the various wavelengths. This spreading, called **dispersion**, is defined as

$$D = \frac{\Delta\theta}{\Delta\lambda} \quad (\text{dispersion defined}). \quad (37-26)$$

Here $\Delta\theta$ is the angular separation of two lines whose wavelengths differ by $\Delta\lambda$. The greater D is, the greater is the distance between two emission lines whose wavelengths differ by $\Delta\lambda$. We show below that the dispersion of a grating at angle θ is given by

$$D = \frac{m}{d \cos\theta} \quad (\text{dispersion of a grating}). \quad (37-27)$$

Thus, to achieve higher dispersion we must use a grating of smaller grating spacing d and work in a higher order m . Note that the dispersion does not depend on the number of rulings. The SI unit for D is the degree per meter or the radian per meter.

Proof of Eq. 37-27

Let us start with Eq. 37-22, the expression for the locations of the lines in the diffraction pattern of a grating:

$$d \sin\theta = m\lambda.$$

Let us regard θ and λ as variables and take differentials of this equation. We find

$$d \cos\theta (d\theta) = m (d\lambda),$$

where the differentials $d\theta$ and $d\lambda$ are placed in parentheses to distinguish them from the product of the center to center slit spacing d and the angle θ or wavelength λ .

For small enough angles, we can write these differentials as small differences, obtaining

$$d \cos\theta (\Delta\theta) = m(\Delta\lambda), \quad (37-30)$$

or

$$\frac{(\Delta\theta)}{(\Delta\lambda)} = \frac{m}{d \cos\theta}.$$

The ratio on the left is simply D (see Eq. 37-26), so we have indeed derived Eq. 37-27.

Resolving Power

To *resolve* lines whose wavelengths are close together (that is, to make the lines distinguishable), the line should also be as narrow as possible. Expressed otherwise, the grating should have a high **resolving power R** , defined as

$$R = \frac{\langle \lambda \rangle}{\Delta \lambda} \quad (\text{resolving power defined}). \quad (37-28)$$

Here $\langle \lambda \rangle$ is the mean wavelength of two emission lines that can barely be recognized as separate, and $\Delta \lambda$ is the wavelength difference between them. The greater R is, the closer two emission lines can be and still be resolved. We shall show below that the resolving power of a grating is given by the simple expression

$$R = Nm \quad (\text{resolving power of a grating}). \quad (37-29)$$

To achieve high resolving power, we must spread out the light beam so it is incident on many rulings (large N in Eq. 37-29).

Proof of Eq. 37-29

We start with Eq. 37-30, which was derived from Eq. 37-22, the expression for the locations of the lines in the diffraction pattern formed by a grating. Here $\Delta \lambda$ is the small wavelength difference between two waves that are diffracted by the grating, and $\Delta \theta$ is the angular separation between them in the diffraction pattern. If $\Delta \theta$ is to be the smallest angle that will permit the two lines to be resolved, it must (by Rayleigh's criterion) be equal to the half-width of each line, which is given by Eq. 37-25:

$$\Delta \theta_{\text{hw}} = \frac{\lambda}{Nd \cos \theta}.$$

If we substitute $\Delta \theta_{\text{hw}}$ as given here for $\Delta \theta$ in Eq. 37-30, we find that

$$\frac{\lambda}{N} = m \Delta \lambda,$$

from which it readily follows that

$$R = \frac{\lambda}{\Delta \lambda} = Nm.$$

This is Eq. 37-29, which we set out to derive.

Dispersion and Resolving Power Compared

The resolving power of a grating must not be confused with its dispersion. Table 37-1 shows the characteristics of three gratings, all illuminated with light of wavelength $\lambda = 589 \text{ nm}$, whose diffracted light is viewed in the first order ($m = 1$ in Eq. 37-22). You should verify that the values of D and R as given in the table can be calculated with Eqs. 37-27 and 37-29, respectively. (In the calculations for D , you will need to convert radians per meter to degrees per micrometer.)

FIGURE 37-24: The intensity patterns for light of two wavelengths sent through the gratings of Table 37-1. Grating *B* has the highest resolving power and grating *C* the highest dispersion.

TABLE 37-1
Three Gratings^a

Grating	Specifications		Calculated Values		
	N	d (nm)	θ	D ($^\circ/\mu\text{m}$)	R
A	10 000	2540	13.4°	23.2	10 000
B	20 000	2540	13.4°	23.2	20 000
C	10 000	1370	25.5°	46.3	10 000

^aData are for $\lambda = 589$ nm and $m = 1$.

For the conditions noted in Table 37-1, gratings *A* and *B* have the same *dispersion* and *A* and *C* have the same *resolving power*.

Figure 37-24 shows the intensity patterns (also called *line shapes*) that would be produced by these gratings for two lines of wavelengths λ_1 and λ_2 , in the vicinity of $\lambda = 589$ nm. Grating *B*, with the higher resolving power, produces narrower lines and thus is capable of distinguishing lines that are much closer together in wavelength than those in the figure. Grating *C*, with the higher dispersion, produces the greater angular separation between the lines.

TOUCHSTONE EXAMPLE 37-5: Diffraction Grating

A diffraction grating has 1.26×10^4 rulings uniformly spaced over width $w = 25.4$ mm (so that it has 496 lines/mm). It is illuminated at normal incidence by yellow light from a sodium vapor lamp. This light contains two closely spaced emission lines (known as the sodium doublet) of wavelengths 589.00 nm and 589.59 nm.

(a) At what angle does the first-order maximum occur (on either side of the center of the diffraction pattern) for the wavelength of 589.00 nm?

SOLUTION ■ The **Key Idea** here is that the maxima produced by the diffraction grating can be located with Eq. 37-22 ($d \sin \theta = m\lambda$). The grating spacing d for this diffraction grating is

$$d = \frac{w}{N} = \frac{25.4 \times 10^{-3} \text{ m}}{1.26 \times 10^4} \\ = 2.016 \times 10^{-6} \text{ m} = 2016 \text{ nm}.$$

The first-order maximum corresponds to $m = 1$. Substituting these values for d and m into Eq. 37-22 leads to

$$\theta = \sin^{-1} \frac{m\lambda}{d} = \sin^{-1} \frac{(1)(589.00 \text{ nm})}{2016 \text{ nm}} \\ = 16.99^\circ \approx 17.0^\circ. \quad (\text{Answer})$$

(b) Using the dispersion of the grating, calculate the angular separation between the two lines in the first order.

SOLUTION ■ One **Key Idea** here is that the angular separation $\Delta\theta$ between the two lines in the first order depends on their

wavelength difference $\Delta\lambda$ and the dispersion D of the grating, according to Eq. 37-26 ($D = \Delta\theta/\Delta\lambda$). A second **Key Idea** is that the dispersion D depends on the angle θ at which it is to be evaluated. We can assume that, in the first order, the two sodium lines occur close enough to each other for us to evaluate D at the angle $\theta = 16.99^\circ$ we found in part (a) for one of those lines. Then Eq. 37-27 gives the dispersion as

$$D = \frac{m}{d \cos \theta} = \frac{1}{(2016 \text{ nm})(\cos 16.99^\circ)} \\ = 5.187 \times 10^{-4} \text{ rad/nm}.$$

From Eq. 37-26, we then have

$$\Delta\theta = D\Delta\lambda = (5.187 \times 10^{-4} \text{ rad/nm})(589.59 \text{ nm} - 589.00 \text{ nm}) \\ = 3.06 \times 10^{-4} \text{ rad} = 0.0175^\circ. \quad (\text{Answer})$$

You can show that this result depends on the grating spacing d but not on the number of rulings there are in the grating.

(c) What is the least number of rulings a grating can have and still be able to resolve the sodium doublet in the first order?

SOLUTION ■ One **Key Idea** here is that the resolving power of a grating in any order m is physically set by the number of rulings N in the grating according to Eq. 37-29 ($R = Nm$). A second **Key Idea** is that the least wavelength difference $\Delta\lambda$ that can be resolved depends on the average wavelength involved and the resolving power R of the grating, according to Eq. 37-28 ($R = \langle\lambda\rangle/\Delta\lambda$).

For the sodium doublet to be barely resolved, $\Delta\lambda$ must be their wavelength separation of 0.59 nm, and $\langle\lambda\rangle$ must be their average wavelength of 589.30 nm.

Putting these ideas together, we find that the least number of rulings for a grating to resolve the sodium doublet is

$$N = \frac{R}{m} = \frac{\langle\lambda\rangle}{m\Delta\lambda} \\ = \frac{589.30 \text{ nm}}{(1)(0.59 \text{ nm})} = 999 \text{ rulings.} \quad (\text{Answer})$$

37-9 X-Ray Diffraction

X rays are electromagnetic radiation whose wavelengths are of the order of 1 \AA ($= 0.1 \text{ nm} = 10^{-10} \text{ m}$). Compare this with a wavelength of 550 nm ($= 5.5 \times 10^{-7} \text{ m}$) at the center of the visible spectrum. Figure 37-25 shows that x rays are produced when electrons escaping from a heated filament F are accelerated by a potential difference V and strike a metal target T .

A standard optical diffraction grating cannot be used to discriminate between different wavelengths in the x-ray wavelength range. For $\lambda = 1 \text{ \AA}$ ($= 0.1 \text{ nm}$) and $d = 3000 \text{ nm}$, for example, Eq. 37-22 shows that the first-order maximum occurs at

$$\theta = \sin^{-1} \frac{m\lambda}{d} = \sin^{-1} \frac{(1)(0.1 \text{ nm})}{3000 \text{ nm}} = 0.0019^\circ.$$

This is too close to the central maximum to be practical. A grating with $d \approx \lambda$ is desirable, but, since x-ray wavelengths are about equal to atomic diameters, such gratings cannot be constructed mechanically.

In 1912, it occurred to German physicist Max von Laue that a crystalline solid, which consists of a regular array of atoms, might form a natural three-dimensional “diffraction grating” for x rays. The idea is that, in a crystal such as sodium chloride (NaCl), a basic unit of atoms (called the *unit cell*) repeats itself throughout the array. In NaCl four sodium ions and four chlorine ions are associated with each unit cell. Figure 37-26a represents a section through a crystal of NaCl and identifies this basic unit. The unit cell is a cube measuring a_0 on each side.

When an x-ray beam enters a crystal such as NaCl, x rays are *scattered*—that is, redirected—in all directions by the crystal structure. In some directions the scattered

FIGURE 37-25: X rays are generated when electrons leaving heated filament F are accelerated through a potential difference V and strike a metal target T . The “window” W in the evacuated chamber C is transparent to x rays.

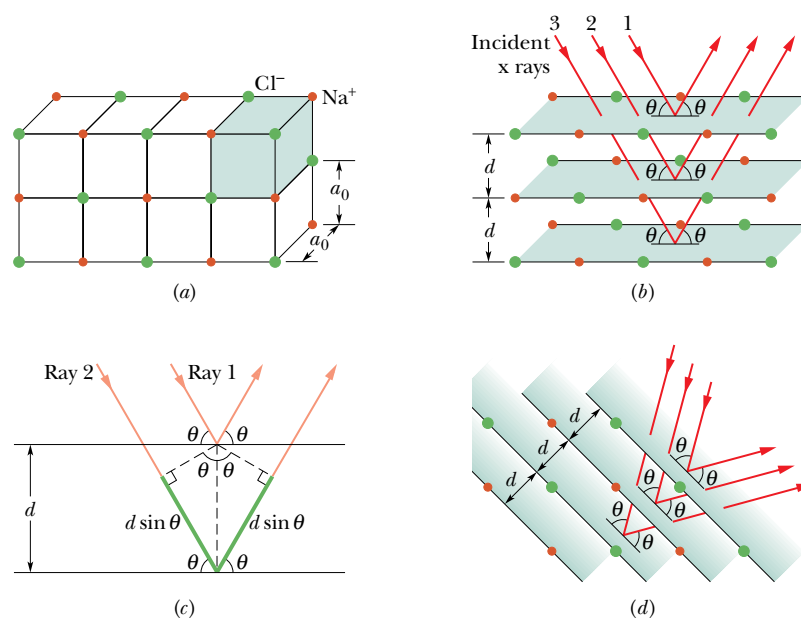

FIGURE 37-26: (a) The cubic structure of NaCl, showing the sodium and chlorine ions and a unit cell (shaded). (b) Incident x rays undergo diffraction by the structure of (a). The x rays are diffracted as if they were reflected by a family of parallel planes, with the angle of reflection equal to the angle of incidence, both angles measured relative to the planes (not relative to a normal as in optics). (c) The path length difference between waves effectively reflected by two adjacent planes is $2d \sin\theta$. (d) A different orientation of the incident x rays relative to the structure. A different family of parallel planes now effectively reflects the x rays.

waves undergo destructive interference, resulting in intensity minima; in other directions the interference is constructive, resulting in intensity maxima. This process of scattering and interference is a form of diffraction, although it is unlike the diffraction of light traveling through a slit or past an edge as we discussed earlier.

Although the process of diffraction of x rays by a crystal is complicated, the maxima turn out to be in directions as if the x rays were reflected by a family of parallel *reflecting planes* (or *crystal planes*) that extend through the atoms within the crystal and that contain regular arrays of the atoms. (The x rays are not actually reflected; we use these fictional planes only to simplify the analysis of the actual diffraction process.)

Figure 37-26*b* shows three of the family of planes, with *interplanar spacing* d , from which the incident rays shown are said to reflect. Rays 1, 2, and 3 reflect from the first, second, and third planes, respectively. At each reflection the angle of incidence and the angle of reflection are represented with θ . Contrary to the custom in optics, these angles are defined relative to the *surface* of the reflecting plane rather than a normal to that surface. For the situation of Fig. 37-26*b*, the interplanar spacing happens to be equal to the unit cell dimension a_0 .

Figure 37-26*c* shows an edge-on view of reflection from an adjacent pair of planes. The waves of rays 1 and 2 arrive at the crystal in phase. After they are reflected, they must again be in phase, because the reflections and the reflecting planes have been defined solely to explain the intensity maxima in the diffraction of x rays by a crystal. Unlike light rays, the x rays have negligible refraction when entering the crystal; moreover, we do not define an index of refraction for this situation. Thus, the relative phase between the waves of rays 1 and 2 as they leave the crystal is set solely by their path length difference. For these rays to be in phase, the path length difference must be equal to an integer multiple of the wavelength λ of the x rays.

By drawing the dashed perpendiculars in Fig. 37-26*c*, we find that the path length difference is $2d \sin \theta$. In fact, this is true for any pair of adjacent planes in the family of planes represented in Fig. 37-26*b*. Thus, we have, as the criterion for intensity maxima for x-ray diffraction,

$$2d \sin \theta = m\lambda, \quad \text{for } m = 1, 2, 3, \dots \quad (\text{Bragg's law}), \quad (37-31)$$

where m is the order number of an intensity maximum. Equation 37-31 is called **Bragg's law** after British physicist W. L. Bragg, who first derived it. (He and his father shared the 1915 Nobel Prize for their use of x rays to study the structures of crystals.) The angle of incidence and reflection in Eq. 37-31 is called a *Bragg angle*.

Regardless of the angle at which x rays enter a crystal, there is always a family of planes from which they can be said to reflect so that we can apply Bragg's law. In Fig. 37-26*d*, the crystal structure has the same orientation as it does in Fig. 37-26*a*, but the angle at which the beam enters the structure differs from that shown in Fig. 37-26*b*. This new angle requires a new family of reflecting planes, with a different interplanar spacing d and different Bragg angle θ , in order to explain the x-ray diffraction via Bragg's law.

Figure 37-27 shows how the interplanar spacing d can be related to the unit cell dimension a_0 . For the particular family of planes shown there, the Pythagorean theorem gives

$$5d = \sqrt{5}a_0,$$

or

$$d = \frac{a_0}{\sqrt{5}}. \quad (37-32)$$

FIGURE 37-27: A family of planes through the structure of Fig. 37-26*a*, and a way to relate the edge length a_0 of a unit cell to the interplanar spacing d .

Figure 37-27 suggests how the dimensions of the unit cell can be found once the interplanar spacing has been measured by means of x-ray diffraction.

X-ray diffraction is a powerful tool for studying both x-ray spectra and the arrangement of atoms in crystals. To study spectra, a particular set of crystal planes, having a known spacing d , is chosen. These planes effectively reflect different wavelengths at different angles. A detector that can discriminate one angle from another can then be used to determine the wavelength of radiation reaching it. The crystal itself can be studied with a monochromatic x-ray beam, to determine not only the spacing of various crystal planes but also the structure of the unit cell.

Problems

SEC. 37-2 ■ DIFFRACTION BY A SINGLE SLIT: LOCATING THE MINIMA

1. Narrow Slit Light of wavelength 633 nm is incident on a narrow slit. The angle between the first diffraction minimum on one side of the central maximum and the first minimum on the other side is 1.20° . What is the width of the slit?

2. Distance Between Monochromatic light of wavelength 441 nm is incident on a narrow slit. On a screen 2.00 m away, the distance between the second diffraction minimum and the central maximum is 1.50 cm. (a) Calculate the angle of diffraction θ of the second minimum. (b) Find the width of the slit.

3. Single Slit A single slit is illuminated by light of wavelengths λ_a and λ_b , chosen so the first diffraction minimum of the λ_a component coincides with the second minimum of the λ_b component. (a) What relationship exists between the two wavelengths? (b) Do any other minima in the two diffraction patterns coincide?

4. First and Fifth The distance between the first and fifth minima of a single-slit diffraction pattern is 0.35 mm with the screen 40 cm away from the slit, when light of wavelength 550 nm is used. (a) Find the slit width. (b) Calculate the angle θ of the first diffraction minimum.

5. Plane Wave A plane wave of wavelength 590 nm is incident on a slit with a width of $a = 0.40$ nm. A thin converging lens of focal length +70 cm is placed between the slit and a viewing screen and focuses the light on the screen. (a) How far is the screen from the lens? (b) What is the distance on the screen from the center of the diffraction pattern to the first minimum?

6. Sound Waves Sound waves with frequency 3000 Hz and speed 343 m/s diffract through the rectangular opening of a speaker cabinet and into a large auditorium. The opening, which has a horizontal width of 30.0 cm, faces a wall 100 m away (Fig. 37-28). Where along that wall will a listener be at the first diffraction minimum and thus have difficulty hearing the sound? (Neglect reflections).

FIGURE 37-28 ■ Problem 6.

7. Central Maximum A slit 1.00 mm wide is illuminated by light of wavelength 589 nm. We see a diffraction pattern on a screen 3.00 m away. What is the distance between the first two diffraction minima on the same side of the central diffraction maximum?

SEC. 37-4 ■ INTENSITY IN SINGLE-SLIT DIFFRACTION, QUANTITATIVELY

8. Off Central Axis A 0.10-mm-wide slit is illuminated by light of wavelength 589 nm. Consider a point P on a viewing screen on which the diffraction pattern of the slit is viewed; the point is at 30° from the central axis of the slit. What is the phase difference between the Huygens wavelets arriving at point P from the top and midpoint of the slit? (*Hint:* See Eq. 37-4.)

9. Explain Quantitatively If you double the width of a single slit, the intensity of the central maximum of the diffraction pattern increases by a factor of 4, even though the energy passing through the slit only doubles. Explain this quantitatively.

10. Monochromatic Monochromatic light with wavelength 538 nm is incident on a slit with width 0.025 mm. The distance from the slit to a screen is 3.5 m. Consider a point on the screen 1.1 cm from the central maximum. (a) Calculate θ for that point. (b) Calculate α . (c) Calculate the ratio of the intensity at this point to the intensity at the central maximum.

11. FWHM The full width at half-maximum (FWHM) of a central diffraction maximum is defined as the angle between the two points in the pattern where the intensity is one-half that at the center of the pattern. (See Fig. 37-7b.) (a) Show that the intensity drops to one-half the maximum value when $\sin^2 \alpha = \alpha^2/2$. (b) Verify that $\alpha = 1.39$ rad (about 80°) is a solution to the transcendental equation of (a). (c) Show that the FWHM is $\Delta\theta = 2\sin^{-1}(0.443\lambda/a)$, where a is the slit width. (d) Calculate the FWHM of the central maximum for slits whose widths are 1.0, 5.0, and 10 wavelengths.

12. Babinet's Principle A monochromatic beam of parallel light is incident on a "collimating" hole of diameter $x \gg \lambda$. Point P lies in the geometrical shadow region on a distant screen (Fig. 37-29a). Two diffracting objects, shown in Fig. 37-29b, are placed in turn

FIGURE 37-29 ■ Problem 12.

over the collimating hole. A is an opaque circle with a hole in it and B is the “photographic negative” of A . Using superposition concepts, show that the intensity at P is identical for the two diffracting objects A and B .

13. Values of α (a) Show that the values of α at which intensity maxima for single-slit diffraction occur can be found exactly by differentiating Eq. 37-5 with respect to α and equating the result to zero, obtaining the condition $\tan\alpha = \alpha$. (b) Find the values of α satisfying this relation by plotting the curve $y = \tan \alpha$ and the straight line $y = \alpha$ and finding their intersections or by using a calculator with an equation solver to find an appropriate value of α (or by using trial and error). (c) Find the (noninteger) values of m corresponding to successive maxima in the single-slit pattern. Note that the secondary maxima do not lie exactly halfway between minima.

SEC. 37-5 ■ DIFFRACTION BY A CIRCULAR APERTURE

14. Entopic Halos At night many people see rings (called *entopic halos*) surrounding bright outdoor lamps in otherwise dark surroundings. The rings are the first of the side maxima in diffraction patterns produced by structures that are thought to be within the cornea (or possibly the lens) of the observer’s eye. (The central maxima of such patterns overlap the lamp.) (a) Would a particular ring become smaller or larger if the lamp were switched from blue to red light? (b) If a lamp emits white light, is blue or red on the outside edge of the ring? (c) Assume that the lamp emits light at wavelength 550 nm. If a ring has an angular diameter of 2.5° , approximately what is the (linear) diameter of the structure in the eye that causes the ring?

15. Headlights The two headlights of an approaching automobile are 1.4 m apart. At what (a) angular separation and (b) maximum distance will the eye resolve them? Assume that the pupil diameter is 5.0 mm, and use a wavelength of 550 nm for the light. Also assume that diffraction effects alone limit the resolution so that Rayleigh’s criterion can be applied.

16. An Astronaut An astronaut in a space shuttle claims she can just barely resolve two point sources on the Earth’s surface, 160 km below. Calculate their (a) angular and (b) linear separation, assuming ideal conditions. Take $\lambda = 540$ nm and the pupil diameter of the astronaut’s eye to be 5.0 mm.

17. Moon’s Surface Find the separation of two points on the Moon’s surface that can just be resolved by the 200 in. (= 5.1 m) telescope at Mount Palomar, assuming that this separation is determined by diffraction effects. The distance from the Earth to the Moon is 3.8×10^5 km. Assume a wavelength of 550 nm for the light.

18. Large Room The wall of a large room is covered with acoustic tile in which small holes are drilled 5.0 mm from center to center. How far can a person be from such a tile and still distinguish the individual holes, assuming ideal conditions, the pupil diameter of the observer’s eye to be 4.0 mm, and the wavelength of the room light to be 550 nm?

19. Estimate Linear Separation Estimate the linear separation of two objects on the planet Mars that can just be resolved under ideal conditions by an observer on Earth (a) using the naked eye and (b) using the 200 in. (= 5.1 m) Mount Palomar telescope. Use the following data: distance to Mars = 8.0×10^7 km, diameter of pupil = 5.0 mm, wavelength of light = 550 nm.

20. Radar System The radar system of a navy cruiser transmits at a wavelength of 1.6 cm, from a circular antenna with a diameter of 2.3 m. At a range of 6.2 km, what is the smallest distance that two speedboats can be from each other and still be resolved as two separate objects by the radar system?

21. Tiger Beetles The wings of tiger beetles (Fig. 37-30) are colored by interference due to thin cuticle-like layers. In addition, these layers are arranged in patches that are $60 \mu\text{m}$ across and produce different colors. The color you see is a pointillistic mixture of thin-film interference colors that varies with perspective. Approximately what viewing distance from a wing puts you at the limit of resolving the different colored patches according to Rayleigh’s criterion? Use 550 nm as the wavelength of light and 3.00 mm as the diameter of your pupil.

FIGURE 37-30 ■ Problem 21. Tiger beetles are colored by pointillistic mixtures of thin-film interference colors.

22. Discovery In June 1985, a laser beam was sent out from the Air Force Optical Station on Maui, Hawaii, and reflected back from the shuttle *Discovery* as it sped by, 354 km overhead. The diameter of the central maximum of the beam at the shuttle position was said to be 9.1 m, and the beam wavelength was 500 nm. What is the effective diameter of the laser aperture at the Maui ground station? (*Hint:* A laser beam spreads only because of diffraction; assume a circular exit aperture.)

23. Millimeter-Wave Radar Millimeter-wave radar generates a narrower beam than conventional microwave radar, making it less vulnerable to antiradar missiles. (a) Calculate the angular width of the central maximum, from first minimum to first minimum, produced by a 220 GHz radar beam emitted by a 55.0-cm-diameter circular antenna. (The frequency is chosen to coincide with a low-absorption atmospheric “window.”) (b) Calculate the same quantity for the ship’s radar described in Problem 20.

24. Circular Obstacle A circular obstacle produces the same diffraction pattern as a circular hole of the same diameter (except very near $\theta = 0$). Airborne water drops are examples of such obstacles. When you see the Moon through suspended water drops, such as in a fog, you intercept the diffraction pattern from many drops.

FIGURE 37-31 ■ Problem 24. The corona around the Moon is a composite of the diffraction patterns of airborne water drops.

The composite of the central diffraction maxima of those drops forms a white region that surrounds the Moon and may obscure it. Figure 37-31 is a photograph in which the Moon is obscured. There are two, faint, colored rings around the Moon (the larger one may be too faint to be seen in your copy of the photograph). The smaller ring is on the outer edge of the central maxima from the drops; the somewhat larger ring is on the outer edge of the smallest of the secondary maxima from the drops (see Fig. 37-3). The color is visible because the rings are adjacent to the diffraction minima (dark rings) in the patterns. (Colors in other parts of the pattern overlap too much to be visible.)

(a) What is the color of these rings on the outer edges of the diffraction maxima? (b) The colored ring around the central maxima in Fig. 37-31 has an angular diameter that is 1.35 times the angular diameter of the Moon, which is 0.50° . Assume that the drops all have about the same diameter. Approximately what is that diameter?

25. Allegheny Observatory (a) What is the angular separation of two stars if their images are barely resolved by the Thaw refracting telescope at the Allegheny Observatory in Pittsburgh? The lens diameter is 76 cm and its focal length is 14 m. Assume $\lambda = 550$ nm. (b) Find the distance between these barely resolved stars if each of them is 10 light-years distant from Earth. (c) For the image of a single star in this telescope, find the diameter of the first dark ring in the diffraction pattern, as measured on a photographic plate placed at the focal plane of the telescope lens. Assume that the structure of the image is associated entirely with diffraction at the lens aperture and not with lens “errors”.

26. Soviet–French Experiment In a joint Soviet–French experiment to monitor the Moon’s surface with a light beam, pulsed radiation from a ruby laser ($\lambda = 0.69 \mu\text{m}$) was directed to the Moon through a reflecting telescope with a mirror radius of 1.3 m. A reflector on the Moon behaved like a circular plane mirror with radius 10 cm, reflecting the light directly back toward the telescope on the Earth. The reflected light was then detected after being brought

to a focus by this telescope. What fraction of the original light energy was picked up by the detector? Assume that for each direction of travel all the energy is in the central diffraction peak.

SEC. 37-6 ■ DIFFRACTION BY A DOUBLE SLIT

27. Bright Fringes Suppose that the central diffraction envelope of a double-slit diffraction pattern contains 11 bright fringes and the first diffraction minima eliminate (are coincident with) bright fringes. How many bright fringes lie between the first and second minima of the diffraction envelope?

28. Slit Separation In a double-slit experiment, the slit separation d is 2.00 times the slit width w . How many bright interference fringes are in the central diffraction envelope?

29. Eliminate Bright Fringes (a) In a double-slit experiment, what ratio of d to a causes diffraction to eliminate the fourth bright side fringe? (b) What other bright fringes are also eliminated?

30. Two Slits Two slits of width a and separation d are illuminated by a coherent beam of light of wavelength λ . What is the linear separation of the bright interference fringes observed on a screen that is at a distance D away?

31. How Many (a) How many bright fringes appear between the first diffraction-envelope minima to either side of the central maximum in a double-slit pattern if $\lambda = 550$ nm, $d = 0.150$ mm, and $a = 30.0 \mu\text{m}$? (b) What is the ratio of the intensity of the third bright fringe to the intensity of the central fringe?

32. Intensity Vs. Position Light of wavelength 440 nm passes through a double slit, yielding a diffraction pattern whose graph of intensity I versus angular position θ is shown in Fig. 37-32. Calculate the (a) slit width and (b) slit separation. (c) Verify the displayed intensities of the $m = 1$ and $m = 2$ interference fringes.

FIGURE 37-32 ■ Problem 32.

SEC. 37-7 ■ DIFFRACTION GRATINGS

33. Calculate d A diffraction grating 20.0 mm wide has 6000 rulings. (a) Calculate the distance d between adjacent rulings. (b) At what angles θ will intensity maxima occur on a viewing screen if the radiation incident on the grating has a wavelength of 589 nm?

34. Visible Spectrum A grating has 315 rulings/mm. For what wavelengths in the visible spectrum can fifth-order diffraction be observed when this grating is used in a diffraction experiment?

35. How Many Orders A grating has 400 lines/mm. How many orders of the entire visible spectrum (400–700 nm) can it produce in a diffraction experiment, in addition to the $m = 0$ order?

36. Confuse a Predator Perhaps to confuse a predator, some tropical gyrinid beetles (whirligig beetles) are colored by optical interference that is due to scales whose alignment forms a diffraction grating (which scatters light instead of transmitting it). When the incident light rays are perpendicular to the grating, the angle between the first-order maxima (on opposite sides of the zeroth-order maximum) is about 26° in light with a wavelength of 550 nm. What is the grating spacing of the beetle?

37. Two Adjacent Maxima Light of wavelength 600 nm is incident normally on a diffraction grating. Two adjacent maxima occur at angles given by $\sin \theta = 0.2$ and $\sin \theta = 0.3$. The fourth-order maxima are missing. (a) What is the separation between adjacent slits? (b) What is the smallest slit width this grating can have? (c) Which orders of intensity maxima are produced by the grating, assuming the values derived in (a) and (b)?

38. Normal Incidence A diffraction grating is made up of slits of width 300 nm with separation 900 nm. The grating is illuminated by monochromatic plane waves of wavelength $\lambda = 600$ nm at normal incidence. (a) How many maxima are there in the full diffraction pattern? (b) What is the width of a spectral line observed in the first order if the grating has 1000 slits?

39. Visible Spectrum Assume that the limits of the visible spectrum are arbitrarily chosen as 430 and 680 nm. Calculate the number of rulings per millimeter of a grating that will spread the first-order spectrum through an angle of 20° .

40. Gaseous Discharge Tube With light from a gaseous discharge tube incident normally on a grating with slit separation $1.73 \mu\text{m}$, sharp maxima of green light are produced at angles $\theta = \pm 17.6^\circ, 37.3^\circ, -37.1^\circ, 65.2^\circ,$ and -65.0° . Compute the wavelength of the green light that best fits these data.

41. Show That Light is incident on a grating at an angle ψ as shown in Fig. 37-33. Show that bright fringes occur at angles θ that satisfy the equation

$$d(\sin \psi + \sin \theta) = m\lambda, \quad \text{for } m = 0, 1, 2, \dots$$

(Compare this equation with Eq. 37-22.) Only the special case $\psi = 0$ has been treated in this chapter.

42. Plot A grating with $d = 1.50 \mu\text{m}$ is illuminated at various angles of incidence by light of wavelength 600 nm. Plot, as a function of the angle of incidence (0 to 90°), the angular deviation of the first-order maximum from the incident direction. (See Problem 41.)

43. Derive Derive Eq. 37-25, the expression for the half-widths of lines in a grating's diffraction pattern.

44. Spectrum Is Formed A grating has 350 rulings per millimeter and is illuminated at normal incidence by white light. A spectrum is formed on a screen 30 cm from the grating. If a hole 10 mm square is cut in the screen, its inner edge being 50 mm from the central

maximum and parallel to it, what is the range in the wavelengths of the light that passes through the hole?

45. Derive Two Derive this expression for the intensity pattern for a three-slit grating (ignore diffraction effects);

$$I_\theta = \frac{1}{9} I^{\text{max}} (1 + 4 \cos \phi + 4 \cos^2 \phi),$$

where $\phi = (2\pi d \sin \theta)/\lambda$. Assume that $a \ll \lambda$; be guided by the derivation of the corresponding double-slit formula (Eq. 36-21).

SEC. 37-8 ■ GRATINGS: DISPERSION AND RESOLVING POWER

46. D Line The *D* line in the spectrum of sodium is a doublet with wave-lengths 589.0 and 589.6 nm. Calculate the minimum number of lines needed in a grating that will resolve this doublet in the second-order spectrum. See Touchstone Example 37-5.

47. Hydrogen–Deuterium Mix A source containing a mixture of hydrogen and deuterium atoms emits red light at two wavelengths whose mean is 656.3 nm and whose separation is 0.180 nm. Find the minimum number of lines needed in a diffraction grating that can resolve these lines in the first order.

48. Smallest Wavelength A grating has 600 rulings/mm and is 5.0 mm wide. (a) What is the smallest wavelength interval it can resolve in the third order at $\lambda = 500$ nm? (b) How many higher orders of maxima can be seen?

49. Dispersion Show that the dispersion of a grating is $D = (\tan \theta)/\lambda$.

50. Sodium Doublet With a particular grating the sodium doublet (see Touchstone Example 37-5) is viewed in the third order at 10° to the normal and is barely resolved. Find (a) the grating spacing and (b) the total width of the rulings.

51. Resolving Power A diffraction grating has resolving power $R = \langle \lambda \rangle / \Delta \lambda = Nm$. (a) Show that the corresponding frequency range Δf that can just be resolved is given by $\Delta f = c/Nm\lambda$. (b) From Fig. 37-18, show that the times required for light to travel along the ray at the bottom of the figure and the ray at the top differ by an amount $\Delta t = (Nd/c) \sin \theta$. (c) Show that $(\Delta f)(\Delta t) = 1$, this relation being independent of the various grating parameters. Assume $N \gg 1$.

52. Product (a) In terms of the angle θ locating a line produced by a grating, find the product of that line's half-width and the resolving power of grating. (b) Evaluate that product for the grating of Problem 38, for the first order.

SEC. 37-9 ■ X-RAY DIFFRACTION

53. Second-Order Reflection X rays of wavelength 0.12 nm are found to undergo second-order reflection at a Bragg angle of 28° from a lithium fluoride crystal. What is the interplanar spacing of the reflecting planes in the crystal?

54. Diffraction by Crystal Figure 37-34 is a graph of intensity versus angular position θ for the diffraction of an x-ray beam by a crystal. The beam consists of two wavelengths, and the spacing between the reflecting planes is 0.94 nm. What are the two wavelengths?

FIGURE 37-33 ■ Problem 41.

FIGURE 37-34 ■ Problem 54.

55. NaCl Crystal An x-ray beam of a certain wavelength is incident on a NaCl crystal, at 30.0° to a certain family of reflecting planes of spacing 39.8 pm. If the reflection from those planes is of the first order, what is the wavelength of the x rays?

56. Two Beams An x-ray beam of wavelength λ undergoes first-order reflection from a crystal when its angle of incidence to a crystal face is 23° , and an x-ray beam of wavelength 97 pm undergoes third-order reflection when its angle of incidence to that face is 60° . Assuming that the two beams reflect from the same family of reflecting planes, find the (a) interplanar spacing and (b) wavelength λ .

57. Not Possible Prove that it is not possible to determine both wavelength of incident radiation and spacing of reflecting planes in a crystal by measuring the Bragg angles for several orders.

58. Reflection Planes In Fig. 37-35, first-order reflection from the reflection planes shown occurs when an x-ray beam of wavelength

FIGURE 37-35 ■ Problem 58.

0.260 nm makes an angle of 63.8° with the top face of the crystal. What is the unit cell size a_0 ?

59. Square Crystal Consider a two-dimensional square crystal structure, such as one side of the structure shown in Fig. 37-26a. One interplanar spacing of reflecting planes is the unit cell size a_0 . (a) Calculate and sketch the next five smaller interplanar spacings. (b) Show that your results in (a) are consistent with the general formula

$$d = \frac{a_0}{h^2 + k^2},$$

where h and k are relatively prime integers (they have no common factor other than unity).

60. X-Ray Beam In Fig. 37-36, an x-ray beam of wavelengths from 95.0 pm to 140 pm is incident at 45° to a family of reflecting planes with spacing $d = 275$ pm. At which wavelengths will these planes produce intensity maxima in their reflections?

61. NaCl In Fig. 37-36, let a beam of x-rays of wavelength 0.125 nm be incident on an NaCl crystal at an angle of 45.0° to the top face of the crystal and a family of reflecting planes. Let the reflecting planes have separation $d = 0.252$ nm. Through what angles must the crystal be turned about an axis that is perpendicular to the plane of the page for these reflecting planes to give intensity maxima in their reflections?

FIGURE 37-36 ■ Problems 60 and 61.

Additional Problems

62. Changing Interference Consider a plane wave of monochromatic green light, $\lambda = 500 \text{ nm}$, that is incident normally upon two identical narrow slits (the widths of the individual slits are much less than λ). The slits are separated by a distance $d = 30 \mu\text{m}$. An interference pattern is observed on a screen located a distance L away from the slits. On the screen, the location nearest the central maximum where the intensity is zero (i.e., the first dark fringe) is found to be 1.5 cm from this central point. Let this particular position on the screen be referred to as P_1 . (a) Calculate the distance, L , to the screen. Show all work. (b) In each of the parts below, one change has been made to the problem above (in each case, all parameters not explicitly mentioned have the value or characteristics stated above). For each case, explain briefly whether the light intensity at location P_1 remains zero or not. If not, does P_1 become the location of a maximum constructive interference (bright) fringe? In each case, explain your reasoning.

- (1) One of the two slits is made slightly narrower, so that the amount of light passing through it is less than that through the other.
- (2) The wavelength is doubled so that $\lambda = 1000 \text{ nm}$.
- (3) The two slits are replaced by a single slit whose width is exactly $60 \mu\text{m}$.

63. Hearing and Seeing Around a Corner We can make the observation that we can hear around corners (somewhat) but not see

around corners. Estimate why this is so by considering a doorway and two kinds of waves passing through it: (1) a beam of red light ($\lambda = 660 \text{ nm}$), and (2) a sound wave playing an "A" ($f = 440 \text{ Hz}$). (See Fig. 37-37.) Treat these two waves as plane waves passing through a slit whose width equals the width of the door. (a) Find the angle that gives the position of the first dark diffraction fringe. (b) From that, assuming you are 2 m back from the door, estimate how far outside the door you could be and still detect the wave. (See the picture for a clarification. The distance x is desired.)

FIGURE 37-37 ■ Problem 63.

Special Relativity

Guest Author: Edwin F. Taylor *Massachusetts Institute of Technology*

Billions of dollars have been spent constructing gigantic particle accelerators, such as this one 4 miles in circumference at Fermi National Accelerator Laboratory. More and more advanced accelerators give more and more energy and momentum to particles being accelerated. Decades of experimentation have verified that every particle, however great its energy and momentum, moves slower than the speed of light in a vacuum.

How can the energy of a particle increase without limit while its speed remains slower than the speed of light?

The answer is in this chapter.

38-1 Introduction

Special relativity and *general* relativity both describe the behavior of radiation and matter moving at or near the speed of light. However, special relativity is limited to situations in which gravitational effects can be neglected. Both special and general relativity are called *classical* theories because they do not describe atomic or molecular effects, for which quantum theory is needed.

Unfortunately, special relativity has a reputation for being difficult and mathematically complex. But if you understand basic algebra and square roots, you have the necessary mathematical tools to comprehend it. What makes special relativity seem difficult is that we have no direct experience with objects moving anywhere near the speed of light. It's no wonder that our idea of space and time, molded by everyday experience, is limited. As a result, the predictions of special relativity—fully verified by experiment—strike us as outlandish and outrageous. But these outlandish predictions not only make special relativity fascinating, they also provide us with deep insights into the nature of space and time—the arena in which we all live and in which science operates.

In this chapter we will show how the outlandish predictions of special relativity can be deduced logically from a single principle proposed by Albert Einstein at the beginning of the 20th century.

FIGURE 38-1 ■ While waiting at a stoplight, you find it hard to tell whether the car next to you is rolling forward or you are drifting backward—unless you are looking at a fixed object such as the speed limit sign.

38-2 Origins of Special Relativity

While waiting at a stoplight, you notice that the car next to yours appears to be moving forward slowly (Fig. 38-1). Instead you suddenly realize that you are drifting backward, so you slam on the brakes, which car is standing still? Which is moving? Without seeing a “stationary” object such as a sign post, you cannot tell! Are such observations about relative motion trivial or profound? Can we cover the windows of our car and carry out some experiment inside—any experiment at all—to detect whether we are in motion or at rest?

Special relativity grew out of questions raised in the late 1800s and early 1900s about relative motions of material objects and waves. Some of these questions involved comparisons between everyday phenomena involving boats and ocean waves. Other questions were raised about the relative motions of objects and light waves. For example, consider ocean waves that move slowly past a swimmer moving in the same direction as the waves. The same waves will move rapidly past a second swimmer traveling in the opposite direction. Will the same thing happen when someone moves toward or away from light waves? Will observers traveling in opposite directions measure different speeds for the same light wave? Do light waves move in a *medium* the way ocean waves move in the medium of water?

From the age of 16 Albert Einstein (Fig. 38-2) puzzled over a thought experiment: Suppose you run very fast while looking at yourself in a mirror that you hold up in front of you. What happens as your running speed approaches the speed of light? Will the light waves move more and more slowly past you? In modern terms, *can you surf light waves?*

While Einstein was growing up, other people were trying to answer such questions with experiments. Some scientists hypothesized that light moves in a medium they called *ether*. In the late 1800s, Albert W. Michelson and Edward W. Morley carried out experiments with light trying to measure the motion of the Earth through this ether, under the assumption that the ether was at rest with respect to the Sun or some other location (such as the center of our galaxy). They used the fastest-moving object available to them: the Earth itself. The Earth moves around the sun at approximately 30

FIGURE 38-2 ■ Albert Einstein in the early 1900s at the patent office in Bern, Switzerland, where he was employed when he published his article on special relativity. In later life he was known to dress much more informally.

kilometers per second in one direction in January and in the opposite direction past the sun in July. Michelson and Morley could detect no motion of the Earth through the hypothesized ether. These negative results caused great puzzlement.

In 1905 Einstein, a 26-year-old patent examiner in Bern, Switzerland, published a paper that changed the face of science.

READING EXERCISE 38-1: You are sitting in a train that stopped at a station ten minutes ago. Suddenly you notice that a second train on the track next to you is gliding past you. You feel a slight vibration that tells you your train is rolling slowly along the track. Is the second train in motion or at rest? ■

38-3 The Principle of Relativity

Einstein's special relativity theory does not assume that light moves through a medium. Even so, it appears that Einstein did not base his ideas on Michelson and Morley's earlier failure to detect ether. Instead, Einstein treasured simplicity, logic, physical intuition, and his now famous thought experiments. He started from a clean assertion that he called the *Principle of Relativity*. Think of an automobile or train either at rest or moving at constant velocity. Define each of these enclosures as a *reference frame*. Then the *Principle of Relativity* says:

All the laws of physics are the same in every reference frame.

In other words: Pull down the shades in your room or vehicle. Then carry out as many experiments as you need to create the laws of physics. Someone who carries out the same experiments inside another vehicle will discover the same laws, as long as this new vehicle moves at a constant velocity relative to yours.

The laws of physics contain fundamental numerical constants, such as the charge e on the electron, Planck's constant h , and the speed of light c in a vacuum. According to the Principle of Relativity, each of these constants must have the same numerical value when measured in any reference frame. In particular, all observers measure the speed of light in a vacuum to have the value presented back in Chapter 1 of $c = 299\,792\,458$ m/s ($\sim 3 \times 10^8$ m/s). The equality of the speed of light in all reference frames eliminates the need to postulate the existence of *ether* through which light propagates. The predictions of special relativity about space, time, mass, and motion all spring from the single *Principle of Relativity*, including the postulate of the “universal speed” of light.

The Principle of Relativity solved Einstein's puzzler about running fast while holding a mirror in front of you. You will not observe light waves to slow down as you move faster. Why not? Because, says the Principle of Relativity, light always moves past you with the same speed c , no matter how fast you run along the ground. *You cannot surf light waves!*

“Relativity theory” is a misleading term that Einstein avoided for years. What we call the special theory of relativity is based on the Principle of Relativity, which tells us that the laws of nature are the *same* for observers in different reference frames. These laws are *not* relative. *General* relativity employs an even more radical version than special relativity, of the Principle of Relativity—that the laws of nature are independent of the observer's viewpoint.

READING EXERCISE 38-2: While standing beside a railroad track, we are startled by a boxcar traveling past us at half the speed of light. A passenger (shown in the figure) standing at the front of the boxcar fires a laser pulse toward the rear of the boxcar. The pulse is

absorbed at the back of the boxcar. While standing beside the track we measure the speed of the pulse through the open side door. (a) Is our measured value of the speed of the pulse greater than, equal to, or less than its speed measured by the rider? (b)

Is our measurement of the distance between emission and absorption of the light pulse greater than, equal to, or less than the distance between emission and absorption measured by the rider? (c) What conclusion can you draw about the relation between the times of flight of the light pulse as measured in the two reference frames? ■

TOUCHSTONE EXAMPLE 38-1: Communications Storm!

A sunspot emits a tremendous burst of particles that travels toward the Earth. An astronomer on the Earth sees the emission through a solar telescope and issues a warning. The astronomer knows that when the particle pulse arrives it will wreak havoc with broadcast radio transmission. Communications systems require ten minutes to switch from over-the-air broadcast to underground cable transmission. What is the maximum speed of the particle pulse emitted by the Sun such that the switch can occur in time, between warning and arrival of the pulse? Take the sun to be 500 light-seconds distant from the Earth.

SOLUTION ■ It takes 500 seconds for the warning light flash to travel the distance of 500 light-seconds between the Sun and the Earth and enter the astronomer's telescope. If the particle pulse moves at half the speed of light, it will take twice as long as light to reach the Earth. If the pulse moves at one-quarter the speed of light, it will take four times as long to make the trip. We generalize this by saying that if the pulse moves with speed v/c , it will take time Δt_{pulse} to make the trip given by the expression:

$$\Delta t_{\text{pulse}} = \frac{500 \text{ s}}{v_{\text{pulse}}/c}.$$

How long a warning time does the Earth astronomer have between arrival of the light flash carrying information about the pulse and the arrival of the pulse itself? It takes 500 seconds for the light to arrive. Therefore the warning time is the difference between the pulse transit time and the transit time of light:

$$\Delta t_{\text{warning}} = \Delta t_{\text{pulse}} - 500 \text{ s}.$$

But we know that the minimum possible warning time is 10 min = 600 s.

Therefore we have

$$600 \text{ s} = \frac{500 \text{ s}}{v_{\text{pulse}}/c} - 500 \text{ s},$$

which gives the maximum value for v_{pulse} if there is to be sufficient time for warning:

$$v_{\text{pulse}} = 0.455c. \quad (\text{Answer})$$

Observation reveals that pulses of particles emitted from the sun travel much slower than this maximum value. So we would have a much longer warning time than calculated here.

38-4 Locating Events with an Intelligent Observer

In devising special relativity, Einstein stripped science to its bare essentials. The essence of science is the description of *events*—occurrences in space and time. Science has a simple task: to tell us how one event is related to another event. One of the most important outcomes of special relativity is the ability to predict how events observed in one reference frame will look to an observer in another frame. We need to start by carefully defining what events are and how to observe them intelligently.

An event is an occurrence that happens at a unique place and time.

Examples of events include a collision, an explosion, the emission of a light flash, and the fleeting touch of a friend's hand. When can an occurrence be called an event? When an observer finds it sufficiently localized in space and time to serve her purposes. Your birth was an event unique in both time and place for a genealogist who

studies family trees. Your birth mother, however, experienced the process as a *series* of events, from first contraction (maybe at home) to delivery (perhaps in a hospital). Since your birth mother's experiences spanned both time and space, she might not call your birth an event (at least while it is taking place!).

Locating an event in space and time is not always as simple as it might seem at first because of the time delay between event and observation. Think about observing a lightning flash in the night sky. We count the seconds, "one-thousand-one, one-thousand-two, one-thousand-three." Then we hear a crash of thunder. "Wow, lightning struck only one kilometer away from us!" We know this from our knowledge that it takes sound about three seconds to travel one kilometer in air. In making our calculation, we *assume* that the time it takes the lightning flash to reach us is negligible. This means that the lapse between receiving the flash and hearing the thunder is entirely due to the travel time of sound. In this case the signal travels with the speed of sound.

A pulse of high-energy particles may move at nearly the speed of light. How do we determine the time of events that occur along its path? Suppose a pulse of high-energy protons emerges from a particle accelerator and passes through detector A, where we are standing. The pulse continues its flight to arrive at detector B that lies 30 meters away. *When* did the pulse arrive at detector B? We arrange in advance for detector B to send us a light flash when the pulse arrives there. We time the arrival of this light flash at detector A and from this arrival time we *subtract* the known time delay that results when the light flash travels 30 meters. This *difference* gives us the time at which the pulse arrived at detector B.

To account for the delay due to the speed of light, we define the **intelligent observer** to be someone who takes into account the time delays required to locate distant events in space and time. Standing by detector A in the example above, we acted as intelligent observers in determining the time at which the pulse reached detector B.

READING EXERCISE 38-3: The Minute Waltz by Friedrich Chopin takes more than a minute for most pianists to perform. Halfway through playing the Minute Waltz at a recital, will you think of your performance as a single event? Is your performance a single event for those who printed the program for the recital? Looking back ten years later, will you think of it as a single event? ■

READING EXERCISE 38-4: When the pulse of protons passes through detector A (next to us), we start our clock from the time $t = 0$ microseconds. The light flash from detector B arrives back at detector A at a time $t = 0.225$ microsecond (0.225×10^{-6} second) later. (a) At what time did the pulse arrive at detector B? (b) Use the result from part (a) to find the speed at which the proton pulse moved, as a fraction of the speed of light. ■

TOUCHSTONE EXAMPLE 38-2: Simultaneous?

You are an intelligent observer standing next to beacon A, which emits a flash of light every 10 s. 100 km distant from you is a second beacon, beacon B, stationary with respect to you, that also emits a light flash every 10 s. You want to know whether or not each flash is emitted from remote beacon B simultaneous with (at the same time as) the flash from your own beacon A. Explain how to do this without leaving your position next to beacon A. Be specific and use numerical values. Assume that light travels 3×10^8 m/s.

SOLUTION ■ You are an intelligent observer, which means that you know how to take into account the speed of light in determining the time of a remote event, in this case the time of emission of a flash by the distant beacon B. You measure the time lapse between

emission of a flash by your beacon A and your reception of the flash from beacon B. If this time lapse is just that required for light to move from beacon B to beacon A, then the two emissions occur at the same time. The two beacons are $100 \text{ km} = 10^5 \text{ m}$ apart. Call this distance L . Then the time Δt for a light flash to move from B to A is:

$$t = \frac{L}{c} = \frac{10^5 \text{ m}}{3 \times 10^8 \text{ m/s}} = 3.33 \times 10^{-4} \text{ s}, \quad (\text{Answer})$$

or 0.333 ms. If this is the time you record between the flash of nearby beacon A and reception of the flash from distant beacon B, then you are justified in saying that the two beacons emit their flashes simultaneously in your frame.

38-5 Laboratory and Rocket Latticeworks of Clocks

There are difficulties with the procedure used by our intelligent observer. First, she needs to make a separate calculation for each remote event. This is bothersome. Second, and more fundamental, she cannot calculate the time delay in reporting remote events unless she *already knows the location of every event she wants to measure*. Sometimes information about event location is easily available, sometimes not. We need a general, conceptually simple way to observe both the location and time of events.

In principle, one way to do this is to assemble a cubical lattice of meter sticks with a recording clock at each intersection (Fig. 38-3). Using this latticework, we say that the *position* of an event is that of the recording clock nearest to the event. The *time* of the event is the time recorded on that nearby clock. *Observing an event* then reduces to recording the position of the clock nearest to the event and the time for the event recorded on that clock. Now there is no delay in recording the position and the time of any event that occurs in the lattice.

Synchronizing Latticework Clocks

Before we can actually observe events with our latticework of meter sticks and clocks, we need to set all the clocks in the lattice to read the *same time*. But how can we *synchronize* all the clocks in the latticework? One method would be to carry a traveling clock around the lattice and synchronize each lattice clock with it. This approach is not only time-consuming but incorrect. You will see in the next section that a clock traveling through the lattice runs at a different rate than a resting clock as recorded by clocks in the lattice. In fact, if you set a lattice clock to the time of the traveling clock and then later bring it back after it has traveled to other clocks, you will find that the traveling clock no longer agrees with that lattice clock!

FIGURE 38-3 ■ Latticework of meter sticks and clocks.

Instead of a traveling clock, we use the speed of light to synchronize all the lattice clocks. Our procedure starts by picking one clock in the lattice as the standard or **reference clock**. We know the distance between the reference clock and every other clock in the lattice. At midnight the reference clock sends out a **synchronizing flash** of light. When an observer at any one of the distant clocks receives the flash, she quickly sets the time on her clock to midnight *plus* the time it took for the light to reach her over the known distance from the reference clock at the known speed of light. We say that after this procedure is complete the clocks in the lattice read the *same time* as one another—they are *synchronized* with respect to this lattice.

Now our latticework of synchronized clocks is ready to record the position and time of events that occur during any experiment. Analyzing the results of that experiment means relating events by collecting event data from all recording clocks in the lattice and analyzing these data at some central location.

Laboratory and Rocket Frames as Inertial Reference Frames

We often hear talk in special relativity about the *laboratory frame* and the *rocket frame*. Envision *each* of these frames as having a latticework of rods and clocks (Fig. 38-4). The rocket coasts at constant velocity in unpowered flight. By convention we assign the positive x direction to be the direction of motion of the rocket with respect to the laboratory lattice.

AN IMPORTANT ASIDE: Strictly speaking, reference frames used in special relativity must be inertial frames, frames with respect to which Newton's First Law of motion holds: *A free particle at rest remains at rest and a free particle in motion continues that motion in a straight line at constant speed* (see Section 3-2). Obviously the surface of the Earth is not an inertial reference frame; a stone released from rest accelerates downward! However, for a particle moving at a substantial fraction of the speed of light with respect to the Earth, the acceleration of gravity can usually be ignored. In this chapter we make no distinction between inertial frames and those at rest or moving at constant velocity with respect to the Earth's surface.

We can detect and record a single event using overlapping rocket and laboratory latticeworks. If the right rear tire of your car hits a nail, it goes flat with a *bang*. For you as the driver (in the “rocket frame”) the bang occurs at the right rear of your car. For the observer on the road (the “laboratory frame”), the bang takes place where the nail sticks up at one end of the bridge that your car has just crossed. Neither you nor the road observer “owns” the event. You both have equal status in observing and recording the bang. The bang exists, *and all other events exist*, independent of reference frames. Events are the nails on which all of science hangs.

FIGURE 38-4 ■ Laboratory and rocket frames. A moment ago the two latticeworks were intermeshed. By convention, the rocket frame moves in the positive x direction of the laboratory frame.

TOUCHSTONE EXAMPLE 38-3: Synchronizing Clocks

You are stationed at a latticework clock with the coordinates $x = 3 \times 10^8$ m, $y = 4 \times 10^8$ m, and $z = 0$ m. The reference clock at coordinates $x = y = z = 0$ emits a reference flash at exactly midnight on its clock. You want your clock to be synchronized with (set to the same time as) the reference clock. To what time do you immediately set your clock when you receive the reference flash?

SOLUTION ■ Your distance D from the reference clock is

$$D = [(3 \times 10^8 \text{ m})^2 + (4 \times 10^8 \text{ m})^2 + 0 \text{ m}]^{1/2} = [25 \text{ m}]^{1/2} \times 10^8 \\ = 5 \times 10^8 \text{ m}.$$

The time Δt that it takes the reference flash to reach you is therefore

$$\Delta t = \frac{D}{c} = \frac{5 \times 10^8 \text{ m}}{3 \times 10^8 \text{ m/s}} = 1.66 \text{ s.} \quad (\text{Answer})$$

So when you receive the reference flash, you quickly set your clock to 1.66 seconds after midnight.

38-6 Time Stretching

Every year hundreds of email messages, letters, and articles “disproving” relativity are sent to textbook authors and scientific journal editors. Many of these papers are extremely ingenious, showing considerable insight and sometimes representing years of labor. (Indeed, fighting a new idea often helps us to understand it and make it our own. As you continue reading this chapter, you may want to make a note of the ideas that seem paradoxical or outrageous. By the time you finish the chapter, see if you can refute or defend some of your initial objections to relativity.)

A primary target of writers who object to special relativity is **time stretching**, the conclusion that the time between two events can have different values as measured in laboratory and rocket frames in relative motion. The clearest case of time stretching is this: *The time between two ticks measured on a clock at rest is always less than the time between the same two ticks measured in a reference frame in which the clock is moving.* Many people remember this result by using a not-quite-exact motto: *Moving clocks run slow.* However we express it, this conclusion is so obviously ridiculous that it stimulates dozens of skeptics to write letters and articles.

Verification of Time Stretching

Time stretching is verified experimentally every day as part of the ongoing enterprise of experimental physics. Here are two examples of time stretching in action.

Time stretching with atomic clocks: In October 1971, J. C. Hafele and R. E. Keating of the U.S. Naval Observatory sent atomic clocks (like the one described in Section 1-5) around the Earth on regularly scheduled commercial airliners. One clock circled the globe traveling eastward, the other clock traveled westward. When the clocks were finally brought together, they did not read the same time. Also, the reading on both clocks was different from that of a third atomic clock, which stayed at home in one place on the Earth’s surface. Why the different readings? Think of the center of the Earth as at rest. (Actually, the center of the Earth is in free fall around the sun.) With respect to the Earth’s center, the speed of the eastward-moving clock is *added* to the speed of the Earth’s rotation; it is the “faster-moving” clock. In contrast, the speed of the westward-moving clock is *subtracted* from the eastward motion of the Earth’s surface; this is the “slower-moving” clock. The stay-at-home clock moves with the Earth’s surface at a speed that is intermediate between that of the other two clocks. The result? The “faster-moving” eastward-going clock runs slow compared with the stay-at-home clock of intermediate speed. And the “slower-moving” westward-going

clock runs fast compared with the stay-at-home clock. In the Hafele–Keating experiment, the magnitudes of the different readings corresponded to the predictions of relativity. There was, however, at least one complication: The airplanes changed altitude as they took off, flew their courses, and landed. General relativity, the theory that includes gravitational effects, predicts that changes in altitude, as well as relative speeds, affect the relative rates at which clocks run. The results of the Hafele–Keating experiment were actually consistent with the predictions of general relativity too, but that is a story for another day.

Time stretching with pions: Our second example of time stretching is more technical than the Hafele–Keating experiment, but a lot more convincing. It involves measuring the lifetimes of **pions**, also called pi-mesons or π^+ mesons. These short-lived particles can be created during cosmic ray interactions or when a beam of protons energized by a particle accelerator strikes a target. On average, half the pions in a beam will decay into other particles in 18 nanoseconds (18×10^{-9} seconds) as measured by a clock carried with the pions. In this pion frame, half of the remainder will decay in the next 18 nanoseconds, and so on. We call this time the pion **half-life** ($t_{1/2}$). If pions are moving at nearly the speed of light, how far can a pion beam travel before half the pions decay? If the time were the same in our laboratory as it is in the rest frame of the speeding pions, the maximum distance would be approximately equal to

$$c \times t_{1/2} = (3 \times 10^8 \text{ m/s}) \times (18 \times 10^{-9} \text{ s}) = 5.4 \text{ m.}$$

However, experiment shows that the flying pions travel tens of meters before half of them decay. We conclude that in our laboratory frame the time for half of the pions to decay is much greater than it is in the rest frame of the pions. Time stretching!

Why Time Stretching Makes Sense

Objections to time stretching have always failed because they attack a result based on an utterly simple idea: All the laws of nature are the same in every reference frame (the Principle of Relativity). In particular, the speed of light is invariant (that is, it has the same value) in every reference frame. The invariance of the speed of light leads directly to the difference in time between two events as measured in laboratory and rocket frames. To illustrate this, let's consider the ticking of a “light clock” diagrammed in Fig. 38-5.

While riding in a transparent unpowered rocket ship, you fire a flash of light upward toward a mirror that you hold on a stick 3 meters directly above you (the left-hand panel in Fig. 38-5). The flash reflects at the mirror and returns to you. Call the emission of light event *A* and its reception upon return event *B*. For you, events *A* and *B* occur at the same place. Between the events, the light moves first straight up

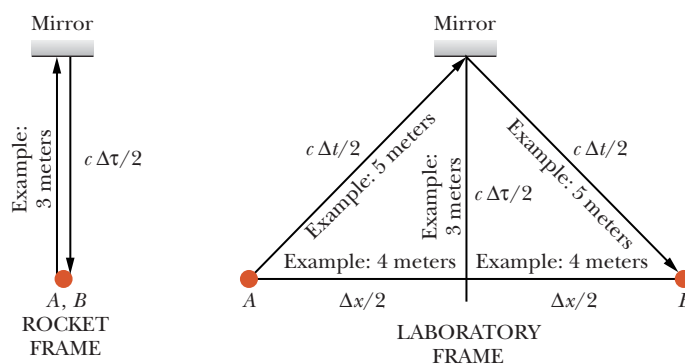

FIGURE 38-5 ■ A flash of light emitted at event *A* reflects from a mirror and returns to the source, arriving as event *B*. Events *A* and *B* are recorded in both the rocket and laboratory frames. Einstein tells us that each observer measures the same speed of light. Therefore different path lengths for the light flash in rocket and laboratory frames mean that different times between events *A* and *B* are measured in the two frames. (The meanings of the symbols Δx , $c \Delta t$, and $c \Delta \tau$ are discussed in the text.)

3 meters then straight down 3 meters. *For you the total time between events A and B equals the time that it takes light to travel a total of 6 meters.*

The unpowered spaceship in which you carry out these experiments moves from left to right past the rest of us, who stand in another transparent container arbitrarily labeled “laboratory” (the right-hand panel in Fig. 38-5). We also observe the same flash of light emitted at event A, reflected at your mirror, and received again at event B. But for us in the laboratory, you and your mirror move together to the right. Thus for us the path of the light slants upward from A along the 5-meter-long (for example) hypotenuse of the first right triangle, reflects from the speeding mirror, then slants back down along the 5-meter hypotenuse of the second right triangle to meet you again at event B. Therefore *for us events A and B are separated by the time it takes light to travel a total of 10 meters.* For us a longer time lapses between events A and B than you measured in your rocket frame.

That’s it! Longer path length for light, longer time for light to travel that path at its “universal speed,” therefore longer time between events as measured in that reference frame. No one has ever found an acceptable way around this simple and powerful result. The light clock demonstrates the longer time between two events in one frame than in another frame. Hence the name for this effect is **time stretching** or **time dilation** (*dilation* is a medical term for *stretching*).

The light flash and mirror make a kind of clock that we define as a **light clock**. The Principle of Relativity assures us that *all kinds of clocks* at rest in a frame, once calibrated, must run at the same rate as one another as observed in every frame in uniform relative motion with respect to the first frame. Otherwise we could tell which frame we are in by detecting different rates of different clocks all at rest in our frame. In any given frame, *properly calibrated clocks of every kind run at the same rate as one another*, including the “clock” of your body—namely, the aging process. Suppose the mirror was so high above your head that it took 6 years in your rocket for the light to return to you—and 10 years by our laboratory clocks. Then you would age 6 years between these new events A and B because your body’s “aging clock” and your “light clock” ride together in your rocket frame. In contrast, between events A and B we in the laboratory frame would age 10 years, and our light clock would also advance 10 years. Between events A and B you would age less than we do!

How strange it is that the speed of light is *invariant* for all observers, no matter what their relative velocity! But experiment continually verifies this result. Consequences of the invariance of the speed of light include the fact that clocks run at different rates for observers in relative motion. Experiment continually verifies this result as well. More than one hundred years of the most rigorous testing have validated beyond reasonable doubt that the speed of light is the same in all reference frames and that clocks tick at different rates when observed in frames that are in motion with respect to each other.

READING EXERCISE 38-5: Suppose that a beam of pions moves so fast that at 25 meters from the target in the laboratory frame exactly half of the original number remain undecayed. As an experimenter, you want to put more distance between the target and your detectors. You are satisfied to have one-eighth of the initial number of pions remaining when they reach your detectors. How far can you place your detectors from the target? ■

READING EXERCISE 38-6: A set of clocks is assembled in a stationary boxcar. They include a quartz wristwatch, a balance wheel alarm clock, a pendulum grandfather clock, a cesium atomic clock, fruit flies with average individual lifetimes of 2.3 days, a clock based on radioactive decay of nuclei, and a clock timed by marbles rolling down a track. The clocks are adjusted to run at the same rate as one another. The boxcar is then gently accelerated along a smooth horizontal track to a final velocity of 300 km/hr. At this constant final speed, which clocks will run at a different rate from the others as measured in that moving boxcar? ■

38-7 The Metric Equation

Time stretching occurs whenever the rocket has a velocity with respect to the laboratory frame. We can prove this in general using symbols in Fig. 38-5. In the laboratory frame we measure Δx as the distance between events A and B and we measure Δt as the time between the events (that is, the time it takes the light flash to slant upward along one hypotenuse at the speed c and then slant downward to the second event). Here delta (Δ) indicates the *lapse* of time and the letter t tells us that the elapsed time refers to the time between two events in our laboratory frame. One hypotenuse has a length given by

$$\text{length} = \text{velocity} \times \text{time} = c \Delta t/2.$$

In your rocket frame the flash moves vertically upward to the mirror and back down again in the time between events A and B . To describe your rocket frame time lapse between events we use the notation $\Delta\tau$. Here delta (Δ) indicates the *lapse* of time and the Greek letter tau (τ) tells us that the elapsed time refers to the time between two events in your unpowered rocket, in which they occur at the same place. So for you the upward distance covered in time $\Delta\tau/2$ is equal to $c \Delta\tau/2$. This vertical span is the same as the vertical leg shared by the right triangles in the diagram at the right. Hence we have expressions for the lengths of all sides of both of these right triangles. If we use the Pythagorean Theorem for right triangles we get

$$(\Delta x)^2 + (c \Delta\tau)^2 = (c \Delta t)^2 \quad (38-1)$$

where each term has dimensions of length squared. If we rearrange the terms in Eq. 38-1 so all the terms that refer to the laboratory frame are on the right, we get a squared time-like interval called the **metric equation**:

$$(c \Delta\tau)^2 = (c \Delta t)^2 - (\Delta x)^2 \quad (\text{squared time-like interval}). \quad (38-2)$$

Now suppose two events occur in the same place ($\Delta x = 0$), such as two sequential ticks of a clock in its rest frame. The time lapse $\Delta\tau$ between the events measured on the clock at rest is called the **proper time** or **wristwatch time**. The German term for proper time is *Eigenzeit*, meaning “one’s own time.” The square root of the difference of squares on the right side of Eq. 38-2 has the formal name **invariant time-like interval**. The interval is *invariant* because it has the same value as calculated by all observers. It is *time-like* because the magnitude of the time part $c \Delta t$ is greater than the magnitude of the space part Δx . (Both sides of Eq. 38-2 are necessarily positive).

The metric equation 38-2 is one of the most amazing equations in all of physics. Look at its outrageous implications:

- First, the metric equation relates *two different* measures of the time between the *same* two events. These are: (1) the time recorded on clocks in the reference frame in which the events occur at different places, and also (2) the wristwatch time read on the clock carried by a traveler who records the two events as occurring at the same place. The ability to relate these two times is one of the greatest scientific innovations in history.
- Second, the metric equation reveals an even deeper insight—space and time combine in a single expression on the right side. We no longer speak of space and time separately, but as a unity: **space-time**!

A wealth of other insights can be gleaned from Eq. 38-2. For example:

1. The time between events A and B as measured in the two frames *cannot have the same value* if the laboratory and rocket frames are in relative motion.

2. Laboratory observers can correctly predict the proper time observers in the rocket frame measure between events A and B on their rocket-frame wristwatches, in spite of the fact that this time is not the same as the time measured in the laboratory frame. (Observers in the laboratory simply put their values for Δt and Δx into Eq. 38-2 and calculate the value of the wristwatch time $\Delta\tau$ that the rocket observer measures.)
3. If the rocket speed relative to the laboratory frame is reduced, then both $\Delta x/2$ (the length of the horizontal leg in Fig. 38-5) and $c \Delta t/2$ (the hypotenuse) will be smaller than before. But these terms become smaller in such a way that the difference between their squares, which represents the vertical distance between the rocket observer and her mirror $c \Delta\tau/2$, will remain the same. So the metric equation (Eq. 38-2) will still hold. No matter how fast or slow the rocket is, the value of the proper time $\Delta\tau$ (also known as the invariant time-like interval) remains the same. Hence we call this interval between two events **invariant**, meaning that it has the same value as measured in *all* reference frames in uniform relative motion.

If a rocket passes by our laboratory frame at a speed v , we can derive an equation that relates $\Delta\tau$ and Δt directly by setting $\Delta x = v \Delta t$. Substituting this expression into Eq. 38-2 and dividing through by c^2 gives us

$$(\Delta\tau)^2 = (\Delta t)^2 - \left(\frac{\Delta x}{c}\right)^2 = (\Delta t)^2 - \left(\frac{v \Delta t}{c}\right)^2 = \left(1 - \frac{v^2}{c^2}\right)(\Delta t)^2.$$

Taking the square root of both sides gives us an expression known as the *time-stretching* or *time dilation equation*,

$$\Delta\tau = \sqrt{1 - v^2/c^2} \Delta t \quad (\text{time-stretching equation}). \quad (38-3)$$

The time-stretching equation (Eq. 38-3) gives us the value of wristwatch time $\Delta\tau$ between two events that occur a time Δt apart in some reference frame. In this equation, v is the speed required for an observer in the rocket frame to move directly from one event to the other event. The equation encompasses all possible values of speed v from the very slow to the very fast.

What Happens at High and Low Speeds?

The speeds we observe in everyday life are so much smaller than the speed of light c that the value of v/c is extremely small compared to 1. Thus, for low relative speeds, the expression $(1 - v^2/c^2)$ is approximately equal to 1. The time-stretching equation (Eq. 38-3) tells us that in this case Δt and $\Delta\tau$ are essentially equal; the time between events A and B is the same for you in a passing airplane as it is for us standing on Earth. So at very low relative speeds special relativity is consistent with our everyday assumption that time is a universal quantity, that everyone measures the time between two events to have the same value. This is the approximating assumption used in Newtonian mechanics.

In contrast, at a high relative speed v the outcome is quite different from what happens at everyday speeds. Imagine that you start from Earth (event A : departure from Earth) and travel to the star Alpha Centauri, about 4 light-years from Earth (event B : arrival at Alpha Centauri). Both events A and B (departure and arrival) occur at the position of your cockpit. Equation 38-3 tells us that by making v/c closer and closer to the value unity, your trip can take place in shorter and shorter wristwatch time $\Delta\tau$ *as measured in your spaceship*. (This is true even though the time Δt measured in the Earth frame can never be less than the time it takes light to move from Earth to Alpha Centauri—4 years.) By extension of this argument, we arrive at a result that frees the human spirit, if not yet the human body. Given sufficient rocket

speed, we can go anywhere in the universe in the lifetime of a single astronaut! At least this is the prediction of special relativity.

Nature's Speed Limit

The time-stretching equation (Eq. 38-3) also gives evidence that the natural speed limit of the universe is the speed of light c . Imagine that we in the laboratory measured your rocket speed v to be greater than the speed of light c . Then v/c (and also v^2/c^2) would have a value greater than unity, and the expression on the right side of Eq. 38-3 would include the square root of a negative number. This would mean that the time measurement $\Delta\tau$ would be proportional to the square root of a negative number. But this is impossible: No real time can be proportional to the square root of a negative number. Careful study and experiment have led to the conclusion, consistent with this formula, that no object can be accelerated to a speed v greater than the speed of light c in a vacuum. Experiment verifies this: Many nations together have spent billions of dollars to build and operate huge particle accelerators that use electric and magnetic fields to urge protons or electrons to ever-higher energies. At higher and higher energies, these particles approach closer and closer to the speed of light but have never been observed to exceed this speed.

READING EXERCISE 38-7: Find the rocket speed v at which the time $\Delta\tau$ between ticks on the rocket clock is recorded by the laboratory clock as $\Delta t = 1.01 \Delta\tau$. ■

TOUCHSTONE EXAMPLE 38-4: Satellite Clock Runs Slow?

An Earth satellite in circular orbit just above the atmosphere circles the Earth once every $T = 90$ min. Take the radius of this orbit to be $r = 6500$ kilometers from the center of the Earth. How long a time will elapse before the reading on the satellite clock and the reading on a clock on the Earth's surface differ by one microsecond? For purposes of this approximate analysis, assume that the Earth does not rotate and ignore gravitational effects due the difference in altitude between the two clocks (gravitational effects described by general relativity).

SOLUTION ■ First we need to know the speed of the satellite in orbit. From the radius of the orbit we compute the circumference and divide by the time needed to cover that circumference:

$$v = \frac{2\pi r}{T} = \frac{2\pi \times 6500 \text{ km}}{90 \times 60 \text{ s}} = 7.56 \text{ km/s.} \quad (38-4)$$

Light speed is almost exactly $c = 3 \times 10^5$ km/s, so the satellite moves at the fraction of the speed of light given by

$$\frac{v}{c} = \frac{7.56 \text{ km/s}}{3 \times 10^5 \text{ km/s}} = 2.52 \times 10^{-5}. \quad (38-5)$$

or

$$v^2/c^2 = (2.52 \times 10^{-5})^2 = 6.35 \times 10^{-10}. \quad (38-6)$$

The relation between the time lapse $\Delta\tau$ recorded on the satellite clock and the time lapse Δt on the clock on Earth (ignoring the Earth's rotation and gravitational effects) is given by Eq. 38-3. Square both sides of that equation to obtain:

$$(\Delta\tau)^2 = (1 - v^2/c^2)(\Delta t)^2. \quad (38-7)$$

We want to know the difference between Δt and $\Delta\tau$. Rearrange this equation to give the difference of squares:

$$v^2/c^2(\Delta t)^2 = (\Delta t)^2 - (\Delta\tau)^2 \equiv (\Delta t - \Delta\tau)(\Delta t + \Delta\tau). \quad (38-8)$$

Substituting the numerical result of Eq. 38-6 into Eq. 38-7, we see that $\Delta\tau$ and Δt have very nearly the same value. Therefore we can set

$$\Delta t + \Delta\tau \approx 2\Delta t. \quad (38-9)$$

With this substitution, Eq. 38-8 becomes

$$v^2/c^2(\Delta t/2) \approx \Delta t - \Delta\tau. \quad (38-10)$$

Substitute from Eq. 38-6:

$$\Delta t - \Delta\tau \approx 3.18 \times 10^{-10}\Delta t. \quad (38-11)$$

We are asked to find the elapsed Δt for which the satellite clock and the Earth clock differ in their reading by one microsecond = 10^{-6} second. Rearrange Eq. 38-11 to read

$$\Delta t \approx \frac{\Delta t - \Delta\tau}{3.18 \times 10^{-10}} = \frac{10^{-6} \text{ s}}{3.18 \times 10^{-10}} = 3.14 \times 10^3 \text{ s.} \quad (\text{Answer})$$

This is approximately equal to 52 minutes, or a little less than one hour. A difference of one microsecond between atomic clocks is easily detectable.

38-8 Cause and Effect

The analysis thus far has omitted from our consideration a large number of possible pairs of events. Suppose two events occur at the same time but not at the same place in a reference frame. For example, what if two firecracker explosions occur simultaneously, one in New York City, the other in San Francisco? Since $\Delta\tau = 0$ for this pair of events, Eq. 38-2 for the space-time interval becomes

$$(c \Delta\tau)^2 = (c \Delta t)^2 - (\Delta x)^2 \rightarrow -(\Delta x)^2 \quad (\text{for } \Delta t = 0).$$

What can this expression possibly mean? The left side contains the square of a time, obviously a positive quantity. Yet on the right is a negative quantity. No clock records a time lapse $\Delta\tau$ whose square is a negative quantity! We have a contradiction here, and a contradiction that applies in a similar way to all possible pairs of events simultaneous in some frame.

The problem is not with physics but with mathematical notation. Pairs of simultaneous events were not envisioned in the derivation of the proper time equation (Eq. 38-2) based on Fig. 38-5. For this new class of event-pairs we need a new formalism. To achieve this, reverse the order of squared quantities on the right side of Eq. 38-2 and give the result a different name. Earlier we used the notation $\Delta\tau$ (involving the Greek letter tau—denoted τ) to represent the elapsed *time* between two events measured on a clock for which the events occur at the same *place*. For our new expression we use the notation $\Delta\sigma$ (involving the Greek letter sigma—denoted σ) to represent the *distance* between two events measured in the frame in which they occur at the same time. This new equation has the form

$$(\Delta\sigma)^2 = (\Delta x)^2 - (c \Delta t)^2 \quad (\text{squared space-like interval}). \quad (38-12)$$

The distance $\Delta\sigma$ between two events, measured in a frame in which the events occur at the same time ($\Delta t = 0$), is called the **proper distance**. This square root of the difference of squares on the right side of Eq. 38-12 also has the formal name **invariant space-like interval**—space-like because the space part Δx is greater than the time part $c \Delta t$.

The right-hand side of Eq. 38-12 also describes the space and time separations between these two events as measured in a second frame that moves past the first; in the second frame Δx and Δt are both different from zero. The proper distance $\Delta\sigma$, like the wristwatch time $\Delta\tau$, is an *invariant* in the following sense: Observers in relative motion may measure different values of Δx and different values of Δt between these two events. However, when each observer substitutes these values into Eq. 38-12, he will obtain the same numerical value for the proper distance $\Delta\sigma$. And the value of $\Delta\sigma$ is just the distance between the two events as measured in that particular reference frame in which they occur at the same time.

Some important consequences for events separated by a space-like interval can be read from Eq. 38-12:

- If Δx is greater in magnitude than $c \Delta t$ in one frame, then Δx is greater in magnitude than $c \Delta t$ in all frames. Why? Because $\Delta\sigma$ is an invariant, so $(\Delta\sigma)^2$ has the same value whatever the values of Δx and $c \Delta t$ in a particular frame. Both sides of Eq. 38-12 must remain positive. But $c \Delta t$ is the distance that light can travel in the time available between these events. Equation 38-12 says that Δx is greater than this distance $c \Delta t$ between the two events in that frame. Nothing, not even a light flash, can move fast enough to travel from one event to the other in the elapsed time Δt between them. Therefore, for events connected by a space-like interval, one event *cannot* cause the other event as observed in *any* frame.

- By definition, $\Delta\sigma$ is the separation between two events in a reference frame in which the time between these events is zero so the events are simultaneous. But the right side of Eq. 38-12 contains *both* Δt and Δx , implying that for another frame in relative motion Δt is *not* zero. That is, in this other frame the two events are *not* simultaneous. As an example, for observers in a rocket streaking across the continent from New York toward San Francisco, the two firecracker explosions in New York and San Francisco will *not* occur at the same time. This leads to a major result of special relativity: *Two events simultaneous in one frame are not necessarily simultaneous in other frames in motion relative to the first.* For many people this is the most difficult concept in special relativity, harder to believe even than the difference in clock rates described by the time-stretching equation (Eq. 38-3). In Section 38-9 we elaborate on this result, which is called the **relativity of simultaneity**.

Suppose that two events are separated in space Δx and time Δt so that a flash of light moving directly between them can *just* make it from one event to the other event in the time Δt . Then the distance between them is given by $\Delta x = c \Delta t$. In this case both the proper distance $\Delta\sigma$ and the proper time $\Delta\tau$ are zero:

$$(c \Delta\tau)^2 = (\Delta\sigma)^2 = 0 \quad (\text{squared light-like interval}). \quad (38-13)$$

Two events that can be connected by a direct light flash are said to be related by an **invariant light-like interval** or **null interval**—null because the space part Δx is equal in magnitude to the time part $c \Delta t$, so the difference between their squares is zero, or null.

Equations 38-2, 38-12, and 38-13 embrace all possible cause-and-effect relations between pairs of events that occur along the x direction as described by special relativity. Equation 38-2 describes two events separated by a time-like interval. Something moving more slowly than light, a rocket for example, can travel directly between these two events in the time between them, so it is possible for the earlier event to cause the later event. This possible cause-and-effect relation between an earlier and a later event is preserved in every reference frame. In contrast, not even light can travel between the two events separated by a space-like interval described in Eq. 38-12, so that neither one of these two events can cause the other event. This *lack* of possible cause-and-effect relation is preserved in every frame. Equation 38-13 provides the boundary between these two cases: the relation between two events that can be connected only by a direct light flash. The earlier event in this pair can cause the other event only through a directly connecting light flash. This cause-and-effect relation between the earlier and later events is also maintained in every reference frame.

In brief, the three-fold categories of time-like, space-like, and light-like intervals between pairs of events preserve the possible cause-and-effect relation between these events in *all* reference frames. Special relativity may be weird, but at least it reaffirms the fact that cause comes before effect for all observers—a statement that most of us consider to be a central requirement of science.

READING EXERCISE 38-8: Points on the surfaces of the Earth and the Moon that face each other are separated by a distance of 3.76×10^8 meters. How long does it take light to travel between these points? A firecracker explodes at each of these two points; the time between these explosions is one second. Is it possible that one of these explosions caused the other explosion? ■

38-9 Relativity of Simultaneity

In the previous section we obtained the following result from the space-like form of the metric equation:

Two events that are simultaneous in one frame are not necessarily simultaneous in a second frame in uniform relative motion.

This result becomes clear when we consider what observers on the ground and the train see as each measures the time between the same two events, as shown in Fig. 38-6. Suppose lightning bolts strike both ends of the train, emitting flashes and leaving char marks on both the train and the track (top image in the figure). Assume that flashes from the front and back of the train reach the observer on the ground at the same time (bottom image in the figure). This ground observer measures his distance from the two char marks on the track and finds these distances to be equal. He concludes that, for him, the two lightning bolts struck *simultaneously*. In contrast, the rider at the middle of the train sees the flash from the front of the train first (because in Fig. 38-6 she moves toward the light flash coming from the front of the train and away from the light flash coming from the back). She measures her distance from the char marks on the two ends of the train and finds these distances equal. Following the Principle of Relativity, she assumes that the speed of light has the same value in her train frame as in every other frame. She concludes that, for her, the lightning struck the front end of the train first. Her reasoning is explained in the caption to Fig. 38-6.

FIGURE 38-6 ■ Einstein's Train Paradox illustrating the relativity of simultaneity. *Top:* Lightning strikes the front and back ends of a moving train, leaving char marks on both track and train. Each emitted flash spreads out in all directions. *Center:* Observer riding in the middle of the train concludes that the two strokes are *not* simultaneous. Her argument: “(1) I am equidistant from the front and back char marks on the train. (2) Light has the standard speed in my frame, and equal speed in both directions. (3) The flash arrived from the front of the train first. (4) Therefore, the flash must have left the front of the train first; the front lightning bolt fell before the rear lightning bolt fell. I conclude that the lightning strokes were not simultaneous.” *Bottom:* Observer standing by the tracks halfway between the char marks on the tracks concludes that the two lightning strokes were simultaneous, since the flashes from the strokes reach him at the same time and he is equidistant from the char marks on the track. *Conclusion:* Two events that are simultaneous in one frame may *not* be simultaneous in another frame.

READING EXERCISE 38-9: Susan, the rider on the train pictured in Fig. 38-6, is carrying an audio tape player. When she receives the light flash from the front of the train she switches on the tape player, which plays *very loud* music. When she receives the light flash from

the back end of the train, Susan switches off the tape player. Will Sam, the observer on the ground, be able to hear this music? Later Susan and Sam meet for coffee and examine the tape player. Will they agree that some tape has been wound from one spool to the other? ■

TOUCHSTONE EXAMPLE 38-5: Principle of Relativity Applied

Divide the following items into two lists. On one list, labeled SAME, place items that name properties and laws that are always the *same* in every frame. On the second list, labeled MAY BE DIFFERENT, place items that name properties that can be *different* in different frames:

- the time between two given events
- the distance between two given events
- the numerical value of Planck's constant h
- the numerical value of the speed of light c
- the numerical value of the charge e on the electron
- the mass m of an electron (measured at rest)
- the elapsed time on the wristwatch of a person moving between two given events
- the order of elements in the periodic table
- Newton's First Law of Motion ("A particle initially at rest remains at rest, and . . .")
- Maxwell's equations that describe electromagnetic fields in a vacuum
- the distance between two simultaneous events

SOLUTION ■ The Principle of Relativity says that the laws of physics are the same in every frame. So items (i) and (j) should go on the SAME list, along with item (h). The Principle of Relativity extends to the values of fundamental constants, so items (c), (d), (e), and (f) should also go on the SAME list.

In contrast, as we have seen in this chapter, the time between a pair of events (item a) may be different in different frames. The

same is true for the distance between two events (item b). So these go in the DIFFERENT list.

This leaves two items, (g) and (k). Item (g), the time on the wristwatch of a person moving between two given events (the so-called "wristwatch time") is an invariant, the same as calculated using space and time separations measured in any frame (Eq. 38-2). So this goes on the SAME list. The same is true of item (k), the "proper distance" between two events. This is also an invariant and goes on the SAME list.

In summary, here are the two lists requested: (Answer)

THE SAME IN ALL FRAMES

- numerical value of h
- numerical value of c
- numerical value of e
- mass of electron (at rest)
- wristwatch time between two events
- order of elements in the periodic table
- Newton's First Law of Motion
- Maxwell's equations
- distance between two simultaneous events

MAY BE DIFFERENT IN DIFFERENT FRAMES

- time between two given events
- distance between two given events

38-10 Momentum and Energy

Shortly after his first paper on special relativity was published, Einstein submitted a paper that added the most famous equation of all time, $E = mc^2$, to his theory. This equation tells us that every particle in the universe with mass is a storehouse of energy, useful to us provided we can find ways to transform this mass into other forms of energy. The explosion of a nuclear weapon and burning of a star provide spectacular examples of transformations of mass to energy, but every single energy-emitting reaction—down to the burning of a match—carries with it a conversion of mass to a significant amount of energy. For example, the wood in a kitchen match contains about 30,000 calories (or 30 food calories). Because of the huge magnitude of the conversion factor c^2 , the corresponding predicted change in mass of the combustion products is less than 2 billionths of a gram.

Where Does $E = mc^2$ Come From?

How does the famous $E = mc^2$ equation grow out of the special theory of relativity discussed so far in this chapter? The connection is not direct. In this section we shall present arguments for the development of $E = mc^2$ using equations we have already

introduced in this and earlier chapters. We shall also explore some of the consequences of the equivalence of mass and energy. Please be patient and follow the logic. It will be rewarding.

Imagine that a moving particle emits two flashes a time $\Delta\tau$ apart as recorded on its own wristwatch. We use these two emissions to track the motion of the particle. These two flashes can be related using the metric equation (38-2):

$$(c \Delta\tau)^2 = (c \Delta t)^2 - (\Delta x)^2$$

where the values of Δx and Δt are measured with respect to the laboratory frame. Starting with this equation, we can extract some important information about the momentum and energy of the particle. We start by multiplying both sides of the equation by $m^2 c^2/(\Delta\tau)^2$, where m is the mass of the particle. This gives us

$$(mc^2)^2 = \left(mc^2 \frac{\Delta t}{\Delta\tau} \right)^2 - \left(mc \frac{\Delta x}{\Delta\tau} \right)^2. \quad (38-14)$$

Note that the famous expression mc^2 appears on the left. The second term on the right contains the fraction $\Delta x/\Delta\tau$ —namely, the distance Δx traveled by the particle as measured by our laboratory observer, divided by the time $\Delta\tau$ it takes to move this distance as recorded on the wristwatch carried by the particle. This measures a kind of velocity. Mass times velocity yields the formula for momentum; call it p . The laboratory observer reckons the momentum to have the value

$$p \equiv m \frac{\Delta x}{\Delta\tau} \quad (\text{lab observer's definition of particle momentum}). \quad (38-15)$$

But, why does the lab observer use $\Delta\tau$ in Eq. 38-15 rather than Δt to define momentum? Newtonian mechanics assumes that the time Δt between two events is a universal quantity, with the same value as measured in all reference frames. But relativity shows us (Eq. 38-3) that the time between the two flashes emitted by the particle has a different value when measured in different frames. We have chosen to use the invariant proper time $\Delta\tau$ (as recorded on the wristwatch carried by the particle) to be the time to use in reckoning the particle's momentum. So Eq. 38-15 results from a decision about time that Newton did not have to make.

What about the first term on the right side of Eq. 38-14, the one containing the squared ratio of time lapses $(\Delta t/\Delta\tau)^2$? According to Eq. 38-3, this squared ratio is related to the ratio of the particle velocity and the speed of light by the equation

$$\left(\frac{\Delta t}{\Delta\tau} \right)^2 = \frac{1}{1 - v^2/c^2}. \quad (38-16)$$

The $(mc^2)^2$ term on the left in Eq. 38-14 has the units of energy squared. Some powerful results follow if we assume that the first term on the right of that equation is the square of the total energy, E , of the particle. Then, using Eqs. 38-14 and 38-16, energy can be written in two ways:

$$E = mc^2 \frac{\Delta t}{\Delta\tau} = \frac{mc^2}{(1 - v^2/c^2)^{1/2}}. \quad (38-17)$$

We can substitute the definition of the momentum, p , from Eq. 38-15 and the definition of energy, E , from Eq. 38-17 into Eq. 38-14 to get

$$(mc^2)^2 = E^2 - (pc)^2. \quad (38-18)$$

When the particle is at rest, the momentum $p = 0$ and this equation takes the famous form

$$E_{\text{rest}} = mc^2 \quad (\text{rest energy of a particle of mass } m). \quad (38-19)$$

Note that Eq. 38-19 describes only a particle that is *at rest* in a given frame. For a particle in motion, observers in that frame must use Eq. 38-17 to predict its energy.

Is there experimental evidence that the expressions for energy and momentum derived above have a useful reality? Yes, overwhelming evidence. In analyzing decades of experiments with high-speed particles, conservation of energy and momentum continue to be valid in special relativity *provided* that one uses the *relativistic* expressions for energy and momentum. In analyzing high-speed particle collisions in an isolated system, one adds up the total energy of particles before a collision, using Eq. 38-17 for each particle (being sure to include the rest energy of any particles at rest). This number will be equal to the total energy of the system of particles after the collision, no matter how many particles are destroyed or created in the process. A similar conservation law holds true for *each* spatial component of the total momentum of the particles, using Eq. 38-15 for the x -component and similar equations for other directions (substituting Δy or Δz for Δx).

Relativistic Kinetic Energy

When a given particle is *not* at rest in a given reference frame, then its momentum p is *not* zero as measured in that frame. In this case the total particle energy, E , must be greater than its rest value to keep the right side of Eq. 38-18 a constant, equal to the left side. The *increase in energy of a particle due to its motion* is called **kinetic energy**. In special relativity the kinetic energy is defined as the difference between the total energy and the rest energy:

$$K \equiv E - E_{\text{rest}} = \frac{mc^2}{(1 - v^2/c^2)^{1/2}} - mc^2. \quad (38-20)$$

Equations 38-17 and 38-20 show that the total energy—and therefore also the kinetic energy—increases without limit as the particle speed v approaches the speed of light c (that is, as v/c approaches 1). And indeed we can add as much kinetic energy as we want to a moving particle in order to increase the energy of collision with other particles, as is done in ever more powerful and ingeniously designed particle accelerators. Yet even the highest-energy particle never moves faster than light as measured in any frame (Fig. 38-7). This result provides the answer to the question asked at the beginning of this chapter: *How can the energy of a particle increase without limit while its speed remains slower than the speed of light?*

Kinetic Energy at Everyday Speeds

In our everyday world the fastest speed we encounter is probably that of a fighter plane moving above the speed of sound at Mach 3 (three times the speed of sound or about 1000 m/s). This speed is not even close to the speed of light. In fact, $v/c = (1000)/(3 \times 10^8 \text{ m/s}) \approx 3 \times 10^{-6}$.

Equation 38-20 looks complicated. However, for speeds much less than the speed of light (that is, for $v \ll c$) the equation reduces to the Newtonian expression for kinetic energy. To see this, we can use the following approximation:

$$(1 + d)^n \approx 1 + nd \quad \text{for } |d| \ll 1 \text{ and } |nd| \ll 1. \quad (38-21)$$

FIGURE 38-7 ■ The dots show measured values of the kinetic energy of an electron plotted against its measured speed. No matter how much energy is given to an electron (or to any other particle having mass), it cannot be accelerated to a speed that equals or exceeds the ultimate limiting speed c . (The curve drawn through the dots shows the predictions of Einstein's special theory of relativity.)

Apply this approximation to the first term on the right of Eq. 38-20. Then in the limit of small values for v^2/c^2 , Eq. 38-20 reduces to

$$\begin{aligned} K &= mc^2(1 - v^2/c^2)^{-1/2} - mc^2 \\ &\approx mc^2(1 + v^2/2c^2) - mc^2 \quad (\text{for } v \ll c). \quad (38-22) \\ &\approx \frac{1}{2}mv^2 \end{aligned}$$

In brief, the expression for kinetic energy reduces to the Newtonian form for speeds very much less than the speed of light. This limiting case helps to justify our assignment of the name *energy* to the relativistic expressions shown in Eqs. 38-17 and 38-20. The total energy in these equations includes *both* relativistic kinetic energy and rest energy.

Proper Time and Proper Distance in Three Space Dimensions

So far, for simplicity, we have used one space dimension x in the equations of this chapter. Of course, there are three space dimensions, the additional two dimensions often labeled with the symbols y and z . The more general expressions for the time-like and space-like intervals, Eqs. 38-2 and 38-12, are

$$(c \Delta\tau)^2 = (c \Delta t)^2 - [(\Delta x)^2 + (\Delta y)^2 + (\Delta z)^2] \quad (\text{squared time-like interval}), \quad (38-23)$$

$$\text{and} \quad (\Delta\sigma)^2 = [(\Delta x)^2 + (\Delta y)^2 + (\Delta z)^2] - (c \Delta t)^2 \quad (\text{squared space-like interval}). \quad (38-24)$$

READING EXERCISE 38-10: Find the speed v at which the energy E of a particle is equal to twice its rest energy. ■

TOUCHSTONE EXAMPLE 38-6: Energy of a Fast Particle

A particle of mass m moves so fast that its total energy is equal to 1.1 times its rest energy.

(a) What is the speed v of the particle?

SOLUTION ■ From Eq. 38-19, the rest energy is equal to

$$E_{\text{rest}} = mc^2.$$

The statement of the example says we are looking for a speed such that the energy is 1.1 times the rest energy. From Eq. 38-17, we have

$$E = \frac{mc^2}{(1 - v^2/c^2)^{1/2}} = 1.1E_{\text{rest}} = 1.1mc^2.$$

Cancel mc^2 from the second and fourth of these equal quantities and equate the results:

$$\frac{1}{(1 - v^2/c^2)^{1/2}} = 1.1.$$

Square both sides and solve the resulting equation for v^2/c^2 :

$$v^2/c^2 = 0.1735$$

from which

$$v = 0.416 c. \quad (\text{Answer})$$

(b) What is the kinetic energy of the particle?

SOLUTION ■ From Eq. 38-20, the kinetic energy is just the total energy minus the rest energy. In our case,

$$K = E - E_{\text{rest}} = 1.1E_{\text{rest}} - E_{\text{rest}} = 0.1E_{\text{rest}}. \quad (\text{Answer})$$

TOUCHSTONE EXAMPLE 38-7: Decay of K^0 Meson

A K^0 meson at rest decays into a π^+ meson and a π^- meson. As is often done in particle physics, we express the masses of these particles in terms of energy divided by c^2 . The masses of the two π mesons are identical, so call both m_π . Then

$$\begin{aligned} m_K &= 497.7 \text{ MeV}/c^2 \\ m_\pi &= 139.6 \text{ MeV}/c^2. \end{aligned}$$

What is the speed of each of the π mesons after the decay?

SOLUTION ■ This is assumed to be an isolated system, in which both the total relativistic energy and the total relativistic momentum are conserved. The initial K^0 meson is at rest, so there is zero momentum before and therefore also after the collision. From this we conclude that the momenta labeled p_1 and p_2 in Fig. 38-8 have equal magnitudes but opposite directions. From Eq. 38-18, this guarantees that the two resulting particles also have equal energies

FIGURE 38-8 ■ BEFORE

AFTER

after the decay. The conservation of energy equates *total* relativistic energy before and after the collision, and this total energy includes rest energy. Before the decay there is only the rest energy of the K^0 meson. After the decay, there are two π mesons of equal mass and equal energy. From Eq. 38-17,

$$m_K c^2 = 2E_\pi = \frac{2m_\pi c^2}{(1 - v^2/c^2)^{1/2}}.$$

Into the first and last expressions in this equation, substitute the values for the masses from the earlier equations. The factors c^2 cancel, and the units MeV cancel, to yield the equation

$$497.7 = \frac{2 \times 139.6}{(1 - v^2/c^2)^{1/2}}.$$

Square both sides of this equation, solve for v^2/c^2 , and take the square root. The answer is

$$v = 0.828c. \quad (\text{Answer})$$

This is the speed of each π meson as the two move in opposite directions after the decay.

38-11 The Lorentz Transformation

Most textbooks on special relativity do not emphasize *invariant* quantities that have the same value for all observers. Instead, they focus on the so-called **Lorentz transformation** equations. These equations connect the distinct space and time separations between two events as measured in one frame with those separations as measured in another frame moving past the first. We display the Lorentz transformation equations here without deriving them. (The derivation is not difficult and depends only on the Principle of Relativity and some symmetry arguments.)

In writing the Lorentz transformations it is customary to let unprimed coordinates represent measurements made in the laboratory frame and primed coordinates represent corresponding measurements made in a rocket frame that moves past the laboratory with relative speed v^{rel} along the positive x direction. Then the Lorentz equations that transform the laboratory space and time separations to rocket space and time separations are

$$\begin{aligned} \Delta x' &= \frac{\Delta x - v^{\text{rel}} \Delta t}{(1 - (v^{\text{rel}})^2/c^2)^{1/2}} \\ \Delta t' &= \frac{\Delta t - (v^{\text{rel}} \Delta x/c^2)}{(1 - (v^{\text{rel}})^2/c^2)^{1/2}} \quad (\text{Lorentz transformation}). \quad (38-25) \\ \Delta y' &= \Delta y \\ \Delta z' &= \Delta z \end{aligned}$$

What happens to these equations when they describe our everyday life in which typical moving objects are trains, airplanes, and automobiles? These vehicles move at

speeds very much less than the speed of light. Assume that v^{rel} is much less than c , so that $v^{\text{rel}}/c \ll 1$ in Eqs. 38-25. Then the first two of these equations become

$$\begin{aligned}\Delta x' &= \Delta x - v^{\text{rel}}\Delta t \\ \Delta t' &= \Delta t\end{aligned}\quad (v^{\text{rel}}/c \ll 1, \text{Galilean transformation}). \quad (38-26)$$

These equations are called the **Galilean transformation equations** because they lay out the consequences of relative motion first described by Galileo Galilei in the 1630s. The second equation tells us that for small relative velocities the time between two events has the same value for the moving observer as for the stationary observer. This is certainly typical of our experience; we do not need to reset our watches after an automobile ride! The first equation makes everyday sense as well. A race begins with a starting gun at the starting line and ends with the firing of an “ending gun” at the finish line when the winner crosses it. For observers in the stands the two firings occur a distance Δx and a time Δt apart. Running as fast as we can, we come in second, behind the winner. For us the ending gun goes off a distance ahead of us given by the distance of the racecourse, Δx , minus the distance we have run ($v^{\text{rel}}\Delta t$) at speed v^{rel} during the time Δt between the starting and ending guns. This is just what the first Galilean transformation (Eq. 38-26) tells us.

On the other hand, the Lorentz transformation (Eq. 38-25) gives us the rocket (primed) coordinates of an event if we know the laboratory (unprimed) coordinates of that event. But “laboratory” is just a label; it could represent simply another unpowered spaceship. Then the only difference between laboratory and rocket frames is the artificial difference we have given them. The rocket moves in the *positive* x direction with respect to the laboratory, so the laboratory moves in the *negative* x direction with respect to the rocket. It follows that the inverse transformation—the one that gives unprimed laboratory space and time separations in terms of primed rocket space-time separations—can be derived from the Lorentz transformation (Eq. 38-25) merely by interchanging primed and unprimed coordinates and reversing the sign of v^{rel} , making all v -terms positive in the numerators. (Reversing the sign of v^{rel} does not change the sign of $(v^{\text{rel}})^2$ in the denominators.) This leads to the equations

$$\begin{aligned}\Delta x &= \frac{\Delta x' + v^{\text{rel}}\Delta t'}{(1 - (v^{\text{rel}})^2/c^2)^{1/2}} \\ \Delta t &= \frac{\Delta t' + v^{\text{rel}}\Delta x'/c^2}{(1 - (v^{\text{rel}})^2/c^2)^{1/2}} \quad (\text{the inverse Lorentz transformation}). \\ \Delta y &= \Delta y' \\ \Delta z &= \Delta z'\end{aligned}\quad (38-27)$$

38-12 Lorentz Contraction

The Lorentz transformation equations predict a relativistic effect important in the history of the subject—namely, that we as observers will measure an object moving past us at high speed to be shortened—contracted—along its direction of relative motion (but not changed in dimension perpendicular to this direction).

The Lorentz transformation describes the space and time separations between a pair of events. What events can we use to measure the length of a moving object? One choice is the explosions of two firecrackers, one at each end of the object *at the same time* ($\Delta t = 0$) in our frame. Then we can define the length to be the distance Δx between the explosions as measured in our frame. By setting $\Delta t = 0$ in the first term of Eqs. 38-25 and multiplying through by the square-root quantity, we get

$$\sqrt{1 - v^2/c^2} \Delta x' = \Delta x. \quad (38-28)$$

This equation tells us that the length Δx we measure for the object in the laboratory frame—the distance between simultaneous firecracker explosions—is less than the distance $\Delta x'$ between the two ends as measured in the rocket frame in which the object is at rest.

The Lorentz contraction is a curiosity, and is not used very often to analyze experiments. However, it is the consequence of a deeper principle, the relativity of simultaneity, discussed following Eq. 38-12 in Section 38-8 and in Section 38-9. The two firecrackers may explode at the same time in our frame ($\Delta t = 0$) but not in the frame of the rocket ($\Delta t' \neq 0$), as you can see by substituting $\Delta t = 0$ into the second of Eqs. 38-25. The same-time explosions at the two ends of the moving rod in our frame yield a measure of the length of the moving object in our frame. In contrast, the *lack* of simultaneity in the rocket frame does not change the rocket measurement of $\Delta x'$ because the object is at rest in the rocket frame; the distance between the explosions at the two ends is the same whether or not these explosions occur at the same time. However, this lack of simultaneity allows observers in the two frames to account for the difference in measured length of the object.

READING EXERCISE 38-11: What is the speed v of a passing rocket in the case that we measure the length of the rocket to be half its length as measured in a frame in which the rocket is at rest? ■

38-13 Relativity of Velocities

The speed of light c is the ultimate speed according to special relativity. No object can be accelerated from rest to a speed greater than c . Yet some have found in this statement a paradox that challenges the validity of special relativity. Someone who objects to relativity says, “I ride in a rocket moving at $3/4$ the speed of light with respect to the laboratory. From my rocket I launch a stone forward at $3/4$ the speed of light as measured in my rocket frame. The result should be an object moving at $3/4 + 3/4 = 1.5$ times the speed of light in the laboratory frame. But relativity says that nothing can move faster than light. So my thought experiment shows special relativity to be illogical—and disproves it!”

Since the Lorentz transformation deals with space and time separation between *events*, we can use it to investigate the validity of this thought experiment. Let the stone that you launch forward from your rocket emit two flashes close together. Call the separation between these flash emissions $\Delta x'$ and $\Delta t'$ in your rocket frame and Δx and Δt in our laboratory frame. Then we can derive the velocities of the stone in the two frames from the differential limits of $\Delta x'/\Delta t'$ (velocity in rocket frame) and $\Delta x/\Delta t$ (velocity in laboratory frame).

Next we can use the first two entries in the Lorentz transformation (38-27):

$$\Delta x = \frac{\Delta x' + v^{\text{rel}}\Delta t'}{(1 - (v^{\text{rel}})^2/c^2)^{1/2}}$$

$$\Delta t = \frac{\Delta t' + v^{\text{rel}}\Delta x'/c^2}{(1 - (v^{\text{rel}})^2/c^2)^{1/2}}.$$

Then we can divide corresponding sides of these two equations into each other. The square root expressions in the denominators cancel and we have

$$\frac{\Delta x}{\Delta t} = \frac{\Delta x' + v^{\text{rel}}\Delta t'}{\Delta t' + v^{\text{rel}}\Delta x'/c^2}. \quad (38-29)$$

On the right side of this equation, divide both the numerator and denominator by $\Delta t'$:

$$\frac{\Delta x}{\Delta t} = \frac{\Delta x'/\Delta t' + v^{\text{rel}}}{1 + v^{\text{rel}}(\Delta x'/\Delta t')/c^2}. \quad (38-30)$$

Finally, we can take the differential limit and define u as the velocity of the stone in the laboratory frame and u' as the velocity of the stone in the rocket frame. Then Eq. 38-30 becomes

$$u = \frac{u' + v^{\text{rel}}}{1 + u'v^{\text{rel}}/c^2} \quad (\text{law of addition of velocities}). \quad (38-31)$$

Although Eq. 38-31 is called the **law of addition of velocities**, this is not a good name, because the addition is not simple.

How does the law of addition of velocities support the conclusion that nothing can move faster than the speed of light? Let's use this law to find the value of the stone's velocity u in our laboratory frame when the rocket moves away from us at $3/4$ the speed of light ($v^{\text{rel}} = 0.75c$) while the stone moves away from the rocket at $3/4$ the speed of light ($u' = 0.75c$) as measured in the rocket frame. Substituting these values into Eq. 38-31 yields

$$u = \frac{0.75c + 0.75c}{1 + (0.75c)^2/c^2} = \frac{1.5c}{1 + 0.5625} = 0.96c. \quad (38-32)$$

The result is that we observe the stone to move at the speed $0.96c$ in our laboratory frame. Its speed does not exceed the speed of light. Once again relativity saves itself from disproof!

READING EXERCISE 38-12: A rocket moves with speed $0.9c$ in our laboratory frame. A flash of light is sent forward from the front end of the rocket. Is the speed of that flash equal to $1.9c$ as measured in our laboratory frame? If not, what is the speed of the light flash in our frame? Verify your answer using Eq. 38-31. ■

TOUCHSTONE EXAMPLE 38-8: Relative Speed of Light

A rocket moves with speed $0.9c$ in our laboratory frame. A flash of light is fired *backward* from the rear of the rocket.

(a) What is the *speed* of that light flash in our laboratory frame?

SOLUTION ■ Using the Principle of Relativity, we can give an answer immediately, without doing any calculations. The speed of light is the same—invariant—in all reference frames. Therefore, the speed of the light flash in our laboratory frame will be c as usual, and in the backward direction. The equations should verify this result.

Use Eq. 38-31:

$$u = \frac{u' + v^{\text{rel}}}{1 + u'v^{\text{rel}}/c^2}.$$

In the example, $v^{\text{rel}} = 0.9c$ and $u' = -c$, with a minus since the light is fired out the back of the rocket:

$$u = \frac{-c + 0.9c}{1 - 0.9c^2/c^2} = \frac{-0.1c}{0.1} = -c. \quad (\text{Answer})$$

Therefore the speed of the light flash is equal to c in our laboratory frame, as it has to be and as predicted at the beginning of this solution.

(b) What is the *direction* of the light flash in our laboratory frame?

SOLUTION ■ The minus sign in the most recent equation tells us that in the laboratory frame the light flash moves in a direction opposite to that of the rocket in the laboratory frame.

38-14 Doppler Shift

A car approaches us and passes while sounding its horn. We hear the pitch of the horn decrease as it passes, a change called the **Doppler shift** or **Doppler effect**. In Chapter 18 we found that the Doppler effect depends on two velocities—namely, the velocity of the source and the velocity of the detector with respect to the air, the medium that transmits the waves.

Light and other electromagnetic waves follow a different rule for the Doppler shift, because they require no transmitting medium and can travel through a vacuum. For this reason, the Doppler effect for light depends on only one velocity, the relative velocity between source and detector.

Suppose that a source of light moves away from us with speed v^{rel} , while sending light backward toward us. Let the frequency of the light as measured by the source be denoted f_0 . We detect a smaller frequency f than the frequency f_0 and for two reasons: (1) Each wave crest is emitted at a greater distance from us than the previous wave crest, so it has to travel farther to reach us, and (2) for us the traveling clock runs slow (Eq. 38-3). These two effects combine to change the frequency of the light that we receive according to the equation

$$f = f_0 \left[\frac{1 - (v^{\text{rel}}/c)}{1 + (v^{\text{rel}}/c)} \right]^{1/2} \quad (\text{source moving away}). \quad (38-33)$$

In the case that the source moves *toward* us with speed v^{rel} , we simply reverse the sign of v^{rel} , which occurs twice in Eq. 38-33.

We can measure the frequencies emitted by luminous elements, such as hydrogen excited by an electric discharge in the laboratory. Looking out at stars in nearby galaxies, we can identify hydrogen from the pattern of emitted frequencies. We notice that galaxies farther from us have light shifted downward in frequency compared with their laboratory value and conclude that these galaxies are moving away from us; we call this the **red shift**.

Solving Eq. 38-33 for v^{rel} , we can determine the velocity with which a galaxy recedes from us. This analysis is approximately correct for nearby galaxies. However, the red shift due to the most remote galaxies is not due to the Doppler shift described by special relativity. Rather, the stretching out of the light waves heading toward us occurs because space itself is stretching as the universe expands over time. Thus, general relativity is required to describe this stretching of space with time.

READING EXERCISE 38-13: A not-too-distant galaxy is moving directly away from the Earth. Light from this galaxy includes a pattern of frequencies recognized as those emitted by hydrogen gas. We detect one of these frequencies to have the value $f = 0.9 f_0$, where f_0 is the corresponding frequency for light from hydrogen gas at rest in the laboratory. How fast is the distant galaxy moving away from the Earth? ■

TOUCHSTONE EXAMPLE 38-9: Colliding with Andromeda

According to some predictions, the Andromeda galaxy, currently two million light-years away from us, is moving toward our galaxy and the two will collide in three billion years. Light of a particular frequency f_0 is emitted from hydrogen gas in the stars of the Andromeda galaxy. What is the frequency f of that light measured on Earth?

SOLUTION ■ Equation 38-33 describes the case in which the source is moving directly *away* from us. But in this example, the

Andromeda galaxy is moving directly *toward* us. For a source moving directly toward us, reverse the sign of v^{rel} in Eq. 38-33:

$$f = f_0 \left[\frac{1 + (v^{\text{rel}}/c)}{1 - (v^{\text{rel}}/c)} \right]^{1/2} \quad (\text{source approaching}).$$

Andromeda is two million light-years distant and is predicted to reach our galaxy in three billion years. Therefore it must be moving

at the following fraction of the speed of light,

$$\frac{v^{\text{rel}}}{c} = \frac{2 \times 10^6 \text{ (light) years}}{3 \times 10^9 \text{ years}} = 6.667 \times 10^{-4}.$$

This has a magnitude very much less than one, so we can apply approximation Eq. 38-21 to the equation above:

$$\begin{aligned} f &= f_0 \left[\frac{1 + (v^{\text{rel}}/c)}{1 - (v^{\text{rel}}/c)} \right]^{1/2} \\ &= f_0 \{1 + (v^{\text{rel}}/c)\}^{1/2} \{1 - (v^{\text{rel}}/c)\}^{-1/2} \\ &\approx f_0 \{1 + (v^{\text{rel}}/2c)\} \{1 + (v^{\text{rel}}/2c)\} \\ &\approx f_0 \{1 + (v^{\text{rel}}/c) + (v^{\text{rel}}/2c)^2\}. \end{aligned}$$

Now, the second term in the last parenthesis has the approximate value 10^{-3} , while the third term has the approximate value 10^{-7} . Therefore we neglect the third term and reach our result:

$$f \approx f_0 \{1 + (v^{\text{rel}}/c)\} = f_0 \{1 + 6.667 \times 10^{-4}\} \approx f_0 \{1 + 7 \times 10^{-4}\}. \quad (\text{Answer})$$

This expression tells us how much higher is the frequency of light from Andromeda than the frequency of the light from a source of the same atoms viewed at rest in a laboratory on Earth.

Bibliography and Acknowledgments

Albert Einstein’s original publication on special relativity is “Zur Elektrodynamik bewegter Körper” (“On the Electrodynamics of Moving Bodies”) in *Annalen der Physik*, Volume 17, pages 891–921 (1905). This is reprinted, along with many other original articles on the subject, in the book *The Principle of Relativity* by Albert Einstein, H. A. Lorentz, H. Weyl, H. Minkowski, and others, Dover Books, New York 1952, ISBN 0-486-60081-5.

Arthur I. Miller presents a modern English translation of Einstein’s original article, together with a wealth of information on the historical and scientific background and immediate consequences, in his book *Albert Einstein’s Special Theory of Relativity: Emergence (1905) and Early Interpretation (1905–1911)*, Addison Wesley, Reading, Massachusetts, 1981, ISBN 0-201-04680-6.

The example of the loud tape player in Reading Exercise 38-9 was devised by Rachel Scherr, Stamatis Vokos, Peter Shaffer, and Andrew Boudreaux.

The author thankfully acknowledges both strategic and detailed suggestions and advice from Patrick J. Cooney, Priscilla W. Laws, and Edward F. Redish. Their help has greatly improved both the physics content and the pedagogical effectiveness of the text, though they are not responsible for any remaining errors.

Problems

SEC. 38-2 ■ ORIGINS OF SPECIAL RELATIVITY

1. Chasing Light. What fraction of the speed of light does each of the following speeds v represent? That is, what is the value of the ratio v/c ? (a) A typical rate of continental drift, 3 cm/y. (b) A highway speed limit of 100 km/h. (c) A supersonic plane flying at Mach 2.5 = 3100 km/h. (d) The Earth in orbit around the Sun at 30 km/s. (e) What conclusion(s) do you draw about the need for special relativity to describe and analyze most everyday phenomena? (*Note: Some* everyday phenomena can be derived from relativity. For example, magnetism can be described as arising from electrostatics plus special relativity applied to the slow-moving charges in wires.)

SEC. 38-3 ■ THE PRINCIPLE OF RELATIVITY

2. Fast Computation. A “serial computer,” one that carries out one instruction at a time, executes an instruction by transmitting data from the memory to the processor (where computation takes place) and then transmitting the result back to the memory. Estimate the maximum size of a serial “teraflop” computer, one that carries out 10^{12} instructions per second.

3. Examples of the Principle of Relativity. Identical experiments are carried out (1) in a high-speed train moving at constant speed along a horizontal track with the shades drawn and (2) in a closed freight container on the platform as the train passes. Copy the following list and mark with a “yes” quantities that will necessarily be the same as measured in the two frames. Mark with a “no” quantities that are not necessarily the same as measured in the two frames. (a) The time it takes for light to travel one meter in a vacuum; (b) the kinetic energy of an electron accelerated from rest through a voltage difference of one million volts; (c) the time for half the number of radioactive particles at rest to decay; (d) the mass of a proton; (e) the structure of DNA for an amoeba; (f) Newton’s Second Law of Motion: $F = ma$; (g) the value of the downward acceleration of gravity g .

4. Riding to Alpha Centauri. You are taking a trip from the solar system to our nearest visible neighbor, Alpha Centauri, approximately 4 light-years distant. At launch you experienced a period of acceleration that increased your speed with respect to Earth from zero to nearly half the speed of light. Now your spaceship is coasting in unpowered flight. Compare and contrast the observations you make now with those you made before the rocket took off from the Earth’s surface. Be as specific and detailed as possible. Distinguish between observations made inside the cabin with the windows covered and those made looking out of uncovered windows at the front, side, and back of the cabin.

SEC. 38-4 ■ LOCATING EVENTS WITH AN INTELLIGENT OBSERVER

5. Deducing a Speed. A pulse of protons arrives at detector D, where you are standing. Prior to this, the pulse passed through detector C, which lies 60 meters upstream. Detector C sent a light flash in your direction at the same instant that the pulse passed through it. At detector D you receive the light flash and the proton

pulse separated by a time of 2 nanoseconds (2×10^{-9} s). What is the speed of the proton pulse?

6. Eruption from the Sun. You see a sudden eruption on the surface of the Sun. From solar theory you predict that the eruption emitted a pulse of particles that is moving toward the Earth at one-eighth the speed of light. How long do you have to seek shelter from the radiation that will be emitted when the particle pulse hits the Earth? Take the light-travel time from the Sun to the Earth to be 8 minutes.

SEC. 38-5 ■ LABORATORY AND ROCKET LATTICEWORKS OF CLOCKS

7. Synchronizing a Clock. In a vast latticework of meter sticks and clocks, you stand next to a lattice clock whose coordinates are $x = 8$ km, $y = 40$ km, $z = 44$ km. When you receive the synchronizing flash, to what time do you quickly set your clock?

8. Earth’s Surface Inertial? Quite apart from effects due to the Earth’s rotational and orbital motion, a laboratory reference frame on the Earth is not an inertial frame, as required by a strict interpretation of special relativity. It is not inertial because a particle released from rest at the Earth’s surface does not remain at rest; it falls! Often, however, the events in an experiment for which one needs special relativity happen so quickly that we can ignore effects due to gravitational acceleration. Consider, for example, a proton moving horizontally at speed $v = 0.992c$ through a 10-m-wide detector in a laboratory test chamber. (a) How long will the transit through that detector take? (b) How far does the proton fall vertically during this time lapse? (c) What do you conclude about the suitability of the laboratory as an inertial frame in this case?

SEC. 38-6 ■ TIME STRETCHING

9. Light Clock for a Faster Rocket. Redo Fig. 38-5 with a vertical distance $c \Delta\tau/2 = 7$ m and horizontal distance in the lab frame $\Delta x/2 = 24$ m. Find the ratio of the times $\Delta t/\Delta\tau$ between events A and B recorded on laboratory and rocket clocks.

SEC. 38-7 ■ THE METRIC EQUATION

10. Where and When? Two firecrackers explode at the same place in the laboratory and are separated by a time of 12 years. (a) What is the spatial distance between these two events in a rocket in which the events are separated in time by 13 years? (b) What is the relative speed of the rocket and laboratory frames? Express your answer as a fraction of the speed of light.

11. Traveling to Vega. Jocelyn DeGuia takes off from Earth and moves toward the star Vega, which is 26 ly distant from Earth. Assume that Earth and Vega are relatively at rest and Jocelyn moves at $v = 0.99c$ in the Earth–Vega frame. How much time will have elapsed on Earth (a) when Jocelyn reaches Vega and (b) when Earth observers receive a radio signal reporting that Jocelyn has arrived? (c) How much will Jocelyn age during her outward trip?

12. Travel to the Dog Star. In the 24th century the fastest available interstellar rocket moves at $v = 0.75c$. Mya Allen is sent in this

rocket at full (constant) speed to Sirius, the Dog Star, the brightest star in the heavens as seen from Earth, which is a distance 8.7 ly as measured in the Earth frame. Assume Sirius is at rest with respect to Earth. Mya stays near Sirius, slowly orbiting around that Dog Star, for 7 years as recorded on her wristwatch while making observations and recording data, then returns to Earth with the same speed $v = 0.75c$. According to Earth-linked observers: (a) When does Mya arrive at Sirius? (b) When does Mya leave Sirius? (c) When does Mya arrive back at Earth? According to Mya's wristwatch: (d) When does she arrive at Sirius? (e) When does she leave Sirius? (f) When does she arrive back on Earth?

13. Fast-Moving Muons. The half-life of stationary muons is measured to be 1.6 microseconds. Half of any initial number of stationary muons decays in one half-life. Cosmic rays colliding with atoms in the upper atmosphere of the Earth create muons, some of which move downward toward the Earth's surface. The mean lifetime of high-speed muons in one such burst is measured to be 16 microseconds. (a) Find the speed of these muons relative to the Earth. (b) Moving at this speed, how far will the muons move in one half-life? (c) How far would this pulse move in one half-life if there were no relativistic time stretching? (d) In the relativistic case, how far will the pulse move in 10 half-lives? (e) An initial pulse consisting of 10^8 muons is created at a distance above the Earth's surface given in part (d). How many will remain at the Earth's surface? Assume that the pulse moves vertically downward and none are lost to collisions. (Ninety-nine percent of the Earth's atmosphere lies below 40 km altitude.)

14. Lifetime of a Fast Particle. An unstable high-energy particle is created in a collision inside a detector and leaves a track 1.05 mm long before it decays while still in the detector. Its speed relative to the detector was $0.992c$. How long did the particle live as recorded in its rest frame?

15. Living a Thousand Years in One Year. You wish to make a round trip from Earth in a spaceship, traveling at constant speed in a straight line for 6 months on your watch and then returning at the same constant speed. You wish, further, to find Earth to be 1000 years older on your return. (a) What is the value of your constant speed with respect to Earth? (b) How much do you age during the trip? (c) Does it matter whether or not you travel in a straight line? For example, could you travel in a huge circle that loops back to Earth?

16. Birthdays. An astronaut traveling in an unpowered spaceship celebrates his 18th, 19th, 20th, and 21st birthdays. Five Earth-years elapse between the 18th and 21st birthday parties. Find (a) the spatial separation between the 18th and 21st birthday parties in the Earth frame and (b) the speed of his spaceship with respect to Earth.

SEC. 38-8 ■ CAUSE AND EFFECT

17. Relations Between Events. The table shows the t and x coordinates of three events as observed in the laboratory frame.

Laboratory Coordinates of Three Events

Event	t years	x light-years
Event 1	2	1
Event 2	7	4
Event 3	5	6

On a piece of paper list vertically every pair of these events: (1, 2), (1, 3), (2, 3). (a) Next to each pair write "time-like," "light-like," or "space-like" for the relationship between those two events. (b) Next to each pair, write "Yes" if it is possible for one of the events to cause the other event and "No" if a cause and effect relation between them is not possible. (For full benefit of this exercise, construct and analyze your own tables.)

18. Proper Distance and Proper Time. Use the equations in Chapter 38 to show the following general results: (a) Given that two events P and Q have a space-like separation, show that in all such cases a reference frame can be found in which the two events occur at the same time. Also show that with respect to this frame the distance between the two events is equal to the proper distance between them. (b) Given that two events P and R have a time-like separation, show that in all such cases a reference frame can be found in which the two events occur at the same place. Also show that in this frame the time lapse between the two events is equal to the proper time between them. (c) Given that two events R and W have a light-like separation, show that in all such cases a light flash can be found that moves from R to W . Also show that the proper time and proper distance between R and W are both equal to zero.

SEC. 38-9 ■ RELATIVITY OF SIMULTANEITY

19. Symmetric Relativity of Simultaneity. In the thought experiment pictured in Fig. 38-6, we arbitrarily chose events so that the two light flashes from the lightning strikes arrived simultaneously at the ground observer. Analyze a new version of this experiment in which a completely different pair of lightning strikes fall at the two ends of the train such that the resulting light flashes arrive simultaneously at the position of the rider at the center of the train. View the experiment in the rest frame of the train. In this new version of the experiment, which lightning bolt falls first according to the observer on the ground?

SEC. 38-10 ■ MOMENTUM AND ENERGY

20. Boosting the Speed. How much work must be done to increase the speed of an electron (a) from $0.08c$ to $0.09c$? (b) from $0.98c$ to $0.99c$? Note that the increase in speed is the same in both cases.

21. Lightbulb Radiating Mass. How much mass does a 100 W lightbulb dissipate (in heat and light) when it burns for one full year?

22. Proton Crosses Galaxy. Find the energy of a proton that crosses our galaxy (diameter 100 000 light-years) in one minute of its own time.

23. Converting Mass to Energy. The values of the masses in the reaction

have been determined by a mass spectrometer to have the values:

$$m(p) = 1.007825u,$$

$$m(F) = 18.998405u,$$

$$m(\alpha) = 4.002603u,$$

$$m(O) = 15.994915u.$$

Here u is the atomic mass unit (Section 1.7). How much energy is released in this reaction? Express your answer in both kilograms and MeV.

24. Aspirin-Powered Automobile. An aspirin tablet contains 5 grains of aspirin (medicinal unit), which is equal to 325 mg. For how many kilometers would the energy equivalent of this mass power an automobile? Assume 12.75 km/L and a heat of combustion of 3.65×10^7 J/L for the gasoline used in the automobile.

25. Converting Energy to Mass. Two freight trains, each of mass 6×10^6 kg (6 000 metric tons) travel in opposite directions on the same track with equal speeds of 150 km/hr. They collide head-on and come to rest. (a) Calculate in joules the kinetic energy $(1/2)mv^2$ for each train before the collision. (Newtonian expression OK for everyday speeds!) (b) After the collision, the mass of the trains plus the mass of the track plus the mass of the roadbed plus the mass of the surrounding air plus the mass of emitted sound and light has increased by what number of milligrams?

26. Electrically Accelerated Electron. Through what voltage must an electron be accelerated from rest in order to increase its energy to 101% of its rest energy?

27. Powerful Proton. A proton exits an accelerator with a kinetic energy equal to N times its rest energy. Find expressions for its (a) speed and (b) momentum.

28. Relativistic Chemistry. One kilogram of hydrogen combines chemically with 8 kilograms of oxygen to form water; about 10^8 J of energy is released. Ten metric tons (10^4 kg) of hydrogen combines with oxygen to produce water. (a) Does the resulting water have a greater or less mass than the original hydrogen plus oxygen? (b) What is the numerical magnitude of this difference in mass? (c) A smaller amount of hydrogen and oxygen is weighed, then combined to form water, which is weighed again. A very good chemical balance is able to detect a fractional change in mass of 1 part in 10^8 . By what factor is this sensitivity more than enough—or insufficient—to detect the fractional change in mass in this reaction?

29. Finding the Mass. (a) Find an equation for the unknown mass m of a particle if you know its momentum p and its kinetic energy K . Show that this expression reduces to an expected result for non-relativistic particle speeds. (b) Find the mass of a particle whose kinetic energy is $K = 55.0$ MeV and whose momentum is $p = 121$ MeV/c. Express your answer as a decimal fraction or multiple of the mass m_e of the electron.

30. A Box of Light. Estimate the power in kilowatts used to light a city of 8 million inhabitants. If all this light generated during one hour in the evening could be captured and put in a box, how much would the mass of the box increase?

31. Creating a Proton–Antiproton Pair. Two protons, each of mass m , are fired toward one another with equal energy (see Fig. 38-9). They collide and create an additional proton–antiproton pair, each with the proton mass m . (a) Show that

FIGURE 38-9 ■ Problem 31.

the lowest total energy E of the incident protons for this creation to take place leaves the resulting four particles at rest with respect to one another. The value of this minimum energy for each incident particle is called the **threshold energy**. (b) What is the threshold kinetic energy K of each incident particle for this creation to occur? Express your answer in terms of the rest energy of the proton. (c)

Given that the mass of a proton is approximately equal to 1 GeV/c², what is the value of the threshold kinetic energy of each incident proton? Explain why this result is reasonable.

SEC. 38-11 ■ THE LORENTZ TRANSFORMATION

32. Really Simultaneous? (a) Two events occur at the same time in the laboratory frame and at the laboratory coordinates $(x_1 = 10$ km, $y_1 = 4$ km, $z_1 = 6$ km) and $(x_2 = 10$ km, $y_2 = 7$ km, $z_2 = -10$ km). Will these two events be simultaneous in a rocket frame moving with speed $v^{\text{rel}} = 0.8c$ in the x direction in the laboratory frame? Explain your answer. (b) Three events occur at the same time in the laboratory frame and at the laboratory coordinates (x_0, y_1, z_1) , (x_0, y_2, z_2) , and (x_0, y_3, z_3) , where x_0 has the same value for all three events. Will these three events be simultaneous in a rocket frame moving with speed v^{rel} in the laboratory x direction? Explain your answer. (c) Use your results of parts (a) and (b) to make a general statement about simultaneity of events in laboratory and rocket frames.

33. Transformation of y -velocity. A particle moves with uniform speed $v_y' = \Delta y'/\Delta t'$ in the y' direction with respect to a rocket frame that moves along the x axis of a laboratory frame. Find expressions for the x -component and for the y -component of the particle's velocity in the laboratory frame.

34. Transformation of Velocity Direction. A particle moves with speed v' in the $x'y'$ plane of the rocket frame and in a direction that makes an angle ϕ' with the x' axis. Find the angle ϕ that the velocity vector of this particle makes with the x axis of the laboratory frame. (*Hint:* Transform space and time displacements rather than velocities.)

35. The Headlight Effect. A flash of light is emitted at an angle ϕ' with respect to the x' axis of the rocket frame. (a) Show that the angle ϕ the direction of motion of this flash makes with respect to the x axis of the laboratory frame is given by the equation

$$\cos\phi = \frac{\cos\phi' + v^{\text{rel}}/c}{1 + (v^{\text{rel}}/c)\cos\phi'}$$

Optional: Show that your answer to Problem 34 gives the same result when the velocity v' is given the value c . (b) A light source at rest in the rocket frame emits light uniformly in all directions. In the rocket frame 50% of this light goes into the forward hemisphere of a sphere surrounding the source. Show that in the laboratory frame this 50% of the light is concentrated in a narrow forward cone of half-angle ϕ_0 whose axis lies along the direction of motion of the particle. Derive the following expression for the half-angle ϕ_0 :

$$\cos\phi_0 = v^{\text{rel}}/c.$$

This result is called the **headlight effect**. (c) What is the half-angle ϕ_0 in degrees for a light source moving at 99% of the speed of light?

SEC. 38-12 ■ LORENTZ CONTRACTION

36. Electron Shrinks Distance. An evacuated tube at rest in the laboratory has a length 3.00 m as measured in the laboratory. An electron moves at speed $v = 0.999\,987c$ in the laboratory along the

axis of this evacuated tube. What is the length of the tube measured in the rest frame of the electron?

37. Passing Time. A spaceship of rest length 100 m passes a laboratory timing station in 0.2 microseconds measured on the timing station clock. (a) What is the speed of the spaceship in the laboratory frame? (b) What is the Lorentz-contracted length of the spaceship in the laboratory frame?

38. Transformation of Angles. A meter stick lies at rest in the rocket frame and makes an angle ϕ' with the x' axis as measured by the rocket observer. The laboratory observer measures the x - and y -components of the meter stick as it streaks past. From these components the laboratory observer computes the angle ϕ that the stick makes with his x axis. (a) Find an expression for the angle ϕ in terms of the angle ϕ' and the relative speed v^{rel} between rocket and laboratory frames. (b) What is the length of the “meter” stick measured by the laboratory observer? (c) *Optional:* Why is your expression in part (a) different from equations derived in Problems 34 and 35?

39. Traveling to the Galactic Center. (a) Can a person, in principle, travel from Earth to the center of our galaxy, which is 23 000 ly distant, in one lifetime? Explain using either length contraction or time dilation arguments. (b) What constant speed with respect to the galaxy is required to make the trip in 30 y of the traveler’s lifetime?

40. Limo in the Garage. Carman has just purchased the world’s longest stretch limo, which has proper length $L_c = 30.0$ m. Part (a) of Figure 38-10 shows the limo parked at rest in front of a garage of proper length $L_g = 6.00$ m, which has front and back doors. Looking at the limo parked in front of the garage, Carman says there is no way that the limo can fit into the garage. “*Au contraire!*” shouts Garageman, “Under the right circumstances the limo can fit into the garage with both garage doors closed and room to spare!” Garageman envisions a fast-moving limo that takes up exactly one-third of the proper length of the garage. Part (b) of Figure 38-10 shows the speeding limo just as the front

(a) Stretch limo and garage, both at rest in frame of garage.

(b) Stretch limo at speed in frame of garage, just as front garage door closes.

(c) Stretch limo at speed in frame of garage, just as back garage door opens.

FIGURE 38-10 ■ Problem 40.

garage door closes behind it as recorded in the garage frame. Part (c) of Figure 38-10 shows the limo just as the back garage door opens in front of it as recorded in the garage frame. Find the speed of the limo with respect to the garage required for this scenario to take place.

SEC. 38-13 ■ RELATIVITY OF VELOCITIES

41. Backfire. An unpowered rocket moves past you in the positive x direction at speed $v^{\text{rel}} = 0.9c$. This rocket fires a bullet out the back that you measure to be moving at speed $v_{\text{bullet}} = 0.3c$ in the positive x direction. With what speed relative to the rocket did the rocket observer fire the bullet out the back of her ship?

42. Separating Galaxies. Galaxy A is measured to be receding from us on Earth with a speed of $0.3c$. Galaxy B, located in precisely the opposite direction, is also receding from us at the same speed. What recessional velocity will an observer on galaxy A measure (a) for our galaxy, and (b) for galaxy B?

43. Decaying K^0 Meson. Touchstone Example 38-7 concluded that when a K^0 meson at rest decays into two daughter π mesons, they move in opposite directions in the rest frame of the original K^0 meson, each with a speed of $0.828c$. Now suppose that the initial K^0 meson moves with speed $v^{\text{rel}} = 0.9c$ as measured in the laboratory frame. What are the maximum and minimum speeds of the daughter π mesons with respect to the laboratory?

44. Transit Time. An unpowered spaceship whose rest length is 350 meters has a speed $0.82c$ with respect to Earth. A micrometeorite, also with speed of $0.82c$ with respect to Earth, passes the spaceship on an antiparallel track that is moving in the opposite direction. How long does it take the micrometeorite to pass the spaceship as measured on the ship?

SEC. 38-14 ■ DOPPLER SHIFT

45. Listening to the Traveler. A spaceship moving away from Earth at a speed $0.900c$ radios its reports back to Earth using a frequency of 100 MHz measured in the spaceship frame. To what frequency must Earth’s receivers be tuned in order to receive the reports?

46. Speed Trap. How fast would you have to approach a red traffic light in order that it appears green to you?

47. Redshift Factor z . Astrophysicists describe the redshift of receding astronomical objects using the **redshift factor z** , defined implicitly in the following equation:

$$\lambda_{\text{observed}} \equiv (1 + z)\lambda_{\text{emitted}}.$$

Here $\lambda_{\text{observed}}$ is the wavelength of light observed from Earth, while λ_{emitted} is the wavelength of the light emitted from the source as measured in the rest frame of the source. The emitted wavelength is known if one knows the emitting atom, identified from the pattern of different wavelengths characteristic of that atom. Astrophysicists measuring the redshifts of light from extremely remote quasars calculate a z -factor in the neighborhood of $z \approx 6$. Use the Doppler

shift equations of special relativity to determine how fast such quasars are moving away from Earth. *Note:* Actually, for such distant objects the unmodified Doppler shift formula of special relativity does not apply. Instead, one thinks of the space between Earth and the source expanding as the universe expands; the wavelength of the light expands with this expansion of the universe as it travels from the source quasar to us.

48. Receding Galaxy. Figure 38-11 shows a graph of intensity versus wavelength for light reaching Earth from galaxy NGC 7319, which is about 3×10^8 light-years away. The most intense light is emitted by the oxygen in that galaxy. In a laboratory, that emission is at wavelength $\lambda = 513$ nm, but in the light from NGC 7319 it has been shifted to 525 nm due to the Doppler effect. (Indeed, all the emissions from that galaxy have been shifted.) (a) According to special relativity Doppler shift theory, what is the radial speed of

galaxy NGC 7319 relative to Earth? (b) Is the relative motion toward or away from Earth?

FIGURE 38-11 ■ Problem 48

Additional Problems

49. Exodus from Earth. A billion years from now our Sun will increase its heat, destroying life on Earth. Still later the sun will expand as a red giant, swallowing the Earth and annihilating any remaining life on all planets in the solar system. In anticipation of these catastrophes, an advanced Earth civilization a million years from now develops a transporter mechanism that reduces living beings to data and sends the data by radio to planets orbiting younger stars. The living beings on Earth are destroyed by this process but are reconstituted and restored to life on the distant planets. Your descendent Rasmia Kirmani leaves Earth as data at a time we will take to be zero and is quickly reconstituted after arrival of her data set on the planet Zircon, 100 ly distant from Earth. Assume that Earth and Zircon are relatively at rest.

- How much does Rasmia age during her outward trip to Zircon?
- How much older is Earth and its civilization when Rasmia is resurrected on Zircon?
- Rasmia has a productive and happy life on Zircon and dies as a pioneer hero after 150 years living on that planet. How soon after her departure from Earth can Rasmia's obituary be received on Earth?
- Over the millennia between our time and then, specialists whom we now call geneticists discover that there is no such thing as a superperson (man or woman), but rather that a minimum variety of genetic types must be maintained and continually recombined (by whatever method is then current) in order to sustain a healthy population. To this end, several dozen healthy individuals are deconstructed on Earth and transported to Zircon, where each individual is quickly reproduced in thousands of copies (using the same data set over and over) in order to populate the planet

rapidly. It takes 5 full generations from birth to death, each generation an average of 200 years, to determine whether or not the new population has been successfully established. How soon after transmission of the dozens of original data sets from Earth can Earth's people learn whether or not this project has been successful?

50. Electron in Orbit. Use Newtonian mechanics to calculate the speed of an electron in the lowest Bohr orbit, which has one quantum of angular momentum:

$$mvr = \hbar = \frac{h}{2\pi}.$$

Carry out this calculation for (a) hydrogen ($Z = 1$) and (b) uranium ($Z = 92$). Insofar as the Bohr model of the atom can be trusted, is relativity required to find the correct answer for (c) hydrogen, (d) uranium?

51. Super Cosmic Rays. The Giant Shower Array detector, spread over 100 square kilometers in Japan, detects pulses of particles from cosmic rays. Each detected pulse is assumed to originate in a single high-energy cosmic proton that strikes the top of the Earth's atmosphere. The highest energy of a single cosmic ray proton inferred from the data is 10^{20} eV. How long would it take that proton to cross our galaxy (10^5 light-years in diameter) as recorded on the wristwatch of the proton? (The answer is not zero!)

52. Synchronization by a Traveling Clock. Evelyn Brown does not approve of our latticework of rods and clocks and the use of a light flash to synchronize them.

- "I can synchronize my clocks in any way I choose!" she exclaims. Is she right?

- (b) Evelyn wants to synchronize two identical clocks, called Big Ben and Little Ben, which are at rest with respect to one another and separated by one million kilometers in their rest frame. She uses a third clock, identical in construction with the first two, that travels with constant velocity between them. As her moving clock passes Big Ben, it is set to read the same time as Big Ben. When the moving clock passes Little Ben, that outpost clock is set to read the same time as the traveling clock. “Now Big Ben and Little Ben are synchronized,” says Evelyn Brown. Is Evelyn’s method correct?
- (c) After Evelyn completes her synchronization of Little Ben by her method, how does the reading of Little Ben compare with the reading of a nearby clock on a latticework at rest with respect to Big Ben (and Little Ben) and synchronized by our standard method using a light flash? Evaluate in milliseconds any difference between the reading on Little Ben and the nearby lattice clock in the case that Evelyn’s traveling clock moved at a constant velocity of 500 000 kilometers per hour from Big Ben to Little Ben.
- (d) Evaluate the difference in the reading between the Evelyn-Brown-synchronized Little Ben and the nearby lattice clock when Evelyn’s synchronizing traveling clock moves 1000 times as fast as the speed given in part (c).

53. Down with Relativity! Sara Settlemyer is an intelligent layperson who carefully reads articles about science in the public press. She has the objections to relativity listed below. Respond to each of Sara’s objections clearly, decisively, and politely—without criticizing her!

- (a) “Observer A says that observer B’s clock runs slow, while B says that A’s clock runs slow. This is a logical contradiction. Therefore relativity should be abandoned.”
- (b) “Observer A says that B’s meter sticks are contracted along their direction of relative motion. B says that A’s meter sticks are contracted. This is a logical contradiction. Therefore relativity should be abandoned.”
- (c) “Anybody with common sense knows that travel at high speed in the direction of a receding light pulse decreases the speed with which the pulse recedes. Hence a flash of light cannot have the same speed for observers in relative motion. With this disproof of the Principle of Relativity, all of relativity collapses.”
- (d) “Relativity is preoccupied with how we *observe* things, not with what is *really* happening. Therefore relativity is not a scientific theory, since science deals with *reality*.”
- (e) “Relativity offers no way to describe an event without coordinates, and no way to speak about coordinates without referring to one or another particular reference frame. However, physical events have an existence independent of all choice of coordinates and reference frames. Therefore the special relativity you talk about in this chapter cannot be the most fundamental theory of events and the relation between events.”

54. The Photon as a Zero-Mass Particle. A photon, the quantum of light, can be considered to be a zero-mass particle.

- (a) Using this definition and Eq. 38-18, show that the relation between energy and momentum for the photon is $E = |pc|$, where the “absolute value” vertical lines ensure that energy is positive.
- (b) A π^0 meson decays rapidly into two gamma rays (high-energy photons). In the rest frame of the original π^0 meson, what are the relative directions of the two outgoing photons?
- (c) If the mass of the π^0 meson is $135 \text{ MeV}/c^2$, what is the energy of each outgoing gamma ray?

55. Pair Production with Gamma Rays. Two gamma rays of equal energy E_p and equal and opposite momenta are incident on a nucleus. (See Figure 38-12.) The collision leads to annihilation of the gamma rays and creation of an electron–positron pair. The lowest energy (the “threshold energy”) of incident photons for this production leaves the resulting electron and positron at rest with respect to the nucleus. (The nucleus acts as midwife to this birth and is not changed by the interaction.)

- (a) What is the threshold energy E_p of each photon for this creation to take place?
- (b) Generalize Eq. 38-18 to *define* the mass M_s of a system of particles, given the total energy E_s and net momentum p_s of the system:

$$M_s^2 c^4 \equiv E_s^2 - p_s^2 c^2.$$

What is the mass M_s of the system of particles after the collision? Before the collision?

- (c) *Mass without mass?* Now let the “nuclear” mass m become less and less. In the limit $m \rightarrow 0$, what is the mass of the system after the collision? Before the collision? Before the collision, you apparently have a system with mass composed of “particles,” each of which has zero mass. Does this make sense?

FIGURE 38-12 ■ Problem 55.

56. Resonant Absorption of a Gamma Ray. A gamma ray (an energetic photon) falls on a nucleus of initial mass m , initially at rest. The energy E_p of the incoming gamma ray matches the energy separation between the lowest energy of the nucleus and its first ex-

cited state, so the incident photon is absorbed. We want to know the mass m^* of the excited nucleus. (see Fig. 38-13.)

- (a) Show that the conservation of energy and momentum equations are, in an obvious notation:

$$E_p + mc^2 = E_{m^*}$$

and
$$\frac{E_p}{c} = p_{m^*} = \frac{(E_{m^*}^2 - m^{*2}c^4)^{1/2}}{c}.$$

- (b) Combine the two conservation equations to find an expression for m^* as a function of E_p , m , and c .
 (c) Show that for very small values of E_p the limiting result is $m^* = m$. Explain why this limiting result is reasonable.

FIGURE 38-13 ■ Problem 56.

57. Photon Braking. A radioactive nucleus of known initial mass M and known initial total energy E_M emits a gamma ray (high-energy photon) in the direction of its motion, drops to its stable nonradioactive state of known mass m , and comes to rest. (see Fig. 38-14). Find an expression for the total energy E_M of the incoming nucleus. The unknown energy E_p of the outgoing gamma ray should not appear in your expression.

FIGURE 38-14 ■ Problem 57.

58. Limo and Garage Paradox. Review Problem 40, in which we concluded that a limo of proper length 30 m can fit into a garage of proper length 6 m with room to spare. This result is possible because the speeding limo is observed by Garageman to be Lorentz-

contracted. Carman protests that in the rest frame of the limo (in which the limo is its full proper length) it is the *garage* that is Lorentz-contracted. As a result, he claims, there is no possibility whatever that the limo can fit into the garage. What could be the possible basis for resolving this paradox? (*Hint:* Think about the space and time locations of two events: event A, front garage door closes and event B, rear garage door opens.)

59. Twin Paradox. The famous **twin paradox** is often introduced as follows: Two identical twins grow up together on Earth. When they reach adulthood, one twin zooms to a distant star and returns to find her stay-at-home sister much older than she is. Thus far no paradox. But Alexis Allen formulates the Twin Paradox for us:

“The theory of special relativity tells us that all motion is relative. With respect to the traveling twin, the Earth-bound twin moves away and then returns. Therefore it is the Earth-bound twin who should be younger than the ‘traveling’ twin. But when they meet again at the same place, it cannot possibly be that each twin is younger than the other twin. This Twin Paradox disproves relativity.”

The paradox is usually resolved by realizing that the traveling twin turns around. Everyone agrees which twin turns around, since the reversal of direction slams the poor traveler against the bulkhead of the decelerating starship, breaking her collarbone. The turnaround, evidenced by the broken collarbone, destroys the symmetry required for the paradox to hold. Good-bye Twin Paradox!

Still, Alexis’s father Cyril Allen has his doubts about this resolution of the paradox. “Your solution is extremely unsatisfying. It forces me to ask: What if the retro-rockets malfunction and will not fire at all to slow me down as I approach a distant star a thousand light-years from Earth? Then I cannot even stop at that star, much less turn around and head back to Earth. Instead, I continue moving away from Earth forever at the original constant speed. Does this mean that as I pass the distant star, one thousand light-years from Earth, it is no longer possible to say that I have aged less than my Earth-bound twin? But if not, then I would never have even gotten to the distant star at all during my hundred-year lifetime! Your resolution of the Twin Paradox is insufficient and unsatisfying.”

Write a half-page response to Cyril Allen, answering his objections politely but decisively.

60. The Runner on the Train Paradox. A train moves at 10 km/h along the track. A passenger sprints toward the rear of the train at 10 km/h with respect to the train. Our knee-jerk motto says that the train clocks “run slow” with respect to clocks on the track, and the runner’s watch “runs slow” with respect to train clocks. Therefore the runner’s watch should “run doubly slow” with respect to clocks on the track. But the runner is at rest with respect to the track. What gives? (This example illustrates the danger of the simple knee-jerk motto “Moving clocks run slow.”)

61. A Summer Evening’s Fantasy. You and a group of female and male friends stand outdoors at dusk watching the Sun set and notic-

ing the planet Venus in the same direction as the Sun. An alien ship lands beside you at the same instant that you see the Sun explode. The aliens admit that earlier they shot a laser flash at the Sun, which caused the explosion. They warn that the Sun's explosion emitted an immense pulse of particles that will blow away Earth's atmosphere. In confirmation, a short time after the aliens land you

notice Venus suddenly change color. You and your friends plead with the aliens to take your group away from Earth in order to establish the human gene pool elsewhere. They agree. Describe the conditions under which your escape plan will succeed. Be specific and use numbers. Assume that the Sun is 8 light-minutes from Earth and Venus is 2 light-minutes from Earth.

The International System of Units (SI)*

1 SI Base Units

1. The SI Base Units			
Quantity	Name	Symbol	Definition
length	meter	m	“... the length of the path traveled by light in vacuum in 1/299 792 458 of a second.” (1983)
mass	kilogram	kg	“... this prototype [a certain platinum–iridium cylinder] shall henceforth be considered to be the unit of mass.” (1889)
time	second	s	“... the duration of 9 192 631 770 periods of the radiation corresponding to the transition between the two hyperfine levels of the ground state of the cesium-133 atom.” (1967)
electric current	ampere	A	“... that constant current which, if maintained in two straight parallel conductors of infinite length, of negligible circular cross section, and placed 1 meter apart in vacuum, would produce between these conductors a force equal to 2×10^{-7} newton per meter of length.” (1946)
thermodynamic temperature	kelvin	K	“... the fraction 1/273.16 of the thermodynamic temperature of the triple point of water.” (1967)
amount of substance	mole	mol	“... the amount of substance of a system which contains as many elementary entities as there are atoms in 0.012 kilogram of carbon-12.” (1971)
luminous intensity	candela	cd	“... the luminous intensity, in a given direction, of a source that emits monochromatic radiation of frequency 540×10^{12} hertz and that has a radiant intensity in that direction of 1/683 watt per steradian.” (1979)

2 The SI Supplementary Units

2. The SI Supplementary Units		
Quantity	Name of Unit	Symbol
plane angle	radian	rad
solid angle	steradian	sr

*Adapted from “The International System of Units (SI),” National Bureau of Standards Special Publication 330, 2001 edition. The definitions above were adopted by the General Conference of Weights and Measures, an international body, on the dates shown. In this book we do not use the candela.

3 Some SI Derivations

3. Some SI Derived Units			
Quantity	Name of Unit	Symbol	In Terms of other SI Units
area	square meter	m ²	
volume	cubic meter	m ³	
frequency	hertz	Hz	s ⁻¹
mass density (density)	kilogram per cubic meter	kg/m ³	
speed, velocity	meter per second	m/s	
rotational velocity	radian per second	rad/s	
acceleration	meter per second per second	m/s ²	
rotational acceleration	radian per second per second	rad/s ²	
force	newton	N	kg · m/s ²
pressure	pascal	Pa	N/m ²
work, energy, quantity of heat	joule	J	N · m
power	watt	W	J/s
quantity of electric charge	coulomb	C	A · s
potential difference, electromotive force	volt	V	W/A
electric field strength	volt per meter (or newton per coulomb)	V/m	N/C
electric resistance	ohm	Ω	V/A
capacitance	farad	F	A · s/V
magnetic flux	weber	Wb	V · s
inductance	henry	H	V · s/A
magnetic flux density	tesla	T	Wb/m ²
magnetic field strength	ampere per meter	A/m	
entropy	joule per kelvin	J/K	
specific heat	joule per kilogram kelvin	J/(kg · K)	
thermal conductivity	watt per meter kelvin	W/(m · K)	
radiant intensity	watt per steradian	W/sr	

4 Mathematical Notation

Poorly chosen mathematical notation can be a source of considerable confusion to those trying to learn and to do physics. For example, ambiguity in the meaning of a mathematical symbol can prevent a reader from understanding the meaning of a crucial relationship. It is also difficult to solve problems when the symbols used to represent different quantities are not distinctive. In this text we have taken special care to use mathematical notation in ways that allow important distinctions to be easily visible both on the printed page and in handwritten work.

An excellent starting point for clear mathematical notation is the U.S. National Institute of Standard and Technology's Special Publication 811 (SP 811), *Guide for the Use of the International System of Units (SI)*, available at <http://physics.nist.gov/cuu/Units/bibliography.html>. In addition to following the National Institute guidelines, we have made a number of systematic choices to facilitate the translation of printed notation into handwritten mathematics. For example:

- Instead of making vectors bold, vector quantities (even in one dimension) are denoted by an arrow above the symbol. So printed equations look like handwritten equations. Example: \vec{v} rather than \mathbf{v} is used to denote an instantaneous velocity.

- In general, each vector component has an explicit subscript denoting that it represents the component along a chosen coordinate axis. The one exception is the position vector, \vec{r} , whose components are simply written as x , y , and z . For example, $\vec{r} = x\hat{i} + y\hat{j} + z\hat{k}$, whereas, $\vec{v} = v_x\hat{i} + v_y\hat{j} + v_z\hat{k}$.
- To emphasize the distinction between a vector's components and its magnitude, we write the magnitude of a vector, such as \vec{F} , as $|\vec{F}|$. However, when it is obvious that a magnitude is being described, we use the plain symbol (such as F with no coordinate subscript) to denote a vector's magnitude.
- We often choose to spell out the names of objects that are associated with mathematical variables—writing, for example, \vec{v}_{ball} and not \vec{v}_b for the velocity of a ball.
- Numerical subscripts most commonly denote sequential times, positions, velocities, and so on. For example, x_1 is the x -component of the position of some object at time t_1 , whereas x_2 is the value of that parameter at some later time t_2 . We have avoided using the subscript zero to denote initial values, as in x_0 to denote “the initial position along the x axis,” to emphasize that *any* time can be chosen as the initial time for consideration of the subsequent time evolution of a system.
- To avoid confusing the numerical time sequence labels with object labels, we prefer to use capital letters as object labels. For example, we would label two particles A and B rather than 1 and 2. Thus, $\vec{p}_{A,1}$ and $\vec{p}_{B,1}$ would represent the translational momenta of two particles before a collision whereas $\vec{p}_{A,2}$ and $\vec{p}_{B,2}$ would be their momenta after a collision.
- To avoid excessively long strings of subscripts, we have made the unconventional choice to write all adjectival labels as *superscripts*. Thus, Newton's Second Law is written $\vec{F}^{\text{net}} = m\vec{a}$ whereas the sum of the forces acting on a certain object might be written as $\vec{F}^{\text{net}} = \vec{F}^{\text{grav}} + \vec{F}^{\text{app}}$. To avoid confusion with mathematical exponents, an adjectival label is never a single letter.
- Following a usage common in contemporary physics, the time average of a variable \vec{v} is denoted as $\langle \vec{v} \rangle$ and not as \vec{v}_{avg} .
- Physical constants such as e , c , g , G , are all **positive** scalar quantities.

5 Significant Figures and the Precision of Numerical Results

Quoting the result of a calculation or a measurement to the correct number of significant figures is merely a way of telling your reader roughly how precise you believe the result to be. Quoting too many significant figures overstates the precision of your result and quoting too few implies less precision than the result may actually possess. So how many significant figures should you quote when reporting your result.

Determining Significant Figures

Before answering the question of how many significant figures to quote, we need to have a clear method for determining how many significant figures a reported number has. The standard method is quite simple:

METHOD FOR COUNTING SIGNIFICANT FIGURES: Read the number from left to right, and count the first nonzero digit and all the digits (zero or not) to the right of it as significant.

Using this rule, 350 mm, 0.000350 km, and 0.350 m each has *three* significant figures. In fact, each of these numbers merely represents the same distance, expressed in different units. As you can see from this example, the number of *decimal places* that a number has is *not* the same as its number of *significant figures*. The first of these distances has zero decimal places, the second has six decimal places, and the third has three, yet all three of these numbers have three significant figures.

One consequence of this method is especially worth noting. Trailing zeros count as significant figures. For example, 2700 m/s has four significant figures. If you really meant it to have only three significant figures, you would have to write it either as 2.70 km/s (changing the unit) or 2.70×10^3 m/s (using scientific notation.)

A Simple Rule for Reporting Significant Figures in a Calculated Result

Now that you know how to count significant figures, how many should the result of a calculation have? A simple rule that will work in most calculations is:

SIGNIFICANT FIGURES IN A CALCULATED RESULT: The common practice is to quote the result of a calculation to the number of significant figures of the *least* precise number used in the calculation.

Although this simple rule will often either understate or (less frequently) overstate the precision of a result, it still serves as a good rule-of-thumb for everyday numerical work. In introductory physics you will only rarely encounter data that are known to better than two, three, or four significant figures. This simple rule then tells you that you can't go very far wrong if you round off all your final results to three significant figures.

There are two situations in which the simple rule should *not* be applied to a calculation. One is when an exact number is involved in the calculation and another is when a calculation is done in parts so that intermediate results are used.

1. **Using Exact Data** There are some obvious situations in which a number used in a calculation is exact. Numbers based on counting items are exact. For example, if you are told that there are 5 people on an elevator, there are exactly 5 people, not 4.7 or 5.1. Another situation arises when a number is exact by definition. For example, the conversion factor 2.54 cm/inch does *not* have three significant figures because the inch is *defined* to be exactly 2.5400000 . . . cm. *Data that are known exactly should not be included when deciding which of the original data has the fewest significant figures.*
2. **Significant Figures in Intermediate Results** Only the final result at the end of your calculation should be rounded using the simple rule. Intermediate results should never be rounded. Spreadsheet software takes care of this for you, as does your calculator if you store your intermediate results in its memory rather than writing them down and then rekeying them. If you must write down intermediate results, keep a few more significant figures than your final result will have.

Understanding and Refining the Simple Significant Figure Rule

Quoting the result of a calculation or measurement to the correct number of significant figures is a way of indicating its precision. You need to understand what limits the precision of data before you fully understand how to use the simple rule or its exceptions.

Absolute Precision There are two ways of talking about precision. First there is *absolute precision*, which tells you explicitly the smallest scale division of the measurement. It's always quoted in the same units as the measured quantity. For example, saying "I measured the length of the table to the nearest centimeter" states the absolute precision of the measurement. The absolute precision tells you how many *decimal places* the measurement has; it alone does not determine the number of significant figures. Example: if a table is 235 cm long, then 1 cm of absolute precision translates into three significant figures. On the other hand, if a table is for a doll's house and is only 8 cm long, then the same 1 cm of absolute precision has only one significant figure.

Relative Precision Because of this problem with absolute precision, scientists often prefer to describe the precision of data *relative* to the size of the quantity being measured. To use the previous examples, the *relative precision* of the length of the real table in the previous example is 1 cm out of 235 cm. This is usually stated as a ratio (1 part in 235) or as a percentage ($1/235 = 0.004255 \approx 0.4\%$). In the case of the toy table, the same 1 cm of absolute precision yields a relative precision of only 1 part in 8 or $1/8 = 0.125 = 12.5\%$.

Inconsistencies between Significant Figures and Relative Precision There is an inconsistency that goes with using a certain number of significant figures to express relative precision. Quoted to the same number of significant figures, the relative precision of results can be quite different. For example, 13 cm and 94 cm both have two significant figures. Yet the first is specified to only 1 part in 13 or $1/13 \approx 10\%$, whereas the second is known to 1 part in 94 or $1/94 \approx 1\%$. This bias toward greater relative precision for results with larger first significant figures is one weakness of using significant figures to track the precision of calculated results. You can partially address this problem, by including one more significant figure than the simple rule suggests, when the final result of a calculation has a 1 as its first significant figure.

Multiplying and Dividing When multiplying or dividing numbers, the *relative* precision of the result cannot exceed that of the least precise number used. Since the number of significant figures in the result tells us its relative precision, the simple rule is all that you need when you multiply or divide. For example, the area of a strip of paper of measured size is 280 cm by 2.5 cm would be correctly reported, according to the simple rule, as $7.0 \times 10^2 \text{ cm}^2$. This result has only two significant figures since the less precise measurement, 2.5 cm, that went into the calculation had only two significant figures. Reporting this result as 700 cm^2 would not be correct since this result has three significant figures, exceeding the relative precision of the 2.5 cm measurement.

Addition and Subtraction When adding or subtracting, you line up the decimal points before you add or subtract. This means that it's the *absolute* precision of the least precise number that limits the precision of the sum or the difference. This can lead to some exceptions to the simple rule. For example, adding 957 cm and 878 cm yields 1835 cm. Here the result is reliable to an absolute precision of about 1 cm since both of the original distances had this reliability. But the result then has four significant figures whereas each of the original numbers had only three. If, on the other hand, you take the difference between these two distances you get 79 cm. The difference is still reliable to about 1 cm, but that absolute precision now translates into only two significant figures worth of relative precision. So, you should be careful when adding or subtracting, since addition can actually increase the relative precision of your result and, more important, subtraction can reduce it.

Evaluating Functions What about the evaluation of functions? For example, how many significant figures does the $\sin(88.2^\circ)$ have? You can use your calculator to answer this question. First use your calculator to note that $\sin(88.2^\circ) = 0.999506$. Now add 1 to the least significant decimal place of the argument of the function and evaluate it again. Here this gives $\sin(88.3^\circ) = 0.999559$. Take the last significant figure in the result to be *the first one from the left that changed* when you repeated the calculation. In this example the first digit that changed was the 0; it became a 5 (the second 5) in the recalculation. So, using the empirical approach gives you five significant figures.

APPENDIX

APPENDIX E

Mathematical Formulas

Geometry

Circle of radius r : circumference = $2\pi r$; area = πr^2 .

Sphere of radius r : area = $4\pi r^2$; volume = $\frac{4}{3}\pi r^3$.

Right circular cylinder of radius r and height h :
area = $2\pi r^2 + 2\pi rh$; volume = $\pi r^2 h$.

Triangle of base a and altitude h : area = $\frac{1}{2}ah$.

Quadratic Formula

If $ax^2 + bx + c = 0$, then $x = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a}$.

Trigonometric Functions of Angle θ

$$\begin{aligned} \sin \theta &= \frac{y}{r} & \cos \theta &= \frac{x}{r} \\ \tan \theta &= \frac{y}{x} & \cot \theta &= \frac{x}{y} \\ \sec \theta &= \frac{r}{x} & \csc \theta &= \frac{r}{y} \end{aligned}$$

Pythagorean Theorem

In this right triangle,
 $a^2 + b^2 = c^2$

Triangles

Angles are A, B, C

Opposite sides are a, b, c

Angles $A + B + C = 180^\circ$

$$\frac{\sin A}{a} = \frac{\sin B}{b} = \frac{\sin C}{c}$$

$$c^2 = a^2 + b^2 - 2ab \cos C$$

Exterior angle $D = A + C$

Mathematical Signs and Symbols

- = equals
- ≈ equals approximately
- ~ is the order of magnitude of
- ≠ is not equal to
- ≡ is identical to, is defined as
- > is greater than (\gg is much greater than)
- < is less than (\ll is much less than)
- ≥ is greater than or equal to (or, is no less than)
- ≤ is less than or equal to (or, is no more than)
- ± plus or minus
- ∝ is proportional to

Σ the sum of

$\langle x \rangle$ the average value of x

Trigonometric Identities

$$\sin(90^\circ - \theta) = \cos \theta$$

$$\cos(90^\circ - \theta) = \sin \theta$$

$$\sin \theta / \cos \theta = \tan \theta$$

$$\sin^2 \theta + \cos^2 \theta = 1$$

$$\sec^2 \theta - \tan^2 \theta = 1$$

$$\csc^2 \theta - \cot^2 \theta = 1$$

$$\sin 2\theta = 2 \sin \theta \cos \theta$$

$$\cos 2\theta = \cos^2 \theta - \sin^2 \theta = 2 \cos^2 \theta - 1 = 1 - 2 \sin^2 \theta$$

$$\sin(\alpha \pm \beta) = \sin \alpha \cos \beta \pm \cos \alpha \sin \beta$$

$$\cos(\alpha \pm \beta) = \cos \alpha \cos \beta \mp \sin \alpha \sin \beta$$

$$\tan(\alpha \pm \beta) = \frac{\tan \alpha \pm \tan \beta}{1 \mp \tan \alpha \tan \beta}$$

$$\sin \alpha \pm \sin \beta = 2 \sin \frac{1}{2}(\alpha \pm \beta) \cos \frac{1}{2}(\alpha \mp \beta)$$

$$\cos \alpha + \cos \beta = 2 \cos \frac{1}{2}(\alpha + \beta) \cos \frac{1}{2}(\alpha - \beta)$$

$$\cos \alpha - \cos \beta = -2 \sin \frac{1}{2}(\alpha + \beta) \sin \frac{1}{2}(\alpha - \beta)$$

Binomial Theorem

$$(1 + x)^n = 1 + \frac{nx}{1!} + \frac{n(n-1)x^2}{2!} + \dots \quad (x^2 < 1)$$

Exponential Expansion

$$e^x = 1 + x + \frac{x^2}{2!} + \frac{x^3}{3!} + \dots$$

Logarithmic Expansion

$$\ln(1 + x) = x - \frac{1}{2}x^2 + \frac{1}{3}x^3 - \dots \quad (|x| < 1)$$

Trigonometric Expansions (θ in radians)

$$\sin \theta = \theta - \frac{\theta^3}{3!} + \frac{\theta^5}{5!} - \dots$$

$$\cos \theta = 1 - \frac{\theta^2}{2!} + \frac{\theta^4}{4!} - \dots$$

$$\tan \theta = \theta + \frac{\theta^3}{3} + \frac{2\theta^5}{15} + \dots$$

Cramer's Rule

Two simultaneous equations in unknowns x and y ,

$$a_1x + b_1y = c_1 \quad \text{and} \quad a_2x + b_2y = c_2,$$

have the solutions

$$x = \frac{\begin{vmatrix} c_1 & b_1 \\ c_2 & b_2 \end{vmatrix}}{\begin{vmatrix} a_1 & b_1 \\ a_2 & b_2 \end{vmatrix}} = \frac{c_1b_2 - c_2b_1}{a_1b_2 - a_2b_1}$$

and

$$y = \frac{\begin{vmatrix} a_1 & c_1 \\ a_2 & c_2 \end{vmatrix}}{\begin{vmatrix} a_1 & b_1 \\ a_2 & b_2 \end{vmatrix}} = \frac{a_1c_2 - a_2c_1}{a_1b_2 - a_2b_1}.$$

Products of Vectors

Let \hat{i} , \hat{j} , and \hat{k} be unit vectors in the x , y , and z directions. Then

$$\hat{i} \cdot \hat{i} = \hat{j} \cdot \hat{j} = \hat{k} \cdot \hat{k} = 1, \quad \hat{i} \cdot \hat{j} = \hat{j} \cdot \hat{k} = \hat{k} \cdot \hat{i} = 0,$$

$$\hat{i} \times \hat{i} = \hat{j} \times \hat{j} = \hat{k} \times \hat{k} = 0,$$

$$\hat{i} \times \hat{j} = \hat{k}, \quad \hat{j} \times \hat{k} = \hat{i}, \quad \hat{k} \times \hat{i} = \hat{j}.$$

Any vector \vec{a} with components a_x , a_y , and a_z along the x , y , and z axes can be written as

$$\vec{a} = a_x\hat{i} + a_y\hat{j} + a_z\hat{k}.$$

Let \vec{a} , \vec{b} , and \vec{c} be arbitrary vectors with magnitudes a , b , and c . Then

$$\vec{a} \times (\vec{b} + \vec{c}) = (\vec{a} \times \vec{b}) + (\vec{a} \times \vec{c})$$

$$(s\vec{a}) \times \vec{b} = \vec{a} \times (s\vec{b}) = s(\vec{a} \times \vec{b}) \quad (s = \text{a scalar}).$$

Let θ be the smaller of the two angles between \vec{a} and \vec{b} . Then

$$\vec{a} \cdot \vec{b} = \vec{b} \cdot \vec{a} = a_xb_x + a_yb_y + a_zb_z = ab \cos \theta$$

$$\vec{a} \times \vec{b} = -\vec{b} \times \vec{a} = \begin{vmatrix} \hat{i} & \hat{j} & \hat{k} \\ a_x & a_y & a_z \\ b_x & b_y & b_z \end{vmatrix}$$

$$= \hat{i} \begin{vmatrix} a_y & a_z \\ b_y & b_z \end{vmatrix} - \hat{j} \begin{vmatrix} a_x & a_z \\ b_x & b_z \end{vmatrix} + \hat{k} \begin{vmatrix} a_x & a_y \\ b_x & b_y \end{vmatrix}$$

$$= (a_yb_z - b_ya_z)\hat{i} + (a_zb_x - b_z a_x)\hat{j} + (a_xb_y - b_x a_y)\hat{k}$$

$$|\vec{a} \times \vec{b}| = ab \sin \theta$$

$$\vec{a} \cdot (\vec{b} \times \vec{c}) = \vec{b} \cdot (\vec{c} \times \vec{a}) = \vec{c} \cdot (\vec{a} \times \vec{b})$$

$$\vec{a} \times (\vec{b} \times \vec{c}) = (\vec{a} \cdot \vec{c})\vec{b} - (\vec{a} \cdot \vec{b})\vec{c}$$

Derivatives and Integrals

In what follows, the letters u and v stand for any functions of x , and a and m are constants. To each of the indefinite integrals should be added an arbitrary constant of integration. The *Handbook of Chemistry and Physics* (CRC Press Inc.) gives a more extensive tabulation.

Derivatives

$$1. \frac{dx}{dx} = 1$$

$$2. \frac{d}{dx}(au) = a \frac{du}{dx}$$

$$3. \frac{d}{dx}(u + v) = \frac{du}{dx} + \frac{dv}{dx}$$

$$4. \frac{d}{dx}x^m = mx^{m-1}$$

$$5. \frac{d}{dx} \ln x = \frac{1}{x}$$

$$6. \frac{d}{dx}(uv) = u \frac{dv}{dx} + v \frac{du}{dx}$$

$$7. \frac{d}{dx}e^x = e^x$$

$$8. \frac{d}{dx} \sin x = \cos x$$

$$9. \frac{d}{dx} \cos x = -\sin x$$

$$10. \frac{d}{dx} \tan x = \sec^2 x$$

$$11. \frac{d}{dx} \cot x = -\csc^2 x$$

$$12. \frac{d}{dx} \sec x = \tan x \sec x$$

$$13. \frac{d}{dx} \csc x = -\cot x \csc x$$

$$14. \frac{d}{dx} e^u = e^u \frac{du}{dx}$$

$$15. \frac{d}{dx} \sin u = \cos u \frac{du}{dx}$$

$$16. \frac{d}{dx} \cos u = -\sin u \frac{du}{dx}$$

Integrals

1. $\int dx = x$

2. $\int au \, dx = a \int u \, dx$

3. $\int (u + v) \, dx = \int u \, dx + \int v \, dx$

4. $\int x^m \, dx = \frac{x^{m+1}}{m+1} \quad (m \neq -1)$

5. $\int \frac{dx}{x} = \ln |x|$

6. $\int u \frac{dv}{dx} \, dx = uv - \int v \frac{du}{dx} \, dx$

7. $\int e^x \, dx = e^x$

8. $\int \sin x \, dx = -\cos x$

9. $\int \cos x \, dx = \sin x$

10. $\int \tan x \, dx = \ln |\sec x|$

11. $\int \sin^2 x \, dx = \frac{1}{2}x - \frac{1}{4}\sin 2x$

12. $\int e^{-ax} \, dx = -\frac{1}{a} e^{-ax}$

13. $\int xe^{-ax} \, dx = -\frac{1}{a^2} (ax + 1)e^{-ax}$

14. $\int x^2 e^{-ax} \, dx = -\frac{1}{a^3} (a^2 x^2 + 2ax + 2)e^{-ax}$

15. $\int_0^{\infty} x^n e^{-ax} \, dx = \frac{n!}{a^{n+1}}$

16. $\int_0^{\infty} x^{2n} e^{-ax^2} \, dx = \frac{1 \cdot 3 \cdot 5 \cdots (2n-1)}{2^{n+1} a^n} \sqrt{\frac{\pi}{a}}$

17. $\int \frac{dx}{\sqrt{x^2 + a^2}} = \ln(x + \sqrt{x^2 + a^2})$

18. $\int \frac{x \, dx}{(x^2 + a^2)^{3/2}} = -\frac{1}{(x^2 + a^2)^{1/2}}$

19. $\int \frac{dx}{(x^2 + a^2)^{3/2}} = \frac{x}{a^2(x^2 + a^2)^{1/2}}$

20. $\int_0^{\infty} x^{2n+1} e^{-ax^2} \, dx = \frac{n!}{2a^{n+1}} \quad (a > 0)$

21. $\int \frac{x \, dx}{x + d} = x - d \ln(x + d)$

The values in parentheses in the column of molar masses are the mass numbers of the longest-lived isotopes of those elements that are radioactive. Melting points and boiling points in parentheses are uncertain. The data for gases are valid only when these are in their usual molecular state, such as H₂, He, O₂, Ne, etc. The specific heats of the gases are the values at constant pressure. *Primary source:* Adapted from J. Emsley, *The Elements*, 3rd ed., 1998, Clarendon Press, Oxford (www.webelements.com). Data on newest elements are current.

The names of elements 104 through 109 (Rutherfordium, Dubnium, Seaborgium, Bohrium, Hassium, and Meitnerium, respectively) were adopted by the International Union of Pure and Applied Chemistry (IUPAC) in 1997. As of early 2004, the discovery of elements 110 through 115 have been reported in scientific journals. See www.webelements.com for the latest information and newest elements.

Answers to Reading Exercises and Odd-Numbered Problems

(Answers that involve a proof, graph, or otherwise lengthy solution are not included.)

Chapter 1

RE 1-1: Examples include second or hour, meter or inch, and gram or kilogram.

RE 1-2: A 12-inch ruler would more likely change less over time than your foot, especially if you are still growing.

RE 1-3: The length of one day or the time it takes for the earth to rotate 360° about its own axis is not constant, because the speed of the earth's rotation is slowly decreasing with time.

RE 1-4: (a) Since 24 h of time occurs for each 360° of rotation or 4 min for each degree of longitude or 240 s for each degree of longitude, 20 min and 13 s will relate to a rotation or longitude change of $(1213 \text{ s})/(240 \text{ s/deg}) = 5.05$ degrees of longitude change. (b) If the clock is off by 2 min or 120 s, the longitude will be off by $(120 \text{ s})/(240 \text{ s/degree}) = 0.5$ degrees of longitude. (c) 360° or one revolution relates to one circumference of length. Therefore $0.5^\circ/360^\circ = x/(24\,000 \text{ nautical miles})$, or $x = 33.3$ nautical miles off course. Sailor beware!

RE 1-5: (a) If your watches are synchronized, you should measure the same time for the flash. For the same duration of time between the flash and thunder you both should have accurate watches and be located close to one another. (b) No, the 12 h (smaller) clock shows a time of 7:44 or a total elapsed time of 464 min since 12 o'clock. This is $464 \text{ min}/(1440 \text{ min/day}) = .322$ day elapsed. The 10 h (larger) clock shows a time of 8.23 hours elapsed since 10 o'clock ($12 \text{ o'clock on the other scale}$) or $8.23/(20 \text{ hr/day}) = .412$ day elapsed.

RE 1-6: One of many possible procedures would be to use the balance to determine the amount of clay equal to 1 kg. Divide the clay into 1000 equal volume pieces. Assuming the density of the clay is uniform, each clay piece now has a mass of 1 gram. Use these pieces with the balance and the object whose mass is to be determined to find its mass.

RE 1-7: (a) It is correct to write $1 \text{ min}/60 \text{ s} = 1$ because 1 minute and 60 seconds are the same *length* of time. It is meaningless to say $1/60 = 1$ when no units are specified. These numbers are not the same in the absence of the context of the units. (b) In terms of conversion factors and chain-link conversions, the number of minutes in a day is given by

$$1 \text{ d} = (1 \text{ d}) \left(\frac{24 \text{ h}}{1 \text{ d}} \right) \left(\frac{60 \text{ min}}{1 \text{ h}} \right) = 1440 \text{ m.}$$

RE 1-8: (a) 2. (b) Exact, if the cows were counted. (c) 6. Remember that the leading zeros don't count. (d) 7. Trailing zeros do count. (e) Exact, by definition.

RE 1-9: (a) 11. (b) Probably 3, we can't be sure. (c) 2.09×10^{10} ft. (d) 10^{10} ft (ten to the tenth feet).

RE 1-10: (a) You should keep all digits for intermediate results; thus you should use $A = 1.96 \text{ cm}^2$ for calculating V . (b) 2.7 cm^3 ; in this situation the answer can be to no more significant figures than the original data. (c) 2.8 cm^3 .

RE 1-11: (a) 27; (b) 198.0; (c) 0.6; (d) 0.9986, see *Evaluating Functions* in Appendix A, Section 5. (e) Since five is an exact number, the four significant numbers in the average length limits the answer to 10.67 m.

RE 1-12: (a) 0.01 s; (b) .01 s out of 1.78 s or $.01/1.78 = 0.00562$, or about 0.6%.

Problems

1. (a) 0.98 ft/ns; (b) 0.30 mm/ps. **3.** C, D, A, B, E; the important criterion is the constancy of the daily variation, not its magnitude. **5.** 0.12 AU/min **7.** 2.1 h. **9.** $1.21 \times 10^{12} \mu\text{s}$. **11.** (a) 160 rods; (b) 40 chains. **13.** (a) $4.00 \times 10^4 \text{ km}$; (b) $5.10 \times 10^8 \text{ km}^2$; (c) $1.08 \times 10^{12} \text{ km}^3$. **15.** $1.9 \times 10^{22} \text{ cm}^3$. **17.** 1.1×10^3 acre-feet. **19.** 9.0×10^{49} . **21.** (a) 10^3 kg ; (b) 158 kg/s. **23.** (a) $1.18 \times 10^{-29} \text{ m}^3$. **25.** 3.8 mg/s. **27.** $8 \times 10^2 \text{ km}$. **29.** 6.0×10^{26} . **31.** (a) 60.8 W; (b) 43.3 Z. **33.** 89 km. **35.** $\approx 1 \times 10^{36}$. **37.** 700 to 1500. **39.** (a) 293 U.S. bushels; (b) 3.81×10^3 U.S. bushels. **41.** 9.4×10^{-3} . **43.** 5.95 km. **45.** $1.9 \times 10^5 \text{ kg}$. **47.** 2×10^4 to 4×10^4 . **49.** 10.7. **59.** (a) 13 597 kg; (b) 4917 L; (c) 6172 kg; (d) 20 075 L; (e) 45%

Chapter 2

RE 2-1: (b), (c), and (d).

RE 2-2: Correct order: (c), (b), and (a).

RE 2-3: Yes, the displacement can be positive as long as the particle moves to a less negative position.

RE 2-4: (a) Average velocity is the displacement divided by the total time $\langle v_x \rangle = 10 \text{ mi}/30 \text{ min} = 0.33 \text{ mi/min}$ due east. (b) Average speed is the total distance traveled divided by the total time $\langle s \rangle = 30 \text{ mi}/30 \text{ min} = 1 \text{ mi/min}$. (c) The answers are different because the displacement is different from the total distance traveled in the 30 minute time period.

RE 2-5: Instantaneous speed. The speedometer only tells you the speed at which you are currently driving, not your acceleration or direction.

Ans-2 Answers to Reading Exercises and Odd-Numbered Problems

RE 2-6: (a) Remember that the velocity is the time derivative of the position equation. The velocity will be constant if it has no time dependence. Position equations 1 and 4 give a constant velocity. (b) The velocity is negative in equations 2 and 3.

RE 2-7: In returning to x_1 the total displacement $\Delta x = x_1 - x_1$ is zero. Since $\langle v_x \rangle = \Delta x / \Delta t$, the average velocity is also zero.

RE 2-8: (a) +, (b) -, (c) -, (d) +; remember that \vec{a} will have the same direction as $\Delta \vec{v}$ or $\vec{v}_2 - \vec{v}_1$.

RE 2-9: The equations of Table 2-1 apply when a_x is constant. Take the second derivative of x with respect to t to find a_x . Only equations 1, 3 and 4 give a constant a_x ($a_x = 0$ is a constant).

Problems

1. 414 ms. **3.** (a) +40 km/h; (b) 40 km/h. **5.** (a) 73 km/h; (b) 68 km/h; (c) 70 km/h; (d) 0. **7.** (a) 0, -2, 0, 12 m; (b) +12 m; (c) +7 m/s. **9.** 1.4 m. **11.** (a) -6 m/s; (b) negative x direction; (c) 6 m/s; (d) first smaller, then zero, and then larger; (e) yes ($t = 2$ s); (f) no. **13.** 100 m. **15.** (a) velocity squared; (b) acceleration; (c) m^2/s^2 , m/s^2 . **17.** 20 m/s^2 , in the direction opposite to its initial velocity. **19.** (a) m/s^2 , m/s^3 ; (b) 1.0 s; (c) 82 m; (d) -80 m; (e) 0, -12, -36, -72 m/s; (f) -6, -18, -30, -42 m/s^2 . **21.** 0.10 m. **23.** (a) 1.6 m/s; (b) 18 m/s. **25.** (a) 3.1×10^6 s = 1.2 months; (b) 4.6×10^{13} m. **27.** 1.62×10^{15} m/s^2 . **29.** 2.5 s. **31.** (a) 3.56 m/s^2 ; (b) 8.43 m/s. **33.** (a) 5.00 m/s; (b) 1.67 m/s^2 ; (c) 7.50 m. **35.** (a) 0.74 s; (b) -6.2 m/s^2 . **37.** (a) 10.6 m; (b) 41.5 s. **39.** (a) 30 s; (b) 300 m. **41.** (a) 54 m, 18 m/s, -12 m/s^2 ; (b) 64 m at $t = 4.0$ s; (c) 24 m/s at $t = 2.0$ s; (d) -24 m/s^2 ; (e) 18 m/s. **49.** (a) 0.75 s; (b) 50 m. **57.** Since there is some latitude in what might be considered “the right answer” here, we have elected to mention some Web sites (current as of May 2002) where graphs for model rocket kinematics are shown: <http://www.rocket-roar.com/rap/alt.html>; <http://mks.nio-brara.com/altitude.html>; <http://www.boilerbay.com/rockets/>; **59.** 40 m.

Chapter 3

RE 3-1: (a) The velocity of the cart on the carpet goes to zero at $t = 1.1$ s. (b) The velocity of the cart on the track at $t = 1.1$ s is approximately 0.65 m/s, so it still has (0.65 m/s/0.80 m/s) or 81% of its initial speed.

RE 3-2: (a) An elevator or car starting or stopping, or a merry-go-round moving at a constant speed. (b) The person feels heavy during startup and light during stopping. Objects, such as a marble, start to move with no apparent reason on the merry-go-round floor.

RE 3-3: (a) No acceleration: Sliding a block along a table with a small steady force or shoving on a huge object like a desk or car, etc., can result in either constant velocity motion or an inability to move the object (desk or car). (b) Acceleration: Pushing hard on a sliding block, pushing on a rolling ball, pushing or pulling someone on a vehicle with wheels, etc.

RE 3-4: You would attach one end of the rubber band to a post and hook the other end of the rubber band to a calibrated spring scale. Then you would record the unstretched length of the rubber band and the fact that the force on it is 0 N. Next you would pull on the rubber band with the spring scale until it reads 1 N and record the new length of the rubber band. Then you would repeat the process as the spring scale reads 2 N, 3 N, etc., recording the rubber-band length each time. In that way you can generate either a look-up table or a graph of force vs. rubber-band length. If greater precision is needed, you could take data for many more force-scale readings.

RE 3-5: (a) $\vec{F} = (-26 \text{ N})\hat{i}$, $\vec{a} = (-0.42 \text{ m}/\text{s}^2)\hat{i}$; (b) $m = F/a = 62$ kg; (c) 62 kg

RE 3-6: (a) The mass measurement in part (b) above uses the ratio of the force to acceleration and hence is the inertial mass. (b) We assumed that the student is on the surface of planet Earth and that the bathroom scale was calibrated for the same planet.

RE 3-7: In both cases (a) and (b) the acceleration is zero, therefore the net force must also be zero. This will require all three forces to add to zero as vectors. (a) This requires \vec{F}_C to point to the left in the diagram with a magnitude of 2 N so $\vec{F}_C = (-2 \text{ N})\hat{i}$. (b) Since the acceleration is also zero in this case, we still have $\vec{F}_C = (-2 \text{ N})\hat{i}$.

RE 3-8: (a) Bottom right cart has a net force of -5 N, top left has +4 N, top right has -1 N, and bottom left has a net force of zero. (b) Since the acceleration and net force are directly proportional, the accelerations rank in the same order.

RE 3-9: In the chosen coordinate system, all the accelerations in the v vs. t graphs shown in Fig. 3-2 are negative since the slopes are negative. (a) The box on carpet acceleration is about -3.9 m/s^2 as determined by calculating the slope of the v vs. t graph. Slope = $(0.00 - 0.90)(\text{m}/\text{s}) / (0.23 - 0.00)(\text{s})$. (b) The cart on track acceleration is about -0.15 m/s^2 as determined by calculating the slope of the v vs. t graph. Slope = $(0.62 - 0.80)(\text{m}/\text{s}) / (1.2 - 0.0)(\text{s})$.

RE 3-10: (a) There appear to be no other horizontal forces on the moving objects except friction. Thus, we can assume that the net force on each object is due to a friction force. This friction force seems to be constant since the acceleration is constant and we assume that $F_x^{\text{net}} = ma_x$. (b) Box on carpet $F_x^{\text{fric}} = ma_x = 0.5 \text{ kg} \times (-3.9 \text{ m}/\text{s}^2) = -2 \text{ N}$. It points to the left. (c) Cart on track $F_x^{\text{fric}} = ma_x = 0.5 \text{ kg} \times (-0.15 \text{ m}/\text{s}^2) = -0.08 \text{ N}$. It also points to the left.

RE 3-11: (a) A tossed object is changing its velocity at all times. Just before it reaches the top of its flight it has a positive velocity and just after it has a negative velocity. Since acceleration is rate of change of velocity over time, even the instantaneous acceleration doesn't go to zero over an infinitesimal time interval. (b) The Fig. 3-22 graph of velocity vs. time is linear with a constant negative slope. Since slope of a v_y vs. t graph represents the acceleration component a_y , then $a_y = \text{constant}$ so $\vec{a} = a_y\hat{j}$ is constant.

RE 3-12: Change every x in the two equations in Table 2-1 to a y . Then replace a_x (previously a_x) with $-g$.

RE 3-13: (a) The unmagnetized paperclip will be attracted to the magnet and, in turn, the magnet will be attracted toward the paperclip. Newton's Third Law tells us that these attractive forces will be equal in magnitude to one another but opposite in direction; the force on the magnet will be to the left and the force on the paperclip will be to the right. (b) Newton's Third Law applies to all forces of interaction of which this is just one example.

Problems

1. 16 N. **3.** (a) 0.02 m/s^2 ; (b) 8×10^4 km; (c) 2×10^3 m/s. **5.** 1.2×10^5 N. **7.** (a) 4.9×10^5 N; (b) 1.5×10^6 N. **9.** (a) 245 m/s^2 ; (b) 20.4 kN. **11.** (a) 8.0 m/s; (b) + x direction. **13.** 8.0 cm/s^2 . **15.** 1.8×10^4 N. **17.** (a) 31.3 kN; (b) 24.4 kN. **19.** $2Ma/(a + g)$. **21.** 2.4 N. **23.** (a) 1.23 N; (b) 2.46 N; (c) 3.69 N; (d) 4.92 N; (e) 6.15 N; (f) 0.25 N. **25.** (a) 3.2 s; (b) 1.3 s. **27.** (a) 3.70 m/s; (b) 1.74 m/s; (c) 0.154 m. **29.**

Chapter 4

RE 4-1: Displacement (1) is identical as the ball ends up going a net distance of 6 meters north and 3 meters west. Displacement (2) is different. It actually has an equal magnitude but the ball has moved in the opposite direction. *Note:* Displacement does not depend on where something starts or ends, but only on how much and in what direction its position has changed relative to where it started.

RE 4-2: (a) The maximum magnitude occurs when the two vectors point in the same direction. This gives a magnitude for vector \vec{c} of $3 \text{ m} + 4 \text{ m} = 7 \text{ m}$. (This answer is not correct without a unit attached.) (b) The minimum magnitude occurs when the two vectors point in the opposite directions. This gives a magnitude for vector \vec{c} of $4 \text{ m} - 3 \text{ m} = 1 \text{ m}$.

RE 4-3: Methods (c), (d), and (f) work since the parallelogram methods (c) and (d) show that the same correct resultant can be obtained regardless of the order in which components are added. Method (f) shows an equivalent construction using components. All the other vectors point in the wrong directions.

RE 4-4: The vectors in figures (b) and (d) have the same components as the standard vector.

RE 4-5: Compare Figs 4-12 and 4-13.

RE 4-6: (a & b). The x - and y -components of \vec{d}_1 are both positive. The x -component of \vec{d}_2 is positive but the y -component points down in a negative direction. (c) Using the parallelogram method to get the vector sum of \vec{d}_1 and \vec{d}_2 results in a vector that has both x - and y -components that are positive.

RE 4-7: This is a kind of artificial question since units of force and acceleration are different as are units of displacement and velocity. However, if the scalars (mass and time respectively) act as compressors or stretchers, then the simplistic answers would be (a) The force vector would point in the same direction as the acceleration vector but be three times as long. (b) The velocity vector would point off in the same direction as the displacement vector and be twice as long since the displacement was divided by 0.5 s.

RE 4-8:

$$(a) \vec{F} = m\vec{a} = 3.0 \text{ kg}[(1.8 \text{ m/s}^2)\hat{i} + (1.0 \text{ m/s}^2)\hat{j}] = (5.4 \text{ N})\hat{i} + (3.0 \text{ N})\hat{j}$$

$$(b) \langle \vec{v} \rangle = \frac{\Delta \vec{r}}{\Delta t} = \frac{(3.2 \text{ m})\hat{i} + (-0.8 \text{ m})\hat{j}}{0.5 \text{ s}} = (6.4 \text{ m/s})\hat{i} + (-1.6 \text{ m/s})\hat{j}$$

Problems

1. The displacements should be (a) parallel, (b) antiparallel, (c) perpendicular. **3.** (a) 5; (b) 1; (c) 7. **5.** (a) -2.5 m ; (b) -6.9 m . **7.** (a) 47.2 m; (b) 122° . **9.** (a) 168 cm; (b) 32.5° above the floor. **11.** (a) 6.42 m; (b) no; (c) yes; (d) yes; (e) a possible answer: $(4.30 \text{ m})\hat{i} + (3.70 \text{ m})\hat{j} + (3.00 \text{ m})\hat{k}$; (f) 7.96 m. **13.** (a) 370 m; (b) 36° north of east; (c) 425 m; (d) the distance. **15.** (a) $(-9 \text{ m})\hat{i} + (10 \text{ m})\hat{j}$; (b) 13 m; (c) $+132^\circ$. **17.** (a) 4.2 m; (b) 40° east of north; (c) 8.0 m; (d) 24° north of west. **19.** (a) $(3.0 \text{ m})\hat{i} - (2.0 \text{ m})\hat{j} + (5.0 \text{ m})\hat{k}$; (b) $(5.0 \text{ m})\hat{i} - (4.0 \text{ m})\hat{j} - (3.0 \text{ m})\hat{k}$; (c) $(-5.0 \text{ m})\hat{i} + (4.0 \text{ m})\hat{j} + (3.0 \text{ m})\hat{k}$. **21.** (a) 38 m; (b) 320° ; (c) 130 m; (d) 1.2° ; (e) 62 m; (f) 130° . **23.** (a) 1.59 m; (b) 12.1 m; (c) 12.2 m; (d) 82.5° . **29.** (a) Put axes along cube edges, with the origin at one corner. Diagonals are $a\hat{i} + a\hat{j} + a\hat{k}$, $a\hat{i} + a\hat{j} - a\hat{k}$, $a\hat{i} - a\hat{j} - a\hat{k}$, $a\hat{i} - a\hat{j} + a\hat{k}$; (b) 54.7° ; (c) $\sqrt{3}a$. **31.** 4.1. **33.** (a) 103 km; (b) 60.9° north of due west. **35.** (a) 15 m; (b) south; (c) 6.0 m; (d) north. **37.** 5.0 km, 4.3° south of due west. **39.** 5.39 m at 21.8° left of forward. **41.** (a) 4.28 m; (b) 11.7 m. **43.** (a) -80 m ; (b) 110 m; (c) 143 m; (d) $+168^\circ$ (counterclockwise). **45.** 3.6 m. **47.** (a) 1.84 m; (b) 69° north of east. **49.** (a) 9.51 m; (b) 14.1 m; (c) 13.4 m; (d) 10.5 m. **51.** (a) $9.19\hat{i} + 7.71\hat{j}$; (b) $14.0\hat{i} + 3.41\hat{j}$

Chapter 5

RE 5-1: (a) No, because in Fig. 5-5 the vertical positions of the ball on the right are the same as those of the ball on the left. (b) No. The horizontal positions of the ball on the right are equally spaced, indicating that horizontal velocity of the ball is constant and unaffected by the falling.

RE 5-2: The skateboarder's vertical motion is independent of his horizontal velocity. This is why the skateboarder lands back on his skateboard after his jump.

RE 5-3: (a) At each of the three points, the force vector points straight down and has a constant magnitude and (b) the same is true for the three acceleration vectors. (c) The horizontal component of each of the three velocity vectors points to the right and has a constant size. The vertical component of the velocity at the left point is directed straight upward and is slightly larger than the common size of the horizontal velocity components. The vertical component of the velocity at the center point is zero, while at the right point it is directed downward and is smaller in size than the horizontal velocity component.

RE 5-4: (a) The x -component of velocity is not changing and is the slope of Fig. 5-9. From the data in the figures, the slope is about 2.3 m/s. The initial y -component of velocity is the initial slope of Fig 5-10, which is about 3.5 m/s. The launch angle will be the inverse tangent of $3.5/2.3$ or about 57° . (b) Using a protractor about 57° , too.

RE 5-5: (a) The horizontal component of velocity remains constant. (b) The vertical component of velocity is changing constantly as there is a vertical acceleration. (c) The horizontal component of its acceleration is zero. The only force (gravity) acting is in the vertical direction. (d) The vertical component of its acceleration is constant (9.8 m/s^2 downward).

Ans-4 Answers to Reading Exercises and Odd-Numbered Problems

RE 5-6: (a) Using Eq. 5-15 and noting that $\Delta x = 8 \text{ m}$ and $\Delta y = -6 \text{ m}$ gives a displacement of $\Delta \vec{r} = (8 \text{ m})\hat{i} + (-6 \text{ m})\hat{j}$. (b) No, since it has components along both axes.

RE 5-7: (a) When traveling clockwise, the x -component of the particle's velocity is positive when it is in the I and II quadrant, and its y -component is negative in the I quadrant, so the particle is now in the I quadrant. (b) When traveling counterclockwise, the x -component of the particle's velocity is positive when it is in the III and IV quadrant, and its y -component is negative in the III quadrant, so the particle is then in the III quadrant.

(a) Quadrant I

(b) Quadrant II

RE 5-8: Remember that the x -component of acceleration will be in the direction of the change in the x -component of velocity and the y -component of acceleration will be in the direction of the change in the y -component of velocity. Just knowing the trajectory or path of the particle does not give you the direction of the acceleration. You also need to know how the velocity is changing as the particle travels along its trajectory. Therefore, if the change in the velocity vector is in the direction of the path of the particle, \vec{a} will be tangent to the trajectory. However, you will study other situations (Section 5-7) where \vec{a} is actually perpendicular to the trajectory, that is, the change in the velocity is perpendicular to the trajectory.

RE 5-9: The centripetal force is always inward toward the center of the curve. According to Newton's First Law, the passenger wants to travel in a straight line unless acted upon by a force. The centripetal force acts on the passenger through the friction between the passenger and the car seat. If that frictional force is not strong enough, the passenger tends to travel in a straight line and slides to the outside edge of the seat, where both the seat and the side of the car can provide the centripetal force needed to move your body in a curved path.

Problems

1. (a) 62 ms; (b) 480 m/s. **3.** (a) 0.205 s; (b) 0.205 s; (c) 20.5 cm; (d) 61.5 cm. **5.** (a) 2.00 ns; (b) 2.00 mm; (c) $1.00 \times 10^7 \text{ m/s}$; (d) $2.00 \times 10^6 \text{ m/s}$. **7.** (a) 16.9 m; (b) 8.21 m; (c) 27.6 m; (d) 7.26 m; (e) 40.2 m; (f) 0. **9.** 4.8 cm. **13.** (a) 11 m; (b) 23 m; (c) 17 m/s; (d) 63° below the horizontal. **15.** (a) 24 m/s; (b) 65° above the horizontal. **17.** (a) 10 s; (b) 897 m. **19.** the third. **21.** (a) 202 m/s; (b) 806 m; (c) 161 m/s; (d) -171 m/s . **23.** (a) yes; (b) 2.56 m. **25.** between the angles 31° and 63° above the horizontal. **27.** (a) $(-5.0 \text{ m})\hat{i} + (8.0 \text{ m})\hat{j}$; (b) 9.4 m; (c) 122° ; (e) $(8 \text{ m})\hat{i} + (-8 \text{ m})\hat{j}$; (f) 11 m; (g) -45° . **29.** (a) $(-7.0 \text{ m})\hat{i} + (12 \text{ m})\hat{j}$; (b) x axis. **31.** 8.43 m at -129° . **33.** 7.59 km/h, 22.5° east of north; **35.** (a) $(3.00 \text{ m/s})\hat{i} + (-8.00 \text{ m/s}^2)\hat{j}$; (b) $(3.00 \text{ m/s})\hat{i} + (-16.00 \text{ m/s})\hat{j}$; (c) 16.3 m/s; (d) -79.4° . **37.** 0.421 m/s at 3.1° west of due north. **39.** (a) $(6.00 \text{ m})\hat{i} + (-106 \text{ m})\hat{j}$; (b) $(19.0 \text{ m/s})\hat{i} + (-224 \text{ m/s})\hat{j}$; (c) $(24.0 \text{ m/s}^2)\hat{i} + (-336 \text{ m/s}^2)\hat{j}$; (d) -85.2° to $+x$. **41.** (a) $(-1.5 \text{ m/s})\hat{j}$; (b) $(4.5 \text{ m})\hat{i} + (-2.25 \text{ m})\hat{j}$. **43.** (a). 45 m; (b) 22 m/s. **45.** (a) $(8 \text{ m/s}^2)t\hat{j}$; (b) $(8 \text{ m/s}^2)t\hat{j}$. **47.** (a) 22 m; (b) 15 s. **49.**

Chapter 6

RE 6-1: If you gather the tails of the three vectors shown in the helicopter diagram, you get the free-body diagram shown in (c).

RE 6-2: Use the balance in Fig. 3-9 and place one object on the left pan and the other object on the right pan. If the two objects have the same mass they will balance one another. They would have the same weight if they both gave the same reading on the spring scale. Also you could realize that if they have the same mass, they have the same weight since $W = mg$ and g is a constant. The weight and mass are not the same. The weight is a force, and the mass is mass. Yes, since the weight and mass are proportional, the ratios are the same.

RE 6-3: It's true that the planet is yanking down on the patient but this is a force equal to his weight. However, since the normal force from the floor is equal and opposite, there is no net force and hence no acceleration.

RE 6-4: (a) In this case, at constant speed a equals zero and thus the net force must equal zero, requiring \vec{N} and \vec{F}^{grav} to be equal in magnitude and opposite in direction. (b) Since the only two forces acting on the block are \vec{N} and \vec{F}^{grav} , to have an upward acceleration we must have a net upward force, meaning that the magnitude of \vec{N} is now larger than that of \vec{F}^{grav} . (c) Slowing down means an acceleration or net force in the downward direction, requiring the magnitude of \vec{F}^{grav} to be larger than that of \vec{N} . What do you think would happen to \vec{N} if the elevator cable broke and the block fell freely with $a = g$?

RE 6-5: In both answers to follow we are assuming the only forces acting on the block in the horizontal direction are the friction force and the pull of the cord, which is what the force sensor is measuring. Since in both cases there is no acceleration, these two forces must be equal and opposite, allowing us to equate the force sensor reading to the frictional force. (a) From the graph it looks like the block breaks free when the force is about 9.5 N. The total mass is 0.7956 kg, and the normal force that equals the weight is mg ; therefore using Eq. 6-11, we find $\mu^{\text{stat}} = 9.5/(0.7956 \times 9.8) = 1.22$. Notice that the coefficient of friction has no units. (b) From the graph, the force needed to keep the block moving at a constant speed is about 3.0 N. Using Eq. 6-10, $\mu^{\text{kin}} = 3.0/(0.7956 \times 9.8) = 0.38$.

RE 6-6: (a) Zero; (b) 5 N; (c) No; (d) Yes, there is now a net force of 2 N on the block causing it to accelerate; (e) 8 N.

RE 6-7: It is true that friction has both a bad side and a good side. Friction always tries to retard motion. If you desire that motion then friction is bad—for example, the pistons in your car engine—and we do everything we can (lubricants) to eliminate it. However, there are other times when we don't want motion (slippage) to occur, as when we are walking or riding a bike, and the force of friction allows us to do these activities.

RE 6-8: Think of the cord as an object with a mass you are trying to accelerate with only two forces—the one at one end from the hand and the other at the other end from the block. We will assume that the length of the cord hanging down on each side is the same so we can ignore the force of gravity on the cord. (a) If the cord is not accelerating then the magnitudes of the two forces are equal and can-

cel. (b) If the block is accelerating then so is the cord and the force of the hand on the cord is greater than that of the block. (c) In this case the acceleration is opposite to b and the pull force of the hand is less than the pull force due to the block.

RE 6-9: Look at Eq. 6-25. The only things in this equation that will change with the size of the drops are the mass, m , and the cross-sectional area A . So for this exercise v_f^2 is proportional to m/A . How will this ratio change with the size of the drops? A changes as r^2 and m changes as $(\rho_{\text{water}})(\text{volume})$ and since volume goes as r^3 , we finally determine that m/A and hence v_f^2 goes as r . Therefore, large drops have greater speeds than small drops.

Problems

1. (a) $F_x = 1.88 \text{ N}$; (b) $F_y = 0.684 \text{ N}$; (c) $(1.88 \text{ N})\hat{i} + (0.684 \text{ N})\hat{j}$.
3. 2.9 m/s^2 . **5.** $(3 \text{ N})\hat{i} + (-11 \text{ N})\hat{j}$. **7.** (a) $(-32 \text{ N})\hat{i} + (-21 \text{ N})\hat{j}$; (b) 38 N ; (c) 213° from $+x$. **9.** (a) 108 N ; (b) 108 N ; (c) 108 N . **11.** (a) 200 N ; (b) 120 N . **13.** 0.61 . **15.** (a) 190 N ; (b) 0.56 m/s^2 . **17.** (a) 0.13 N ; (b) 0.12 . **19.** (a) no; (b) $(-12 \text{ N})\hat{i} + (5 \text{ N})\hat{j}$. **23.** (a) 300 N ; (b) 1.3 m/s^2 .

Chapter 7

RE 7-1: (a) The 60 s encounter between the *Titanic* and an iceberg was a collision. (b) A tennis ball encountering a racket for 2 s is not a collision.

RE 7-2: (a) $|\vec{F}_1| > |\vec{F}_3| > |\vec{F}_2| = |\vec{F}_4| = 0$. Since the slopes represent $\Delta\vec{p}/\Delta t$ the magnitude is greatest where the slope is steepest. Thus, ranking is by steepness of slope. (b) Since the momentum is initially positive, the particle speeds up in region 1, drifts in region 2, and slows down in region 3, where its momentum is becoming less positive (and hence more negative).

RE 7-3: The change in the egg's momentum is $m\vec{v}_2 - m\vec{v}_1$, and since \vec{v}_2 is zero the change is just $m\vec{v}_1$. The time you take in catching the egg does not affect the momentum change since the initial and final velocities are still the same. However the time taken in the catch will affect the average force the egg experiences. Since the change in momentum equals the impulse, which equals the average force times the time the force acts, making the time of the catch longer makes the average force on the egg less and hence a greater likelihood of a successful catch. In order to make Δt as large as possible, you move your hands and body backwards once the catch is made in order to bring the egg to zero speed over the largest time interval possible.

RE 7-4: (a) p_{1x} is to the right and $+p_{2x}$ is to the left and $-$, therefore Δp_x is $-$. Remember that Δ is always final minus initial, and here we have a negative number minus a positive number giving a negative re-

sult. (b) Δp_y is zero since the y component of the momentum does not change in the bounce. (c) The direction of $\Delta\vec{p}$ is left. To see this, draw the two momentum vectors and subtract the initial from the final. Remember: To subtract vectors add the negative of the second to the first.

RE 7-5: (1) Assuming the carts are frictionless, the system consisting of the firecracker and the two carts is an isolated system and momentum should be conserved. In fact, if the firecracker is initially at rest and explodes symmetrically, then the carts should move off at the same speed in opposite directions. (2) Assuming the carts are not frictionless, then the track and the table and the Earth become part of the system. We might not see the carts come off with the same speeds in opposite directions. Instead the Earth might move (imperceptibly) to make up the difference. However, momentum is always conserved, so it should be so for our new system.

RE 7-6: (a) Zero, since no external forces are acting and hence the total momentum is conserved. (b) No, since the y -component of momentum must also be conserved. (c) The second piece must be moving in the negative direction on the x axis so that the total momentum after the explosion is zero.

RE 7-7: We need a mass for the grapefruit—let's say 1.0 kg . The grapefruit's momentum starts at zero and goes to $(1 \text{ kg})(2 \text{ m/s}) = 2 \text{ kg} \cdot \text{m/s}$, therefore $\Delta p = 2 \text{ kg} \cdot \text{m/s}$. The change in the Earth's momentum will be equal and opposite, therefore the change in the Earth's speed will be $2 \text{ kg} \cdot \text{m/s}$ divided by the mass of the Earth. If you look at the inside front cover of this text, you find $m_{\text{Earth}} = 5.98 \times 10^{24} \text{ kg}$. Dividing, you get $v_{\text{Earth}} = 3.3 \times 10^{-25} \text{ m/s}$. Did you feel the Earth move?

Problems

1. 24 km/h . **3.** (a) $(-4.0 \times 10^4 \text{ kg} \cdot \text{m/s})\hat{i}$; (b) west. **5.** (a) 30° ; (b) $(-0.572 \text{ kg} \cdot \text{m/s})\hat{j}$. **7.** 2.5 m/s . **9.** 3000 N . **11.** 67 m/s , in opposite direction. **13.** (a) $42 \text{ N} \cdot \text{s}$; (b) 2100 N . **15.** (a) $(7.4 \times 10^3 \text{ N} \cdot \text{s})\hat{i} + (-7.4 \times 10^3 \text{ N} \cdot \text{s})\hat{j}$; (b) $(-7.4 \times 10^3 \text{ N} \cdot \text{s})\hat{i}$; (c) $2.3 \times 10^3 \text{ N}$; (d) $2.1 \times 10^4 \text{ N}$; (e) -45° . **17.** 10 m/s . **19.** (a) $1.0 \text{ kg} \cdot \text{m/s}$; (b) 10 N ; (c) 1700 N ; (d) the answer for (b) includes time between pellet collisions. **21.** 41.7 cm/s . **23.** (a) 46 N ; (b) none. **25.** $\approx 2 \text{ mm/y}$. **27.** 3.0 mm/s , away from the stone. **29.** (a) 4.6 m/s ; (b) 3.9 m/s ; (c) 7.5 m/s . **31.** increases by 4.4 m/s . **33.** 190 m/s . **35.** (a) $\{m_A/(m_A + m_B)\}v_{A1}$. **37.** (a) 7290 m/s ; (b) 8200 m/s . **39.** 4400 km/h . **41.** 8.1 m/s at 38° south of east. **43.** (a) 11.4 m/s ; (b) 95.1° clockwise from $+x$. **45.** (a) 61.7 km/h ; (b) 63.4° south of west. **47.** (a) 2.5 m/s . **49.** 1.0 m/s north. **51.** (a) $1.4 \times 10^{-22} \text{ kg} \cdot \text{m/s}$; (b) 150° ; (c) 120° . **53.** 14 m/s , 135° from the other pieces. **55.** 3.0 m/s . **57.** 120° . **59.** (a) $4.15 \times 10^5 \text{ m/s}$; (b) $4.84 \times 10^5 \text{ m/s}$. **61.** (a) 41° ; (b) 4.76 m/s ; (c) no. **63.** 2.0 m/s , $-x$ direction. **65.** 108 m/s . **67.** (a) $1.57 \times 10^6 \text{ N}$; (b) $1.35 \times 10^5 \text{ kg}$; (c) 2.08 km/s . **69.** 2.2×10^{-3}

Chapter 8

RE 8-1: (a) At the center; (b) in the lower right quadrant; (c) on the negative y axis; (d) at the center; (e) in the lower left quadrant; (f) at the center

RE 8-2: (a) The spacing between successive halfway points is the same, which suggests that the velocity represented by these points is constant.

(b) $v = |\Delta\vec{r}|/\Delta t = 0.41 \text{ m}/[(12/15)\text{s}] = 0.51 \text{ m/s}$

RE 8-3: Since there are no outside forces on the system, the center of mass of the system will not change. Thus, the skaters will end up meeting at the origin of the original coordinate system in all three sit-

Ans-6 Answers to Reading Exercises and Odd-Numbered Problems

uations (a), (b), and (c). The only difference is that in case (a) Ethel will be holding one end of the “massless” pole at the end, in case (b) Fred will be holding an end of the “massless” pole, and in case (c) one-third of the “massless” pole will be sticking out behind Fred and two-thirds will be sticking out behind Ethel.

(a) -4.5 m; (b) -5.5 m. **3.** (a) 4600 km; (b) $0.73R_e$. **5.** (a) 1.1 m; (b) 1.3 m; (c) shifts toward topmost particle. **7.** (a) -0.25 m; (b) 0. **9.** 6.8×10^{-12} m from the nitrogen atom, along axis of symmetry. **11.** (a) $H/2$; (b) $H/2$; (c) descends to lowest point and then ascends to $H/2$; (d) $\frac{HM}{m} \left(\sqrt{1 + \frac{m}{M}} - 1 \right)$. **13.** $x_{\text{com}} = B/2$ and $y_{\text{com}} = H/3$. **15.** $x_{\text{com}} = B/2$ and $y_{\text{com}} = 4R/(3\pi)$. **17.** (a) 0,0; (b) 0. **19.** $(-1.50$ m, -1.43 m). **21.** 29 m. **23.** 72 km/h. **25.** (a) 28 cm; (b) 2.3 m/s. **27.** 53 m. **29.** (a) halfway between the containers; (b) 26 mm toward the heavier container; (c) down; (d) -1.6×10^{-2} m/s². **31.** 4.2 m. **33.** 1.2 m/s, 132° counterclockwise from east. **37.** (a) 33 m/s; (b) 8.7 m/s. **39.** (a) 540 m/s; (b) 40.4° . **41.** (a) $0.2000v^{\text{rel}}$; (b) $0.2103v^{\text{rel}}$; (c) $0.2095v^{\text{rel}}$. **43.** (a) 1.0 m/s north; (b) 3 m north

Chapter 9

RE 9-1: (a) Decreases. (b) Remains the same. Remember that the kinetic energy is a scalar and depends on the velocity squared, so -2 m/s and 2 m/s give the same kinetic energy. (c) Negative for situation (a) and zero for situation (b). Situation (b) is interesting. How can the net work done be zero? Try breaking the velocity change into two changes: first from -2 m/s to zero, then from zero to 2 m/s. For the first change the work is negative and for the second change the work is positive. When we add the two works together, we get zero for the total.

RE 9-2: $c > a > b = d$

RE 9-3: Use Eq. 9-19: (a) positive; (b) negative; (c) zero. Think through your calculated answers. Do they make sense? For example, in (a) as the block moves from -3 cm to the origin, the spring force and displacement are in the same direction giving a positive work; from the origin to 2 cm the spring force and displacement are in opposite directions giving a negative work, but the positive work is larger because the displacement is larger giving a net positive work.

RE 9-4: $d > c > b > a$

RE 9-5: The power is zero at all times since \vec{F} and \vec{v} are always perpendicular in uniform circular motion.

Problems

Chapter 10

RE 10-1: No, for the force to be conservative the work done in going between two points must not depend on the path taken. Also, if you go from 2 to 1 instead of 1 to 2 the work will change sign. Therefore, for the force in the exercise to be conservative the work for the bottom path should have a negative sign.

RE 10-2: A Hot Wheels[®] car that traverses path b should lose more kinetic energy than one that traverses path a . This is because path b is longer so the friction forces have more distance to act on path b .

RE 10-3: The kinetic energy of the barbell is zero before the lift and zero after the lift, as evidenced by the fact that y vs. t is a constant at $t = 0.0$ s and at $t = 2.0$ s. Since the kinetic energy change $\Delta K = 0.0$ J, then the net work on the barbells should be zero. An examination of graph 10-10b shows that the positive work is approximately given by the area under the F^{net} vs. y curve. $W^+ =$ area under the positive portion of the curve $= (0.5)(116 \text{ N})(.15 \text{ m}) = +8.7$ J and $W^- =$ area under the negative portion of the curve $(0.5)(58 \text{ J})(.45 - .15) \text{ m} = -8.7$ J. So $W^{\text{net}} = W^+ + W^- = 0.0$ J.

RE 10-4: Use Eq. 10-13. Note that the change in the potential energy is the negative of the area under the curves in the figure. The most positive will be (3) and the least positive (2).

RE 10-5: Without friction, the decrease in the potential energy will equal the increase in the kinetic energy. (a) Therefore, since all four blocks are losing the same amount of potential energy, they will all have the same kinetic energy at point B . (b) Since the kinetic energies are the same, the speeds are the same.

RE 10-6: Use the equation $F_x^{\text{int}}(x) = -dU(x)/dx$. The force is the negative of the slope of the U vs. x curve. (a) Ranking magnitudes with the greatest first: CD, AB, BC . (b) The slope is negative, hence the force is in the positive x direction.

RE 10-7: $b > a > c$ as determined by the equation $\Delta E^{\text{thermal}} = f_x^{\text{kin}} \Delta x$.

RE 10-8: (a) 4 kg · m/s; (b) 8 kg · m/s; (c) assuming an elastic collision, 3 J.

RE 10-9: (a) 2 kg · m/s. (b) Since the initial y -component is zero, the final must be zero. Therefore, the final y -component of momentum for the target is 3 kg · m/s.

Problems

1. 89 N/cm. **3.** (a) 4.31 mJ; (b) -4.31 mJ; (c) 4.31 mJ; (d) -4.31 mJ; (e) all increase. **5.** (a) mgL ; (b) $-mgL$; (c) 0; (d) $-mgL$; (e) mgL ; (f) 0; (g) same. **7.** (a) 184 J; (b) -184 J; (c) -184 J. **9.** -320 J. **11.** (a) 2.08 m/s; (b) 2.08 m/s; (c) increase. **13.** (a) $\sqrt{2gL}$; (b) $2\sqrt{gL}$; (c) $\sqrt{2gL}$; (d) all the same. **15.** (a) 260 m; (b) same; (c) decrease. **17.** (a) 21.0 m/s; (b) 21.0 m/s; (c) 21.0 m/s. **19.** (a) 0.98 J; (b) -0.98 J; (c) 3.1 N/cm. **21.** (a) 39.2 J; (b) 39.2 J; (c) 4.00 m. **23.** (a) 35 cm; (b) 1.7 m/s. **25.** 10 cm. **27.** 1.25 cm. **31.** (a) $2\sqrt{gL}$; (b) $5mg$; (c) 71° . **33.** $mgL/32$. **37.** (a) $1.12(A/B)^{1/6}$; (b) repulsive; (c) attractive. **39.** (a) -3.7 J; (c) 1.29 m; (d) 9.12 m; (e) 2.16 J; (f) 4.0 m; (g) $(4 - x)e^{-x/4}$ N; (h) 4 m. **41.** (a) 30.1 J; (b) 30.1 J; (c) 0.22. **43.** (a) 5.6 J; (b) 3.5 J. **45.** 11 kJ. **47.** 20 ft · lb. **49.** (a) 1.5 MJ; (b) 0.51 MJ; (c) 1.0 MJ; (d) 63 m/s. **51.** (a) 67 J;

Chapter 11

RE 11-1: (a) Positive, since θ is increasing. (b) Negative, since θ is decreasing.

RE 11-2: (a) Positive; (b) negative; (c) negative; (d) positive

RE 11-3: Find the angular acceleration, α , by taking the second derivative of θ with respect to t . The accelerations for (a) and (d) do not depend on t and are therefore constant, and hence the equations of Table 11-1 apply.

RE 11-4: Since the speeds are being squared, v^2 and ω^2 will always be positive quantities.

RE 11-5: (a) Yes, the centripetal acceleration; (b) no, since α is zero; (c) yes; (d) yes, since α is no longer zero.

RE 11-6: Calculate mr^2 for each, and you'll find they are all the same.

RE 11-7: (1) $>$ (2) $>$ (4) $>$ (3). Remember that I depends not only on the mass but also on how far that mass is from the chosen axis.

RE 11-8: $I_a = I_d = mr^2$, $I_b = \frac{1}{2}mr^2$, $I_c = \frac{5}{8}mr^2$, so $a = d > c > b$.

RE 11-9: $A = C > D > B = E = \text{zero}$. For A and C , ϕ is 90° ; for D , ϕ is between zero and 90° ; for E , ϕ is zero; and for C , r is zero.

RE 11-10: (a) Same direction. (b) Less.

Problems

Chapter 12

RE 12-1: (a) When is the sin of the angle between the vectors zero? Sin is zero for 0° and 180° . (b) Here the sin needs to equal ± 1 . This occurs at 90° and 270° . (c) Here $|\vec{c}||\vec{d}|\sin \phi = 3 \cdot 4 \sin \phi = 6$ so $\phi = \sin^{-1}(6/12)$ so $\phi = 30^\circ$ or 150° .

RE 12-2: The time rate of change of the rotational momentum is equal to the net torque. $3 > 1 > 2 = 4 = \text{zero}$.

RE 12-3: (a) $1 = 3 > 2 = 4 > 5 = \text{zero}$, since r_\perp is 4 m for both 1 and 3 and 2 m for both 2 and 4 and zero for 5. (b) Particles 2 and 3 have negative rotational momentum about o , since $\vec{\ell} = \vec{r} \times \vec{p}$ points into the page for each of them.

RE 12-4: (a) Since the rate of change of the rotational momentum is equal to the applied torque, which is the same for all three cases, all three objects increase their rotational momentum at the same rate; and assuming all three started from rest, they will all have the same rotational momentum at any given time. (b) Look at Table 11-2 (Some Rotational Inertias). Note that $I_{\text{hoop}} > I_{\text{disk}} > I_{\text{sphere}}$. Since $L = I\omega$ and they all have the same L , the object with the biggest I will have the smallest ω ; $\omega_{\text{sphere}} > \omega_{\text{disk}} > \omega_{\text{hoop}}$.

RE 12-5: (a) Decrease, since although the total mass of the system has not changed, it is distributed closer to the axis of rotation. (b) Remain the same, since there is no net external torque. (c) If I decreases and L is constant, then ω must increase.

Problems

Chapter 13

RE 13-1: Situations (c), (e), and (f) can yield static equilibrium, since in each case both the net force and the net torque can be zero. In (a), (b), and (d) the net force can be zero but the net torque cannot.

RE 13-2: The apple's center of gravity will end up directly below the rod, since only in that position is the net torque on the apple *stably* zero. The net torque on the apple is also zero when the apple's center of gravity is directly *above* the rod, but this is an *unstable* equilibrium point and the slightest rotation will cause the apple to rotate away from this position.

Ans-8 Answers to Reading Exercises and Odd-Numbered Problems

RE 13-3: You are better off if there is no friction between the ladder and the wall. With no friction between the ladder and the ground, the ground cannot exert any *horizontal* force to counter the horizontal force that the wall must exert on the ladder to keep it in place.

RE 13-4: In each of these three cases, the net horizontal force is zero independent of the magnitudes of the three unknown forces. This leaves only two independent equations for equilibrium—namely, net vertical force equals zero and net torque equals zero. But we have three unknowns to solve for. Since we can't do this, each of these three situations is indeterminate.

RE 13-5: Equation 13-29 tells us that, for elastic stretching, Young's modulus is just the stress (F/A) divided by the strain ($\Delta L/L$). Relative to rod 1, rod 2 has the same stress and twice the strain, and so its Young's modulus is half that of rod 1. By the same reasoning, rod 3 also has half the Young's modulus of rod 1, and rod 4 has a Young's modulus that is four times larger than that of rod 1. So, from higher to lower Young's modulus, rod 4 is the largest, rod 1 is next, and rods 2 and 3 tie for smallest.

RE 13-6: During bending, the particles on the inside of the bend are pushed closer together while those on the outside of the bend are pulled farther apart. During a shear deformation, adjacent planes of particles shift laterally with respect to one another. While the planes remain the same distance from one another, the "springs" (bonds) between adjacent planes are each stretched by the same amount.

Problems

Chapter 14

RE 14-1: The ratio (relative amount) of the magnitudes of these two forces depends only on the square of the ratio of the two center-to-center distances between the Earth and the other mass.

RE 14-2: Equation 14-2 tells us that g (the acceleration of a freely falling body) is just (Gm_{Earth}/r^2) where r is the distance to the center of the Earth to the point where g is measured. This is consistent with the model that assumes that the Moon stays in its orbit simply because it is in free fall. Although the observations are consistent with this model, this does not "prove" that the model is "true." It only establishes that this model is "good enough" to account for the data at hand.

RE 14-3: Since the location of the particle lies outside each of the spheres at the same distance from the center of the sphere in each case, each of the spheres will exert exactly the *same* magnitude force on the particle.

RE 14-4: \vec{F}^{grav} due to the Earth *always* points directly toward the center of the Earth. However, the object's apparent weight associated with \vec{N} , (the "normal" force exerted on an object "at rest" on the surface of the rotating Earth), is *not* always directed exactly away from the center of the Earth! In fact, \vec{N} points directly away from the center of the Earth only at the Earth's poles and at its equator. Why?

RE 14-5: In each case the direction of \vec{F}^{grav} would be toward the center of the Earth. Case A: The magnitude of \vec{F}^{grav} would decrease as $1/r^2$ where r is the distance to the center of the Earth. Case B: The magnitude of \vec{F}^{grav} would be proportional to r , and hence decrease. Case C: Because of the considerably higher density of the Earth's core compared with its surface crust, the magnitude of \vec{F}^{grav} would increase at first but then decrease to zero as we moved toward the center of the Earth.

RE 14-6: (a) The gravitational potential energy of the ball–sphere system increases. (b) The gravitational force between the ball and the sphere is attractive (inward), and the displacement is outward. Since the force and displacement are in opposite directions, the work done by the gravitational force is negative.

Problems

1. 19 m **3.** 29 pN **5.** $1/2$ **7.** $2.60 \times 10^5 \text{ km}$ **9.** 0.017 N, toward the 300 kg sphere **11.** $3.2 \times 10^{-7} \text{ N}$ **13.** $\frac{GmM}{d^2} \left[1 - \frac{1}{8(1 - R/2d)^2} \right]$ **15.** $2.6 \times 10^6 \text{ m}$ **17.** (b) 1.9 h **21.** (a) $0.414R$; (b) $0.5R$ **23.** (a) $(3.0 \times 10^{-7} \text{ N/kg})m$; (b) $(3.3 \times 10^{-7} \text{ N/kg})m$; (c) $(6.7 \times 10^{-7} \text{ N/kg}\cdot\text{m})mr$ **25.** (a) 9.83 m/s^2 ; (b) 9.84 m/s^2 ; (c) 9.79 m/s^2 **27.** (a) $-1.3 \times 10^{-4} \text{ J}$; (b) less; (c) positive; (d) negative **29.** (a) 0.74; (b) 3.7 m/s^2 ; (c) 5.0 km/s **31.** (a) $5.0 \times 10^{-11} \text{ J}$; (b) $-5.0 \times 10^{-11} \text{ J}$ **35.** (a) 1700 m/s; (b) 250 km; (c) 1400 m/s **37.** (a) 82 km/s; (b) $1.8 \times 10^4 \text{ km/s}$ **39.** $2.5 \times 10^4 \text{ km}$

Chapter 15

RE 15-1: Half the weight of the woman, $(125 \text{ lb}/2)(9.8 \text{ N}/2.2 \text{ lb}) \approx 300 \text{ N}$, is supported by her two spike heels. Let's say that each heel makes contact with $1 \text{ cm}^2 = 10^{-4} \text{ m}^2$ of the floor. Then the pressure of her heels on the floor is $P = F/A = (300 \text{ N}/10^{-4} \text{ m}^2) = 3 \times 10^6 \text{ Pa}$. This estimate is close to that presented in the table. This pressure is high because of the small contact area over which this otherwise modest force is applied. An automobile has a much larger contact area.

RE 15-2: If air and water are made up of molecules that are about the same size and mass, then the average distance between the molecules in air at sea level must be about $1000^{1/3} = 10$ times larger than those of the water. This suggests that there is significantly more empty space around each air molecule, allowing them to be compressed closer together by quite a bit before they fill all of the available volume.

RE 15-3: The force the air exerts on the book is about $(10^5 \text{ N/m}^2)(2.54 \times 10^{-2} \text{ m/in})^2 (2.2 \text{ lb}/9.8 \text{ N})(8 \text{ in})(10 \text{ in}) \approx 1200 \text{ lb}$. The close fit and the flexibility of the rubber mat prevents air from leaking into the space between the mat and the smooth tabletop, holding the mat down against the table with close to the full 1200 lb of force the air exerts on the top surface of the mat. The rougher surface of the book, as well as its rigidity, let air readily leak into the space between the book and the table when you start to pick up the book. This "equalizes" the pressure on each side of the book, reducing the net force that the air exerts on the book to a negligible amount.

RE 15-4: The density of air is only about one-thousandth that of water.

RE 15-5: The pressure at a depth Δy is the *same* in each container of oil. The shape of the container does not matter.

RE 15-6: Compressible fluids, like compressible springs, can “absorb” work and store it as elastic potential energy. Increasing the pressure of the compressible fluid in the hydraulic jack will thus store some of the work done on the fluid as elastic potential energy and slightly reduce the amount of work that the fluid does on the output by that amount.

RE 15-7: The pressure at the bottom of this container is determined solely by the depth of the fluid above the bottom and the pressure that the air exerts on the surface of that fluid. In particular, the weight of the “extra” fluid that lies outside the central column is *not* carried by the horizontal bottom of the container and does *not* increase the pressure there.

RE 15-8: (a) Since the penguin floats in each of the three fluids, each fluid supplies a buoyant force exactly equal to the penguin’s weight, so each fluid supplies the *same* buoyant force ($A = B = C$). (b) The penguin must displace the amount of fluid that matches her weight. Thus she *displaces* more of the least dense fluid B than of A , and even less of the most dense fluid C ($B > A > C$).

RE 15-9: You need to make sure that the weight of the canoe and its load is less than that of the water it displaces before the water starts coming in over the top edge of the hull. Although a chunk of concrete cannot displace its weight with water, a thin concrete canoe and its riders can.

RE 15-10: The net flow into (+) and out of (–) the entire system must be zero. So: $+x + (4 + 8 + 4 - 6 + 5 - 2) \text{ cm}^3/\text{s} = 0 \text{ cm}^3/\text{s}$ or $x = -13 \text{ cm}^3/\text{s}$, so fluid flows out of the unlabeled pipe at a rate of $13 \text{ cm}^3/\text{s}$.

RE 15-11: (a) The area of face 1 is $4.0 \text{ cm}^2 = 4.0 \times 10^{-4} \text{ m}^2$. Face 2 has an area of $5.7 \text{ cm}^2 = 5.7 \times 10^{-4} \text{ m}^2$. Face 3 has an area of $8.0 \text{ cm}^2 = 8.0 \times 10^{-4} \text{ m}^2$. (b) The total surface area of all 6 faces is $69.7 \text{ cm}^2 = 69.7 \times 10^{-4} \text{ m}^2$.

RE 15-12: (a) The flux through any face is $v \Delta A \cos(\theta)$. Thus the flux through face 1 is $(0.5 \text{ m/s})(4.0 \times 10^{-4} \text{ m}^2)(\cos(0^\circ)) = +2.0 \times 10^{-4} \text{ m}^3/\text{s}$. The flux through face 2 is $(0.5 \text{ m/s})(5.7 \times 10^{-4} \text{ m}^2)(\cos(45^\circ)) = +2.0 \times 10^{-4} \text{ m}^3/\text{s}$. The flux through face 3 is $(0.5 \text{ m/s})(8.0 \times 10^{-4} \text{ m}^2)(\cos(180^\circ)) = -4.0 \times 10^{-4} \text{ m}^3/\text{s}$. (b) The flux through the front, back, and bottom faces is zero because $\theta = 90^\circ$ for each of these faces and so the $\cos(\theta)$ term in the expression for the flux is zero. (c) Adding the contributions from all six faces yields zero net flux through this closed surface, as expected.

RE 15-13: (a) The volume flow rate is the *same* through each of the four sections. (b) The flow speed is largest in section 1, followed by section 2 and section 3, where it will be the same, and finally section 4 has the smallest flow speed. Recall that the flow speed is inversely proportional to the local cross-sectional area of the pipe. (c) The pressure will be greatest in section 4, less in section 3, still less in section 2, and least in section 1. The pressure difference between sections 2 and 3 is due to their difference in altitude. The pressure differences between sections at the same altitude are due to differences in the flow speed.

Chapter 16

RE 16-1: The amplitude and the angular frequency will stay the same. The initial phase will differ from ϕ_0 by 90° or $\pi/2$ since you can think of a cosine as a sine that has been shifted 90° to the left.

RE 16-2: (a) When $t = 2.00 T$ the particle will have moved through two full oscillations and will be back where it started from—namely, at $x = -X$. (b) When $t = 3.50 T$ the particle will have moved through three full oscillations and an additional half oscillation and so will be at $x = +X$. (c) When $t = 5.25 T$ the particle will have moved through five full oscillations and an additional quarter oscillation and so will be at $x = 0$.

RE 16-3: Equation 16-12 tells us that the period of a mass on a given spring increases as the amount of oscillating mass increases. The fact that the mass of the spring itself oscillates along with the mass on its end suggests that some of the spring’s mass should be included in the mass that appears in Eq. 16-12. Since the spring oscillates with a progressively smaller amplitude as we go from its moving end to its fixed end, only some fraction of the spring’s mass needs to be included in this corrected total oscillating mass.

RE 16-4: Only (a) implies simple harmonic motion. Although (b) is a restoring type of force, it is quadratic, not linear in x . Force (c) is repulsive rather than attractive, driving the particle away from $x = 0$ rather than back toward it. Force (d) is both repulsive and nonlinear.

RE 16-5: The particle’s velocity component is zero at $t = t_2$ and t_4 . The particle is moving to the left at its greatest speed at $t = t_1$ and it is moving to the right at its greatest speed at $t = t_3$. Considering v_x as a mathematical function of t , we can indeed say that v_x is a minimum at t_1 and a maximum at t_3 , but do remember that it is actually moving at its fastest speed when the velocity component is both a minimum and a maximum.

RE 16-6: The vertical component a_x of the acceleration is *increasing* in regions 1 and 2 and it is *decreasing* in regions 3 and 4. Note, however, that the *magnitude* of this acceleration is actually *decreasing* in regions 1 and 3 while the magnitude is *increasing* in regions 2 and 4. Pause and reflect on this!

RE 16-7: In each of these cases, the net force acting on the pendulum mass is proportional to the mass itself. Since Newton’s Second Law tells us that acceleration is net force divided by mass, the mass cancels out here and so acceleration will be independent of the mass in these cases.

RE 16-8: “Same shape and size” for these three pendula means that the rotational inertia of each is simply proportional to its mass

Ans-10 Answers to Reading Exercises and Odd-Numbered Problems

with the same constant of proportionality in each case. “Suspended at the same point” means the same distance from the point of suspension to the center of mass in each case. Since l/m and h are the same for each of the three, Eq. 16-26 tells us that each will have the same period.

RE 16-9: Since $K = 3 \text{ J}$ and $U = 2 \text{ J}$ at a given point, then the total mechanical energy of this system is $E = K + U = 5 \text{ J}$ at every point in its motion. Conservation of mechanical energy rules! (a) In particular, when the block is at $x = 0$, the system’s potential energy is zero and so its kinetic energy must be 5 J . (b) At $x = -X$, the system’s kinetic energy is zero so then $U = 5 \text{ J}$.

RE 16-10: From Eq. 16-39 the time it takes for the mechanical energy of a damped oscillator to fall to one-fourth (or to any given fraction, for that matter) of its initial value is proportional to m/b . The ratio of m/b for set 2 is $4/6 = 2/3$ that of set 1, and for set 3 it is $1/3$ of that for set 1. Thus set 1 takes the longest time to lose one-fourth of its mechanical energy, followed by set 2, then by set 3. (set 1 > set 2 > set 3)

Chapter 17

RE 17-1: (a) None of these graphs correctly shows the displacement of the rope versus position along the rope at $t = 0 \text{ s}$. Graph (b) is the closest to correct of the four but fails to show the considerable length of undisturbed rope that lies between $x = 0$ and the trailing (left) edge of the pulse at $t = 0 \text{ s}$. (b) Graph (a) correctly shows the displacement of the rope versus time at $x = x_1$ as the pulse passes by.

RE 17-2: Realizing that each of these phase expressions is of the form $(kx - \omega t)$ and that the wavelength $\lambda = 2\pi/k$, we see that wave 1 has the smallest wavelength and thus the largest k so it must correspond to case (c). Wave 2 has the smallest k and so must go with case (a), and wave 3 has the middle value of k and so matches case (b).

RE 17-3: The velocity v_y^{string} describes the up and down (transverse) motion of a particular small segment of the string as the wave passes by that location. Typically the velocity varies rapidly between positive and negative values as the wave goes by. The magnitude of the maximum of this velocity increases with increasing amplitude of passing wave having the same wavelength and frequency. The other velocity, v_x^{wave} tells us how fast and in what direction any given crest of the wave itself moves along the rope. For a uniform rope its time does not

vary at all and it does not depend on the amplitude of the wave. In the derivation in this section, v_x^{wave} is used to obtain the mass of the segment of string under study and v_y^{string} is used to obtain the momentum change of the segment.

RE 17-4: If you increase the frequency of the oscillations driving waves in a string, holding the tension constant, then (a) the speed of the waves remains the same and (b) the wavelength decreases. If you instead increase the tension keeping the driving frequency constant, then (c) the wave speed increases and (d) the wavelength also increases.

RE 17-5: (a) Equation (1) represents the interference of a pair of waves traveling in the positive x direction. (b) Equation (3) represents the interference of a pair of waves traveling in the negative x direction. (c) Equation (2) represents the interference of a pair of waves traveling in opposite directions.

RE 17-6: (a) The missing frequency is 75 Hz. (b) The seventh harmonic has a frequency of $7 \times 75 \text{ Hz} = 525 \text{ Hz}$.

Problems

Chapter 18

RE 18-1: We express units in terms of very basic elements of length [L], mass [M] and time [T]. Since B is a force per unit area, its units are $B \sim \frac{[M][L]/[T^2]}{[L^2]} = [M]/[L][T^2]$. ρ is a mass per unit volume so $\rho \sim [M]/[L^3]$. $B/\rho \sim [L^2]/[T^2]$ and $\sqrt{B/\rho} \sim [L]/[T]$ or a “velocity” given by [m]/[s] in SI units.

RE 18-2: The measured wave speed for the round trip is $v^{\text{wave}} = (2)(2.4 \text{ m})/(.0133 - .0002)(\text{s}) = 366 \text{ m/s}$, which is in reasonable agreement with the stated 343 m/s in room-temperature air.

RE 18-3: Since energy per unit time passing through a surface that faces a source of sound is just the product of the sound intensity there and the area of the surface, and since sound intensity falls off with distance from the source, (a) the intensity of the sound is the same at surfaces 1 and 2 and is smaller at surface 3, and (b) the areas of surfaces 1 and 2 are equal while that of surface 3 is larger.

RE 18-4: The second harmonic of the longer pipe B has the same frequency as the first harmonic of the shorter pipe A.

RE 18-5: (a) and (e) have greater detected frequency than emitted frequency. (b) and (f) have reduced detected frequencies. (c) and (d) are indeterminate.

Chapter 19

RE 19-1: Some properties that are measurable include mass, volume, hardness, elasticity, and breaking strength. Flavor and color, for example, are less easily quantified.

RE 19-2: For comfort we often want to maintain the temperature inside our homes significantly higher (in winter) or lower (in summer) than that of the environment outside. Thermal insulation inside the walls of our homes reduces the amount of heat energy that would otherwise flow out of the house in winter or into the house in summer, reducing the expenditure of energy needed to maintain a comfortable interior temperature.

RE 19-3: Equation 19-5 tells us that, for the same amount of heat energy added to the same mass, the temperature increase is inversely proportional to the specific heat of the material being heated. Thus object A has a greater specific heat than object B.

RE 19-4: The good news for the firefighter is that each kilogram of water sprayed on the fire can remove a relatively large amount of heat from the burning object. The bad news is that this heat can easily be transferred to the firefighter's body if the steam condenses on her skin. One gram of steam at 100 °C condensing on one gram of (water-like) flesh at 37 °C will yield two grams of water-like material at a temperature of $(100\text{ °C} + 37\text{ °C})/2 = 69\text{ °C}$.

RE 19-5: For the net work done by the gas on its environment to be positive, the top curve must go from left (lower pressure) to right (higher pressure.) For maximum positive work each cycle that area on the *P-V* diagram enclosed by the cycle must be as large as possible. So curves *c* and *e* yield the maximum possible positive work here.

RE 19-6: (a) The change in the internal energy of the gas is the same in each case. (b) The work done by the gas is greatest for path 4, then path 3, path 2, and finally path 1. (c) The thermal energy added to the gas is also greatest for path 4, then path 3, path 2, and finally path 1.

RE 19-7: (a) For any cyclic process, $Q - W = 0$ or $Q = W$. (b) Because the net work that the gas does on its environment is negative here, that means that the net thermal energy Q transfer to the system is also negative and has the same value as the work. Thus thermal energy equal in magnitude to the work done by the system must be transferred *from the gas to the environment* each cycle.

RE 19-8: (a) Plates 2 and 3 will be tied for the largest increase in their vertical heights, followed by plate 1 and then plate 4. (b) Plate 3 will have the greatest increase in area, followed by plate 2, with plates 1 and 4 tied for last place.

RE 19-9: The hole gets larger as the plate's temperature increases, as would a circle drawn on the plate.

RE 19-10: The pressure at the base of the rod decreases, since the weight of the rod remains constant while the area of the base supporting that weight increases a bit.

RE 19-11: The greater the thermal conductivity, the smaller is the temperature difference between the two faces of samples of the same thickness. Since the temperature differences here, going from left to right, are 10 °C, 5 °C, 15 °C, and 5 °C, slabs b and d tie for greatest thermal conductivity, followed by slab a, with slab c having the smallest thermal conductivity.

Problems

1. (a) 320 °F; (b) -12.3 °F **3.** (a) Dimensions are inverse time. **5.** (a) 523 J/kg·K; (b) 26.2 J/mol·K; (c) 0.600 mole **7.** 42.7 kJ **9.** 1.9 times as great **11.** (a) 33.9 Btu; (b) 172 F° **13.** 160 s **15.** 2.8 days **17.** 742 kJ **19.** 73 kW **21.** 33 g **23.** (a) 0°C; (b) 2.5°C **25.** A: 120 J, B: 75 J, C: 30 J **27.** -30 J **29.** (a) 6.0 cal; (b) -43 cal; (c) 40 cal; (d) 18 cal, 18 cal **31.** 348 K **33.** (a) -40°; (b) 575°; (c) Celsius and Kelvin cannot give the same reading **35.** 960 μm **37.** 2.731 cm **39.** 29 cm³ **41.** 0.26 cm³ **43.** 360°C **47.** 0.68 s/h, fast **49.** 7.5 cm **51.** (a) 0.13 m; (b) 2.3 km **53.** 1660 J/s **55.** (a) 16 J/s; (b) 0.048 g/s **57.** 0.50 min **59.** (a) 17 kW/m²; (b) 18 W/m² **61.** 0.40 cm/h

Chapter 20

RE 20-1: Processes (a), (b), (d), and (e) start and end on the same isotherm because each has $PV = 12$ units.

RE 20-2: (a) The average translational kinetic energy doubles when the temperature in kelvins of the gas doubles. (b) The average translational kinetic energy would be zero if the temperature of the gas were 0 K. However, all real gases condense into liquids before reaching 0 K.

RE 20-3: (a) The average kinetic energy of each of the three types of molecules is the same. (b) Since that is true, the rms speed of each is inversely related to its molecular mass, so type 3 has the greatest rms speed, followed by type 2, with type 1 the smallest.

RE 20-4: Since the internal energy of an ideal gas depends only on its temperature, path 5 has the greatest change in E^{int} , followed by the other four paths, all of which tie for second place.

Problems

1. 0.933 kg **3.** 6560 **5.** (a) 5.47×10^{-8} mol; (b) 3.29×10^{16} **7.** (a) 0.0388 mol; (b) 220°C **9.** (a) 106; (b) 0.892 m³ **11.** $A(T_2 - T_1) - B(T_2^2 - T_1^2)$ **13.** 5600 J **15.** 100 cm³ **17.** 2.0×10^5 Pa **19.** 180 m/s **21.** 9.53×10^6 m/s **23.** 1.9 kPa **25.** 3.3×10^{-20} J **27.** (a) 6.75×10^{-20} J; (b) 10.7 **31.** (a) 6×10^9 km **33.** 15 cm **35.** (a) 3.27×10^{10} ; (b) 172 m **37.** (a) 6.5 km/s; (b) 7.1 km/s **39.** (a) 1.0×10^4 K; (b) 1.6×10^5 K; (c) 440 K, 7000 K; (d) hydrogen, no; oxygen, yes **41.** (a) 7.0 km/s; (b) 2.0×10^{-8} cm; (c) 3.5×10^{10} collisions/s **43.** (a) $\frac{2}{3}v_0$; (b) $N/3$; (c) $122v_0$; (d) $1.31v_0$ **45.** $RT \ln(V_f/V_i)$ **47.** $(n_1C_1 + n_2C_2 + n_3C_3)/(n_1 + n_2 + n_3)$ **49.** (a) 6.6×10^{-26} kg; (b) 40 g/mol **51.** 8000 J **53.** (a) 6980 J; (b) 4990 J; (c) 1990 J; (d) 2990 J **55.** (a) 14 atm; (b) 620 K **59.** 1.40 **61.** (a) In joules, in the order $Q, \Delta E^{\text{int}}, W$: 1 → 2: 3740, 3740, 0; 2 → 3: 0, -1810, 1810; 3 → 1: -3220, -1930, -1290; cycle: 520, 0, 520; (b) $V_2 = 0.0246$ m³, $p_2 = 2.00$ atm, $V_3 = 0.0373$ m³, $p_3 = 1.00$ atm

Chapter 21

RE 21-1: As the putty falls to the floor, gravitational potential energy is converted into translational kinetic energy. When the putty hits the floor it looks at first as if all the mechanical energy is somehow destroyed. But a closer look at the putty after the fall reveals that the putty and the floor beneath it have warmed up a bit. How so? As the putty collides with the floor, the floor does work on the putty. Since the putty doesn't bounce back, the work done on the putty system serves to raise its internal energy. Now the putty's temperature rises and it begins transferring microscopic thermal energy to its surroundings (air and floor) until thermal equilibrium is achieved. Even more careful observations show, in fact, that all of the mechanical energy present in the system before the fall is still there after the putty hits the floor, just in other forms, primarily as thermal energy.

RE 21-2: Driving a nail into a board, letting your hot coffee cool, and saying hello to your friend are all examples of irreversible processes in the sense that if you saw a movie of them running backward you would know something was wrong.

RE 21-3: Process (c) and (b) involve the same amount of heat energy transfer to the water, while (a) adds twice as much heat to the water. Process (a) also happens at the lowest average temperature, so it involves the greatest entropy change of the water, followed by (b) and then (c).

RE 21-4: Equation 21-11 relates the efficiency of a Carnot engine to the two thermodynamic temperatures between which it operates. Applying this to these three cases yields Carnot efficiencies of (a) 0.20, (b) 0.25, and (c) 0.33, so ranking the efficiencies, greatest first, yields (c), then (b), then (a).

RE 21-5: (a) Raising the lower temperature T_L by (δT) increases the numerator of Eq. 21-14 by (δT) and simultaneously decreases the denominator by the same amount. This yields the *greatest increase* in the coefficient of performance of the refrigerator. (b) Lowering the lower temperature T_L by (δT) decreases the numerator of Eq. 21-14 by (δT) and simultaneously decreases the denominator by the same amount. This yields the *greatest decrease* in the coefficient of performance of the refrigerator. (c) Increasing the higher temperature T_H by (δT) makes the denominator bigger by (δT) with no change in the numerator, decreasing the coefficient of performance of the refrigerator, but not as much as in (b). (d) Decreasing the higher temperature T_H by (δT) makes the denominator smaller by (δT) with no change in the numerator, increasing the coefficient of performance of the refrigerator, but not as much as in (a). So, from greatest to least, the changes in the coefficient of performance of the refrigerator are (a), (d), (c), and finally (b).

RE 21-6: If we had, say, 6 molecules, then the number of microstates corresponding to 3 molecules in each half of the box would be $6!/(3!)^2 = 20$. Generalizing Eq. 21-18 to three bins in the box with 2 molecules in each bin would have $6!/(2!)^3 = 90$. In this case a greater number of microstates is associated with dividing the box up into a larger number of equally populated equal subvolumes. This remains true as the number of molecules is increased, so (b) has more microstates than (a).

Problems

1. 14.4 J/K **3.** (a) 9220 J; (b) 23.0 J/K; (c) 0 **5.** (a) 5.79×10^4 J; (b) 173 J/K **7.** (a) 14.6 J/K; (b) 30.2 J/K **9.** (a) 57.0°C; (b) -22.1 J/K; (c) +24.9

(N/2)!]/[(N/3)! (N/3)! (N/3)!]$; (c) 4.2×10^{16}

Chapter 22

RE 22-1: Electric stove, microwave, lights, car starter motor, toothbrush, computer, tape recorder, CD player, FM radio, amplifier, etc.

RE 22-2: (a) Since the two tapes have identical histories, they should have like charges and repel. (b) The observations were consistent with my predictions. The two tapes repelled each other.

RE 22-3: (a) If woodolin was a new type of charge then two wooden rods charged with linen would repel each other. A wooden rod would have to attract *both* the charged amber (or plastic) rod *and* the charged glass rod. (b) According to the text statements, this observation has never been made. It has always been the case that a suspected new type of charge (such as woodolin) always repels either a charged amber rod or a charged glass rod and attracts the other type rod. This makes it the same as one of the existing charges.

RE 22-4: A very simple explanation is that in a solid, all parts are stiff. But since one can melt ice into water and then boil water into a gas (water vapor) the atomic explanation seems quite plausible.

RE 22-5: I would discharge one of the spheres by touching it. Then I would allow the two spheres to touch each other. They should share the charge q equally so each sphere has charge $q/2$. If I repeat the process, then each sphere will have charge $(q/2)/2 = q/4$.

RE 22-6: (a) If the paper bits are uncharged, then there is no mutual attraction or repulsion. (b) "Induction" always causes the neutral object to be *attracted* toward the charged object, independent of the sign of the charge on the charged object. So, no, you can't tell the sign of the charge on the charged object in this way.

RE 22-7: (1) A, B is attractive (unlike charges), (2) A, A is repulsive (like charges), (3) B, B is repulsive (like charges), (4) B, C attract (by induction), (5) C, C nonexistent forces (both neutral), and (6) C, A attract (by induction).

RE 22-8: (a) Scotch tape acts like an insulator since charge doesn't draw away as you handle the tape at its ends. (b) A balloon behaves like an insulator, because when you charge it, it can stick by induction to a wall rather than touch and pull away.

RE 22-9: (a) No, since charges on it are not mobile. (b) If we start with a positively charged glass plate as the bottom plate in Fig. 22-10 and perform all the same steps, the aluminum pie plate will be negatively charged.

RE 22-10: All of these assertions are inconsistent with the experimental results in the text.

RE 22-11: (a) The central proton is attracted toward the electron, so this force is to the left. (b) The central proton is repelled by the other proton, so this force is also to the left. (c) Thus the net force on the central proton is to the left. (d) There are no locations along the line connecting the charges where the force on the former central

proton can be zero. Since the magnitudes of the charges on the proton and electron are the same, the only location where the force magnitudes on the other proton are zero is halfway between the first two, but we know the forces don't cancel there.

Problems

1. -1.32×10^{13} C **3.** 6.3×10^{11} **5.** 122 mA **7.** (a) positron; (b) electron
9. 1.38 m **11.** (a) 4.9×10^{-7} kg; (b) 7.1×10^{-11} C **13.** (a) 0.17 N; (b) -0.046 N **15.** either $-1.00 \mu\text{C}$ and $+3.00 \mu\text{C}$ or $+1.00 \mu\text{C}$ and $-3.00 \mu\text{C}$ **17.** (a) charge $-4q/9$ must be located on the line joining the two positive charges, a distance $L/3$ from charge $+q$. **19.** $q = Q/2$
21. (a) 3.2×10^{-19} C; (b) two **23.** (a) 0; (b) 1.9×10^{-9} N **25.** (a) 6.05 cm; (b) 6.05 cm from central bead **27.** $+13e$ **29.** (a) positive; (b) $+9$
31. 9.0 kN **33.** 1.72a, directly rightward **35.** $-11.1 \mu\text{C}$ **37.** $q = 0.71Q$
39. (b) $1e$, 0.654 rad; $2e$, 0.889 rad; $3e$, 0.988 rad; $4e$, 1.047 rad; $5e$, 1.088 rad **41.** (a) Let $J = qQ/4\pi\epsilon_0 d^2$. For $\alpha < 0$, $F = -J[\alpha^{-2} + (1 + |\alpha|)^{-2}]$; for $0 < \alpha < 1$, $F = J[\alpha^{-2} - (1 - \alpha)^{-2}]$; for $1 < \alpha$, $F = J[\alpha^{-2} + (\alpha - 1)^{-2}]$
43. (a) 5.7×10^{13} C, no; (b) 6.0×10^5 kg **45.** (b) $\pm 2.4 \times 10^{-8}$ C
47. (a) $\frac{L}{2} \left(1 + \frac{1}{4\pi\epsilon_0} \frac{qQ}{Wh^2} \right)$; (b) $\sqrt{3qQ/4\pi\epsilon_0 W}$

Chapter 23

RE 23-1: $F^{\text{elec}} \propto 1/r^2$. Thus at 4 cm, F^{elec} would be $(1/2)^2 = 1/4$ of its value at 2 cm, or 9 mm. At 6 cm, F^{elec} would be $(1/3)^2 = 1/9$ of its value at 2 cm, or 4 mm.

RE 23-2: Since the force on the test object to the sources, $\vec{F}_{s \rightarrow t}$, varies from point to point in space, the test object must be small enough spatially to test the "local" value rather than the average value over too large a volume of space.

RE 23-3: The type of test charge makes no difference! For a negative test charge we would still use Eq. 23-9 to determine the electric field vector. But, the new $(\vec{F}^{\text{elec}})' = -\vec{F}^{\text{elec}}$ and the new negative charge $q'_i = -q_i$. So \vec{E}'_i will equal E'_i (no charge).

RE 23-4: (a) Rightward, (b) leftward, (c) leftward, (d) rightward (p and e have the same charge magnitude and p is farther).

RE 23-5: (a) To the left, (b) to the left in a parabolic path, (c) its speed decreases at first, then increases. It will move in a straight line first rightward, then leftward.

RE 23-6: All four experience the same magnitude torque.

RE 23-7: Near a positive charge, \vec{E} points always away from the charge; near a negative charge, \vec{E} points always toward the charge.

RE 23-8: Just as for the two equidistant point charges in Fig. 23-10, we can "pair up" equal patches of charge equidistant from the point at which we are calculating \vec{E} for all such patches of charge on the sheet, canceling the contributions to \vec{E} parallel to the sheet.

Problems

1. 56 pC **3.** 3.07×10^{21} N/C, radially outward **5.** 50 cm from q_A and 100 cm from q_B **7.** 0 **9.** 1.02×10^5 N/C, upward **11.** (a) 47 N/C; (b) 27 N/C **13.** $4kQ/3d^2$ or $Q/3\pi\epsilon_0 d^2$ **15.** 1.38×10^{-10} N/C, 180° from $+x$ **17.** 6.88×10^{-28} C \cdot m **23.** $q/\pi^2\epsilon_0 r^2$, vertically downward **25.** (a) $-q/L$; (b) $q/4\pi\epsilon_0(L+a)$ **29.** (a) -1.72×10^{-15} C/m; (b) -3.82×10^{-14} C/m²; (c) -9.56×10^{-15} C/m²; (d) -1.43×10^{-12} C/m³ **31.** $E = 2k|Q|(\sin \theta/2)/\theta R^2$ **33.** 217° **35.** 3.51×10^{15} m/s² **37.** 6.6×10^{-15} N **39.** (a) 1.5×10^3 N/C; (b) 2.4×10^{-16} N, up; (c) 1.6×10^{-26} N; (d) 1.5×10^{10} **41.** (a) 1.92×10^{12} m/s²; (b) 1.96×10^5 m/s **43.** (a) 2.7×10^6 m/s; (b) 1000 N/C

- 45.** $27 \mu\text{m}$ **47.** (a) yes; (b) upper plate, 2.73 cm **49.** (a) 27 km/s; (b) 50 μm **51.** 5.2 cm **53.** (a) 0; (b) 8.5×10^{-22} N \cdot m; (c) 0 **55.** $(1/2\pi)\sqrt{pE/I}$ **57.** 1.92×10^{-21} J **59.** (a) 6.4×10^{-18} N; (b) 20 N/C **63.** (a) to the right in the figure; (b) $(2kqQ \cos 60^\circ)/a^2$

Chapter 24

RE 24-1: (a) $\phi = \vec{v} \cdot \Delta\vec{A} = (3 \text{ m/s})(2 \times 10^{-4} \text{ m}^2) \cos 60^\circ = (3 \times 10^{-4} \text{ m}^3/\text{s})$. Whatever fluid that is represented by this vector velocity field is flowing through this surface area dA . (b) $\phi = \vec{E} \cdot \Delta\vec{A} = (3 \text{ N/C})(2 \times 10^{-4} \text{ m}^2) \cos 60^\circ = 3 \times 10^{-4} \text{ N} \cdot \text{m}^2/\text{C}$. Nothing is flowing through the small area. Instead, the flux represents the product of the E -field component normal to the area.

RE 24-2: To find the answers we simply sum the flux through all six faces. We get $\phi_{\text{cube } 1}^{\text{net}} = 0 \text{ N} \cdot \text{m}^2/\text{C}$, $\phi_{\text{cube } 2}^{\text{net}} = +5 \text{ N} \cdot \text{m}^2/\text{C}$, and $\phi_{\text{cube } 3}^{\text{net}} = -3 \text{ N} \cdot \text{m}^2/\text{C}$. (a) Cube 2, (b) cube 3, and (c) cube 1.

RE 24-3: The central charge always acts along the central line. For each noncentral charge (for example, the one to the left) that acts at a point on this central line, there is a conjugate charge (in this example, the one to the right of center) that is exactly the same distance from the point as the original point. The E -field vectors have the same magnitude. The E -components perpendicular to the plane act in the same direction and add vectorially. The parallel components act in opposite directions and cancel.

RE 24-4: Since Gauss' law states that $\phi^{\text{net}} = q^{\text{enc}}/\epsilon_0$ as long as the same charge is enclosed by the new Gaussian surfaces, ϕ^{net} is unchanged.

RE 24-5: Negative charges would be induced on the inside surface of the cavity so that $q^{\text{enc}} = q^{\text{induced}} + q^{\text{center}} = 0$. Thus, the net flux at the cavity's Gaussian surface would be zero.

Problems

1. (a) 0; (b) $-3.92 \text{ N} \cdot \text{m}^2/\text{C}$; (c) 0; (d) 0 for each field **3.** $2.0 \times 10^5 \text{ N} \cdot \text{m}^2/\text{C}$ **5.** (a) $8.23 \text{ N} \cdot \text{m}^2/\text{C}$; (b) $8.23 \text{ N} \cdot \text{m}^2/\text{C}$; (c) 72.8 pC in each case **7.** $3.54 \mu\text{C}$ **9.** 0 through each of the three faces meeting at q , $q/24\epsilon_0$ through each of the other faces **11.** -7.5 nC **15.** -1.04 nC **19.** (a) $E = (q/4\pi\epsilon_0 a^3)r$; (b) $E = q/4\pi\epsilon_0 r^2$; (c) 0; (d) 0; (e) inner, $-q$; outer, 0 **21.** $q/2\pi a^2$ **23.** $6K\epsilon_0 r^3$ **25.** $5.0 \mu\text{C}/\text{m}$ **27.** (a) $E = q/2\pi\epsilon_0 LR$, radially inward; (b) $-q$ on both inner and outer surfaces; (c) $E = q/2\mu\epsilon_0 Lr$, radially outward **29.** (a) 2.3×10^6 N/C, radially out; (b) 4.5×10^5 N/C, radially in **31.** (b) $\rho R^2/2\epsilon_0 r$ **33.** (a) 5.3×10^7 N/C; (b) 60 N/C **35.** $5.0 \text{ nC}/\text{m}^2$ **37.** 0.44 mm **39.** $2.0 \mu\text{C}/\text{m}^2$ **41.** (a) 37 μC ; (b) $4.1 \times 10^6 \text{ N} \cdot \text{m}^2/\text{C}$

Chapter 25

RE 25-1: Question 1: Because charges that are infinitely far apart exert no forces on each other. Question 2: Zero separation between particles would involve infinite attractive or repulsive forces.

RE 25-2: (a) If we assume the E -field does not change as a result of the reconfiguration of the charge then the positive charge displacement is opposite to the direction of the E -field, so the E -field does negative work. (b) It takes external work to move the charge against the field so ΔU increases, and (c) because we are interested in the change of electric potential between points 1 and 2.

RE 25-3: (a) The external force does positive work. (b) The proton moves to a higher potential so $V_2 > V_1$.

RE 25-4: (a) The E -field acts from left to right. (b) Positive external work is done on the electron in paths 1, 2, 3, and 5. Negative work is done on Path 4. (c) $\Delta V_3 > \Delta V_1 = \Delta V_2 = \Delta V_5 > \Delta V_4$.

Ans-14 Answers to Reading Exercises and Odd-Numbered Problems

RE 25-5: Given the charge distribution, we can simply add the contribution to the potential at a point P due to each of the charges, taken separately, using Eq. 25-25. If all we know is $\vec{E}(\vec{r})$ then we must calculate $V(\vec{r})$ using Eq. 25-17.

RE 25-6: V at P is the same for all three of these configurations. The potential at P due to each proton only depends on how far away that proton is from P and not on the direction.

RE 25-7: Using Eq. 25-29 for case (a) $\theta = 0$ and so $\cos\theta = +1$, for case (b) $\theta = 180^\circ$ and $\cos\theta = -1$, and for case (c) $\theta = 90^\circ$ so $\cos\theta = 0$. All other terms remain constant, so ranked from most to least positive, $V_a > V_c > V_b$.

RE 25-8: (a) $E_2 > E_1 = E_3$, (b) Pair 3. (c) It accelerates leftward.

RE 25-9: Since potential energy is a scalar quantity, its superposition involves only scalar addition while the superposition of electric fields requires adding vectors.

RE 25-10: (a) A is wrong since it originates on $-$ and terminates on $+$. B is wrong since it is not perpendicular to the plate near the plate. C is wrong since it has a kink. D is wrong for the same reason as A. E is wrong since it both originates and terminates on a $+$ charge. F is ok. (b) A correct drawing would have curves like A, D, and F but with arrows pointing toward the negatively-charged sphere.

RE 25-11: Because her skin is a conductor and thus an equipotential surface. Charges will redistribute so they have a higher density near the top of her head, which has more curvature than the sides of her head. The strength of the electric field is higher where the charges bunch so the equipotential surfaces are closer together than they were.

Problems

1. (a) 3.0×10^5 C; (b) 3.6×10^6 J **3.** (a) 3.0×10^{10} J; (b) 7.7 km/s; (c) 9.0×10^4 kg **5.** 8.8 mm **7.** (a) 136 MV/m; (b) 8.82 kV/m **9.** (b) because $V = 0$ point is chosen differently; (c) $q/(8\pi\epsilon_0 R)$; (d) potential differences are independent of the choice for the $V = 0$ point

Chapter 26

RE 26-1: Volta probably felt a tingling sensation or perhaps a shock or jolt that would cause him to let go of the terminals.

RE 26-2: "Circuit" means a full round trip around some route. This is just what the electric charge does.

RE 26-3: (a) If the overall circuit had $q^{\text{net}} = 0$ before the switch was closed, it will remain charge neutral after the switch is closed since the circuit is a closed system and charge is neither created nor destroyed, but merely flows around the circuit. (b) Individual wires in the circuit can and do acquire a (small) net positive or negative charge, but this charge must come from other parts of the circuit.

RE 26-4: Electrical current *is* the net transport of charge past a given point in a circuit in a given time. If equal amounts of positive charge moving, say, right, and negative charge moving right go past the same point, there is no net transport of charge past that point, so $i = 0$ A.

RE 26-5: Let's assume that the unknown current i flows from right to left. Then the net current flowing into (+) or out of ($-$) the *middle* node is $(+2 + 3 + 4 - 1 + 2 - 2 + i)$ A. But currents must all add to zero at this node. Thus $i = -8$ A, meaning our assumption was wrong and that $i = 8$ A flowing from left to right.

RE 26-6: A voltmeter is attached *across* a circuit element because it is designed to measure the potential difference *between* the ends of the circuit. An ammeter is inserted in a branch of a circuit because it is designed to measure the current *through* that part of the circuit. In a series circuit where there are no branches or alternate paths for current to flow, it doesn't matter whether the ammeter is placed before or after a series circuit element.

RE 26-7: Device 1 is ohmic since $(\Delta V/i) = 2.25 \Omega = \text{constant}$ and $i = 0$ A when $\Delta V = 0$ V. Device 2 is nonohmic since $(\Delta V/i) \neq \text{constant}$. Device 3 is nonohmic. Although a plot of ΔV vs. i is a straight line, i is nonzero at $\Delta V = 0$, so i is not proportional to ΔV .

RE 26-8: If the cross-sectional area of the Nichrome wire is cut in half, its resistance will double, so the slope of the i vs. ΔV graph which is $1/R$ will be cut in half.

RE 26-9: (a) $R \propto 1/r^2$ for most wires, suggesting the current flows through the whole cross-sectional area of the wire, not just on its surface as indicated in Eq. 26-8. (b) If the current flowed only in a thin layer near the surface then I'd expect $R \propto 1/r$ since the circumference is $2\pi r$ for a wire with a circular cross section.

RE 26-10: Since $R = \rho L/A$, (a) = (c) $>$ (b).

RE 26-11: (a) = (b) $>$ (d) $>$ (c).

RE 26-12: Only the cross-sectional area A matters in comparing current densities, so (a) = (d) $>$ (b) = (c).

RE 26-13: Since the current density is $(I/A) = (\Delta V/(RA))$ and $RA = \rho L$, we see here that the current density is just inversely proportional to the length of each wire. So (b) = (d) $>$ (a) = (c).

Problems

1. (a) 1200 C; (b) 7.5×10^{21} **3.** 5.6 ms **5.** 100 V **7.** $2.0 \times 10^{-8} \Omega \cdot \text{m}$ **9.** 2.4 Ω **11.** 54 Ω **13.** 3.0 **15.** (a) 0.43%, 0.0017%, 0.0034% **17.** 560 W **19.** (a) 1.0 kW; (b) 25 μ **21.** 0.135 W **23.** (a) 10.9 A; (b) 10.6 Ω ; (c) 4.5 MJ **25.** 660 W **27.** (a) 3.1×10^{11} ; (b) 25 μ A; (c) 1300 W, 25 MW **29.** (a) 17 mV/m; (b) 243 J **31.** (a) 6.4 A/m², north; (b) no, cross-sectional area **33.** 0.38 mm **35.** (a) 2×10^{12} ; (b) 5000; (c) 10 MV **37.** 13 min **39.** $8.2 \times 10^{-4} \Omega \cdot \text{m}$ **41.** (a) 0.67A; (b) toward the negative terminal **43.** (a) 1.73 cm/s; (b) 3.24 pA/m²

Chapter 27

RE 27-1: $R = \rho L/A; A = \pi r^2 = \frac{1}{4} \pi d^2$

$$\rho_{\text{Cu}} = 1.7 \times 10^{-8} \Omega \cdot \text{m}; d = 2.4 \times 10^{-4} \text{ m}; L = 0.30 \text{ m}$$

$$\begin{aligned} \therefore R &= (1.7 \times 10^{-8} \Omega \cdot \text{m})(0.30 \text{ m}) / (\frac{1}{4} \pi (2.4 \times 10^{-4} \text{ m})^2) \\ &= 0.113 \Omega. \end{aligned}$$

RE 27-2: (a) If all the current were “used up” in the first bulb, the second and third bulbs would be dark. (b) If most of the current were “used up” in the first bulb, the second bulb would glow more dimly than the first and the third bulb would glow more dimly than the second. (c) If only a small amount were “used up” in the first bulb, the third would be dimmer than the second, and the second would be a bit dimmer than the first.

RE 27-3: $i_a = i_b = i_c$ and $V_b > V_c > V_a$

RE 27-4: (a) $i_1 = i_2 = i_3$, (b) $\Delta V_1 > \Delta V_2 > \Delta V_3$.

RE 27-5: Since the ammeter is wired *in series* with the resistors, its resistance *adds* to theirs. (a) With no ammeter, the current will be largest. (b) with $R_A \ll R_1 + R_2$ the current will be reduced, but only a little. (c) With $R_A = R_1 + R_2$ the current would be cut in half. Thus a good ammeter should have as *small* a resistance as possible.

RE 27-6: (a) $R_1 = R_2$ in series so $i_1 = i_2$ and $\Delta V_1 = \Delta V_2 = \frac{1}{2} \Delta V_B$ and so $i = i_1 = i_2 = \Delta V_B / (R_1 + R_2)$. (b) $R_1 = R_2$ in parallel so $i_1 = i_2$ and $\Delta V_1 = \Delta V_2 = \Delta V_B$ so now $i = i_1 + i_2 = 2 \Delta V_B / R_1 = 2 \Delta V_B / R_2$

RE 27-7: Note that R_V is in parallel with R_1 . Thus if $R_V \ll R_1$, the effective resistance between d and e in Fig. 27-7 would be dramatically decreased from R_1 to less than R_V . This would “pull down” ΔV_{de} to a smaller value that it had before I installed the voltmeter. However, if $R_V \gg R_1$, then the effective resistance between d and e remains just about R_1 and the value of ΔV_{de} is about what it was without the meter present. Thus $R_V \gg R$ gives more accurate measurements of potential differences.

RE 27-8: Since the bulbs are identical and wired in parallel, $i_1 = i_2 = i_3$. If only one bulb were connected to the battery its brightness would be the same as before, since the potential difference across it is still ΔV_B .

Chapter 28

RE 28-1: The capacitance of a capacitor remains the same, whatever the amount of excess charge on its plates and whatever potential difference is applied across it. Doubling $|q|$ doubles ΔV_c while tripling ΔV_c triples $|q|$.

RE 28-2: Each of these three types of capacitors becomes electrically isolated when removed from a battery so the excess charge on each of the “plates” does not change.

RE 28-3: In these cases ΔV is constant and C and hence $|q|$ must change when spacings change, so $|q|$ (a) decreases, (b) increases, and (c) decreases.

RE 28-4: Each capacitor initially has the same $|q|$ and the same $|\Delta V|$. (a) Wiring them in parallel, positive plate to positive and negative to negative, leaves $|q|$ and $|\Delta V|$ on each unchanged. Wiring them in parallel, positive to negative, makes $|\Delta V| = 0$ and so $|q| = 0$ on each. (b) Wiring them in series leaves these quantities unchanged.

RE 28-5: (a) Since $i_0 = |\Delta V_B|/R$, $(i_0)_1 > (i_0)_2 > (i_0)_3 > (i_0)_4$. (b) Since $t_{(1/2)}$ is proportional to $\tau = RC$, $(t_{(1/2)})_4 > (t_{(1/2)})_1 = (t_{(1/2)})_2 > (t_{(1/2)})_3$.

Problems

1. 7.5 pC **3.** 3.0 mC **5.** (a) 140 pF; (b) 17 nC **7.** $5.04 \pi \epsilon_0 R$ **11.** 9090 **13.** 3.16 μF **17.** 43 pF **19.** (a) 50 V; (b) $5.0 \times 10^{-5} \text{ C}$; (c) $1.5 \times 10^{-4} \text{ C}$

21. $q_1 = \frac{C_1 C_2 + C_1 C_3}{C_1 C_2 + C_1 C_3 + C_2 C_3} C_1 \Delta V_0$,
 $q_2 = q_3 = \frac{C_2 C_3}{C_1 C_2 + C_1 C_3 + C_2 C_3} C_1 \Delta V_0$

23. 72 F **25.** 0.27 J **27.** (a) 2.0 J **29.** (a) $2 \Delta V$; (b) $U_i = \epsilon_0 A \Delta V^2 / 2d$, $U_f = 2U_i$; (c) $\epsilon_0 A \Delta V^2 / 2d$ **35.** Pyrex **37.** 81 pF/m **39.** 0.63 m² **43.** (a) 10 kV/m; (b) 5.0 nC; (c) 4.1 nC

45. (a) $C = 4 \pi \epsilon_0 \kappa \left(\frac{ab}{b-a} \right)$; (b) $q = 4 \pi \epsilon_0 \kappa \Delta V \left(\frac{ab}{b-a} \right)$;

Chapter 29

RE 29-1: (a) z axis, (b) $-x$ axis, (c) no direction since $\vec{F} = 0 \text{ N}$.

RE 29-2: (a) The electron, because it’s less massive and “bends” more easily in the presence of a perpendicular force, (b) the electron travels clockwise.

RE 29-3: $\vec{F}_{\text{net}} = \vec{F}_{\text{elec}} + \vec{F}_{\text{mag}}$. The force exerted on the charge by the E -field is the same in all 4 cases and points out of the page. In cases 1 and 3, \vec{B} and \vec{v} are parallel so there is no magnetic force on the charged particle. In cases 2 and 4, \vec{B} and \vec{v} are perpendicular with magnetic forces out of and into the page respectively. (a) In terms of force magnitude $|\vec{F}_{2\text{net}}| > |\vec{F}_{1\text{net}}| = |\vec{F}_{3\text{net}}|$, $|\vec{F}_{4\text{net}}|$ can take on any value from zero to larger than $|\vec{F}_{3\text{net}}|$ and so can not be ranked. (b) A zero net force is only possible for case 4.

RE 29-4: The equation $|\vec{F}_{\text{mag}}| = |i\vec{L} \times \vec{B}|$ is a maximum for a given $|\vec{B}|$ when \vec{B} is perpendicular to both \vec{F}_{mag} and \vec{L} . This is true whenever $\vec{B} = \pm |\vec{B}| \hat{j}$. Trying each direction, the right-hand rule yields \vec{B} pointing along the $-y$ axis.

RE 29-5: (a) $\tau = |\vec{\mu}| |\vec{B}| \sin \phi$ where $\phi = \theta$ for cases 2 and 3 and $\phi = \pi - \theta$ for cases 1 and 4. But $\sin \theta = \sin(\pi - \theta)$ so τ is the same for all 4 cases. (b) $U(\phi) = -\vec{\mu} \cdot \vec{B} = -|\vec{\mu}| |\vec{B}| \cos \phi$. Now for cases 2

Ans-16 Answers to Reading Exercises and Odd-Numbered Problems

and 3, $\phi = \theta < \pi/2$ so $\cos \theta > 0$, and for cases 1 and 4 $\phi = \pi - \theta > \pi/2$ so $\cos \phi = -\cos \theta < 0$, thus $U_1 = U_4 > U_3 = U_2$.

Problems

1. (a) 6.2×10^{-18} N; (b) 9.5×10^8 m/s²; (c) remains equal to 550 m/s **3.** (a) 400 km/s; (b) 835 eV **5.** (a) east; (b) 6.28×10^{14} m/s²; (c) 2.98 mm **7.** 21 μ T **9.** (a) 2.05×10^7 m/s; (b) 467 μ T; (c) 13.1 MHz; (d) 76.3 ns **11.** (a) 0.978 MHz; (b) 96.4 cm **15.** (a) 1.0 MeV; (b) 0.5 MeV **17.** (a) 495 mT; (b) 22.7 mA; (c) 8.17 MJ **19.** (a) 0.36 ns; (b) 0.17 nm; (c) 1.5 mm **21.** (a) 3.4×10^{-4} T, horizontal and to the left as viewed along \vec{v}_1 ; (b) yes, if its velocity is the same as the electron's velocity **23.** 0.27 mT **25.** 680 kV/m **27.** (b) 2.84×10^{-3} **29.** 38.2 cm/s **31.** 28.2N, horizontally west **33.** 467 mA, from left to right **35.** 0.10 T, at 31° from the vertical **37.** 4.3×10^{-3} N·m, negative y **41.** $2\pi aiB \sin \theta$, normal to the plane of the loop (up) **43.** 2.45 A **45.** (a) 12.7 A; (b) 0.0805 N·m **47.** (a) 0.30 J/T; (b) 0.024 N·m **49.** (a) 2.86 A·m²; (b) 1.10 A·m² **51.** (a) $(8.0 \times 10^{-4} \text{ N}\cdot\text{m})(-1.2\hat{i} - 0.90\hat{j} + 1.0\hat{k})$; (b) -6.0×10^{-4} J

Chapter 30

RE 30-1: (a) \vec{B} is to the left at point 1, (b) \vec{B} is up at point 2, (c) \vec{B} is to the right at point 1, (d) \vec{B} is down at point 2.

RE 30-2: (a) If $\vec{B}^{\text{net}} = 0$ at point 1 then the current in the wire is coming out of the page. (b) Since $\vec{B}^{\text{net}} = \vec{B}^{\text{ext}} + \vec{B}^{\text{wire}}$, and since \vec{B}^{wire} at point 2 points straight down and has the same magnitude as \vec{B}^{ext} , \vec{B}^{net} is directed 45 degrees down and toward the right at point 2 and its magnitude is $\sqrt{2} B^{\text{ext}}$.

RE 30-3: $F_b > F_c > F_a$.

RE 30-4: $\oint \vec{B} \cdot d\vec{s} = \mu_0 i^{\text{enc}}$ where i^{enc} is the net current flowing

through the loop. Therefore, $\left| \frac{1}{\mu_0} \oint \vec{B} \cdot d\vec{s} \right| = i$ for case (a)

$$\begin{aligned} &= 0 \text{ for case (b)} \\ &= i \text{ for case (c)} \\ &= 2i \text{ for case (d)}. \end{aligned}$$

(d) > (a) = (c) > (b).

RE 30-5: For $z \gg R$, $|\vec{B}|$ due to any one loop is proportional to $|\vec{\mu}| = iA$. Since all the i 's are equal, $|\vec{B}| \propto A$ for each loop. Taking the directions of the currents into account and calling B_1 the magnetic field magnitude for one small loop, and $B_2 = 4B_1$, the magnetic field magnitude for one large loop, $B_a = 2B_1$; $B_b = 0$; $B_c = 0$; $B_d = 2B_1 + B_2 = 2B_1 + 4B_1$. $\therefore |\vec{B}_d| > |\vec{B}_a| > |\vec{B}_b| = |\vec{B}_c| = 0$.

Problems

1. (a) 3.3 μ T; (b) yes **3.** (a) 16 A; (b) west to east **5.** $\mu_0 qvi/2\pi d$, antiparallel to i ; (b) same magnitude, parallel to i **7.** 2 rad

Chapter 31

RE 31-1: They were trying to relate induction to the presence of a magnetic field rather than to a changing field.

RE 31-2: Since the magnetic field is uniform, the left and right segments are polarized symmetrically as shown in the diagram. There is no favored direction in which current can flow.

RE 31-3: This case is similar to the one shown in Fig. 31-7. However, now the polarization will always be stronger on the right side of the coil than it is on the left side, so the current will flow continuously in a counter clockwise direction.

RE 31-4: Yes, since observations show that the \vec{v} in the magnetic force law ($\vec{F} = q\vec{v} \times \vec{B}$) turns out to be the relative velocity between the object producing the B -field and the charge.

RE 31-5: The magnet is accelerating downward as it falls at $\vec{a} = (-9.8 \text{ m/s}^2)\hat{j}$. By the time its rear end is passing through the area subtended by the loop, it is traveling faster than the front pole was as it passed by, so the rate of change of the B -field is greater at $t = 0.20$ s than it was at $t = 0.10$ s and the amount of induced current is also greater.

RE 31-6: (a) $b > d = e > a = c$. (b) The magnitude $|dB/dt|$ determines that the amount of induced emf is greatest when the slope is greatest.

RE 31-7: (a) into the page to add to the decreasing field, (b) out of the page to subtract from the decreasing field.

RE 31-8: In each semicircular area $|d\Phi^{\text{mag}}/dt|$ is identical. The only issue is the "sense" of the induced emf contributed by each semicircle. Using Lenz's law, loop (a) has a nonzero, clockwise (CW) induced current. Loop (b) has a counterclockwise (CCW) current in both the upper and lower halves, so $|i_a| = |i_b|$. In loop (c), the induced emfs in the upper and lower half circles cancel one another out so $|i_c| = 0$ so $|i_a| = |i_b| > |i_c|$.

RE 31-9: As each loop enters or leaves the region where $B \neq 0$, $|\mathcal{E}| = |d\Phi^{\text{mag}}/dt| \propto (h)(v)$ where h = height of the loop and v is its speed. Since $v = \text{constant}$ for each, $|\mathcal{E}_c| = |\mathcal{E}_d| = 2|\mathcal{E}_a| = 2|\mathcal{E}_b|$.

RE 31-10: (a) Out (given), (b) out since path 3 has $|\mathcal{E}| = 3(\text{mag})$, (c) out since path 3 has $|\mathcal{E}| = 3(\text{mag})$, (e) in, since path 4 has $|\mathcal{E}| = 0$, (d) in since path 2 has $|\mathcal{E}| = 2(\text{mag})$.

RE 31-11: When we pointed a right thumb in the direction of the current our fingers wrapped around the wire in the direction of the magnetic field. This is consistent with the direction of the magnetic field shown in Fig. 31-24.

RE 31-12: The quantity $i^{\text{dis}} = \mathcal{E}_0 d\Phi^{\text{elec}}/dt$ has the units of current. We can use the right hand rule to find the direction of \vec{B} and we can use it to find the magnitude of \vec{B} induced by a capacitor.

RE 31-13: (a) $|\Phi_d| > |\Phi_b| > |\Phi_c| > |\Phi_a|$. Since $\oint \vec{B} \cdot d\vec{A} = 0$ (Eq. 31-49),

$$\Phi^{\text{net}} = \oint_{\text{ends}} \vec{B} \cdot d\vec{A} + \oint_{\text{curve}} \vec{B} \cdot d\vec{A} \text{ so } \Phi_{\text{curve}} = -\oint_{\text{ends}} \vec{B} \cdot d\vec{A}.$$

RE 31-14: They both involve the integration of a field vector over a closed Gaussian surface. Each integral determines a net flux at the closed surface that is proportional to the net electric or magnetic charge enclosed by the surface. The major difference between the electric and magnetic situation is that the net magnetic charge enclosed is always zero (that is, north and south poles always appear together), and the net electric charge enclosed can be positive, negative, or zero.

RE 31-15: A statement of Faraday's law is that a changing magnetic field produces an electric field. The Ampère-Maxwell law states that a changing electric field produces a magnetic field. So there is a mathematical symmetry between the two fields.

Problems

1. 1.5 mV **3.** (a) 31 mV; (b) right to left **5.** (a) $1.1 \times 10^{-3} \Omega$; (b) 1.4 T/s **7.** 30 mA **9.** 2.9 mV **11.** (a) $\mu_0 i R^2 \pi r^2 / 2x^3$; (b) $3\mu_0 i \pi R^2 r^2 v / 2x^4$; (c) in the same direction as the current in the large loop **13.** (b) no **15.** 29.5 mC **17.** (a) 21.7 V; (b) counterclockwise **19.** (b) design it so that $Nab = (5/2\pi) m^2$ **21.** 5.50 kV **23.** 80 μ V, clockwise **25.** (a) 13 μ Wb/m; (b) 17%; (c) 0 **27.** 3.66 μ W **29.** (a) 48.1 mV; (b) 2.67 mA; (c) 0.128 mW **31.** (a) 600 mV, up the page; (b) 1.5 A, clockwise; (c) 0.90 W; (d) 0.18 N; (e) same as (c) **33.** (a) 240 μ V; (b) 0.600 mA; (c) 0.144 μ W; (d) 2.88×10^{-8} N; (e) same as (c) **35.** (a) 71.5 μ V/m; (b) 143 μ V/m **39.** 2.4×10^{13} V/m \cdot s **41.** (a) 1.18×10^{-19} T; (b) 1.06×10^{-19} T **43.** (a) 5.01×10^{-22} T; (b) 4.51×10^{-22} T **45.** 52 nT \cdot m **51.** (a) 0.63 μ T; (b) 2.3×10^{12} V/m \cdot s **53.** (a) 710 mA; (b) 0; (c) 1.1 A **55.** (A) 2.0 A; (b) 2.3×10^{11} V/m \cdot s; (c) 0.50 A; (d) 0.63 μ T \cdot m **57.** (a) 75.4 nT; (b) 67.9 nT **59.** (a) 27.9 nT; (b) 15.1 nT **61.** (b) sign is minus; (c) no, there is compensating positive flux through open end near magnet **63.** 47.4 μ Wb, inward

Chapter 32

RE 32-1: Combine Eqs. 32-1 and 32-2 to get $L = \mu_0 A n^2 l$. (a) If n doubles $L \rightarrow 4L$. (b) If l doubles $A \rightarrow 2A$.

RE 32-2: (d) decreasing rightward or (e) increasing and leftward.

RE 32-3: (a) $R_{\text{eq}} = (N_p/N_s)^2 R$ we want R_{eq} seen by the generator to be smaller. So N_s must be greater than N_p . (b) This would be a step up transformer.

RE 32-4: A refrigerator magnet is ferromagnetic; a standard paper clip is also ferromagnetic, since it is made of steel, a ferromagnetic material; a silver wire is diamagnetic (the book says so).

RE 32-5: (a) Spin down or (2). (b) Since the proton has the opposite sign of charge, spin up or (1).

RE 32-6: A ferromagnetic material must have well more than 50% of its domains aligned with each other to act like a strong magnet. If no one alignment of the domains dominates, then it is not a permanent magnet.

RE 32-7: Hysteresis is a lack of retraceability of a magnetization curve. It occurs because the reorientation of domains are not completely reversible.

RE 32-8: (a) \vec{F}^{mag} is directed *toward* the magnet. (b) The dipole moments are also directed *toward*. (c) The force on sphere 1 is *less*.

RE 32-9: (a) \vec{F}^{mag} is directed *away* from the magnet. (b) The dipole moments are also directed *away*. (c) The force on sphere 1 is *less*.

RE 32-10: The Earth's B -field has a different declination and inclination at different locations at any one time. But, it also varies in time. Currently the geographic poles are moving daily. They can also reverse themselves in time periods on the scale of 1000 years.

Problems

Chapter 33

RE 33-1: Using Eq. 33-6, $a = b > c$. (Note that coil area doesn't matter here.)

RE 33-2: At $t = 0$ s, $U^{\text{elec}} = \max$ and $U^{\text{mag}} = 0$. $T = \text{period} = 1/f$. (a) $|q(t)|$ is a maximum again at $t = T/2$. (b) Δv_C is next the same at $t = T$. (c) U^{elec} is next a maximum at $t = T/2$. (d) i is next a maximum at $t = T/4$.

RE 33-3: The unit for ω is [rad/s]. Since $L = \mathcal{E}_L / (di/dt)$, we get $[H] = [V/(A/s)]$. Since $C = q/\Delta V$ we get $[F] = [Q/V]$. $\omega = 1/\sqrt{LC}$ and the units of $1/\sqrt{LC}$ are $[1/(V \cdot s/A)(Q/V)]^{1/2}$ but $[A] = [Q/s]$ so $[1/s^2]^{1/2}$ or $[1/s]$. This matches the ω unit of [rad/s].

RE 33-4: (a) According to the loop rule, $\Delta v_C + \Delta v_L = 0$. Since $\mathcal{E}_L = \Delta v_L$, $\mathcal{E}_L = -5$ V. (b) $U^{\text{mag}} = U - U^{\text{elec}} = 160 \mu\text{J} - 10 \mu\text{J} = 150 \mu\text{J}$.

RE 33-5: (a) $C > B > A$. (b) 1 & A, 2 & B, 3 & S, 4 & C. (c) A.

RE 33-6: (a) (1) lags, (2) leads, (3) in phase. (b) (3) ($\omega^{\text{dr}} = \omega$ when $X_L = X_C$).

RE 33-7: (a) Increase since the circuit is mainly capacitive; increase C to decrease X_C to be closer to resonance for maximum $\langle P \rangle$. (b) Closer.

Chapter 35

RE 35-1: a

RE 35-2: 0.2d, 1.8d, 2.2d.

RE 35-3: When you look into a flat mirror, you see the portion of light scattering off your face that bounces off the mirror and travels straight back into your eyes. But you assume that the light entering your eyes has traveled in a straight line to reach you, so you see an image of your face behind the mirror. The image of your face is right side up. The light from your hair hits the mirror at a slight angle and then bounces into your eyes from above which is why you see your hair on top. Left and right are a different story. If you are standing face to face with another person and your right ear points toward the east, her left ear will point toward the east. If, instead, you face a flat mirror, the light from your right ear will bounce off the mirror and enter your eyes from the east. Even though your east ear is the east ear of the image, your right ear has become the left ear of the image.

RE 35-4: Ray 1: A ray that is initially parallel to the central axis reflects as if it came originally from the focal point *behind* the mirror. Ray 2: A ray that comes from the object and is traveling toward the

focal point behind the mirror emerges parallel to the central axis. Ray 3: A ray that comes from the object and is traveling toward the center of curvature C of the mirror returns along itself. Ray 4: A ray that comes from the object and reflects from the mirror at its intersection c from the central axis is reflected symmetrically from the central axis.

RE 35-5: (a) Real; (b) inverted; (c) same.

RE 35-6: (a) e; (b) virtual, same.

Chapter 38

RE 38-1: We observe that the second train is moving with respect to our train. The “slight vibration” we feel is evidence that our own train is moving along the tracks, but this does not tell us either the speed or the direction of that motion. Without this information on our own motion, we cannot determine whether or not the second train is at rest with respect to the tracks.

RE 38-2: (a) Our measured value of the speed of light is equal to its value measured by the rider. (b) With respect to our frame, it takes some time for the light to move from one end of the boxcar to the other. During that time the boxcar moves in a direction opposite to that of the light. As a result, we measure the distance between emission and absorption of the light to be smaller than the length of the boxcar. (c) Part (b) shows that the distance between emission and absorption is shorter in our frame than in the frame of the rider on the boxcar. The speed of light is the same for both of us. Therefore, the time between emission and detection is shorter as measured in our frame is shorter than the time measured in the boxcar frame. (You should revisit this analysis after reading Section 38-12 Lorentz Contraction. Will this re-analysis lead to the same conclusion or a different one?)

RE 38-3: These questions concern individual impressions, so there are no objective answers. Here are mine: Halfway through the performance I would experience it as a whole series of events: hard parts, easy parts, mistakes! Those who printed the program probably listed the Minuet Waltz as one event in the concert. Looking back ten years later, I will probably (but not necessarily) remember it as a single event.

RE 38-4: (a) Recall that, in general, distance = velocity*time. We know the velocity (c) and the distance (30 meters) of the returning light pulse. Therefore the time taken for this return is $(30 \text{ m})/(3 \times 10^8 \text{ m/s}) = 10^{-7} \text{ second} = 0.1 \text{ microsecond}$. Therefore the pulse arrived at detector B $0.225 - 0.1 = 0.125 \text{ microsecond}$ after it passed us at detector A. (b) The proton pulse left detector A at $t = 0$ and, according to part (a) arrived at detector B at $t = 0.125 \text{ microseconds}$. Therefore its speed from A to B is $(30 \text{ m})/(0.125 \times 10^{-6} \text{ s}) = 2.4 \times 10^8 \text{ m/sec}$, or $2.4/3 = 0.8$ of the speed of light.

RE 38-5: Decay reduces the remaining number of pions by a factor of two for every 25 meters of distance they travel (at that particular speed, whatever it is). So there will be one-quarter remaining after 50 meters of travel and one-eighth at a distance of 75 meters from the target.

RE 38-6: All the clocks will run at the rate of every other clock. If this were not so, you could use the difference between rates of different clocks to detect which inertial reference frame you are in, contrary to the principle of relativity.

RE 38-7: Rearrange Eq. 38-3 to read $\Delta\tau/\Delta t = \sqrt{1 - v^2/c^2}$. Square both sides of this equation, solve for v^2/c^2 , and substitute the values given in the statement of the exercise, $v^2/c^2 = 1 - \Delta\tau/\Delta t = 1 - 1/1.01 = 0.0099$. Take the square root of both sides to obtain approximately $v/c = 0.1$. This is a rough-and-ready criterion for the speed above which relativistic effects become significant in reasonably accurate experiments.

RE 38-8: The time a light pulse takes to travel one way from Earth’s surface to the moon’s surface is $3.76 \times 10^8 \text{ m}/3.00 \times 10^8 \text{ m/s} = 1.25 \text{ second}$. The two firecrackers, one on each surface explode one second apart in the earth-moon frame. Nothing, not even light can

travel from the first explosion to the second explosion. Therefore one explosion cannot have caused the other one.

RE 38-9: Music has been emitted from the tape player. There are vibrations in the air. This is a fact that must be true in both frames of reference. (For example, it might be arranged to have the noise set off a firecracker, whose explosion must be acknowledged by all.) Air currents and distance permitting, Sam on the ground will be able to hear the music sometime (with what distortions we do not bother to analyze here). When Sam and Susan meet over coffee, they will both verify that some tape has been wound from one spool to the other in the tape recorder.

RE 38-10: Rearrange Eq. 38-17 to read $E/mc^2 = (1 - v^2/c^2)^{-1/2}$. Take the reciprocal of both sides, then square both sides and substitute values for the ratio of energy to rest energy given in the statement of the exercise. The result is $(mc^2/E)^2 = 1/4 = 1 - v^2/c^2$. Rearrange and take a square root to obtain $v = \sqrt{3/4} c = 0.866c$.

RE 38-11: The algebraic equations for this solution are essentially identical to those for the solution to the preceding reading exercise 38-10. Rearrange Eq. 38-28 to read $\Delta x'/\Delta x = (1 - v^2/c^2)^{-1/2}$. Take the reciprocal of both sides, then square both sides and substitute values for the ratio of measured lengths given in the statement of the exercise. The result is $(\Delta x'/\Delta x)^2 = 1/4 = 1 - v^2/c^2$. Rearrange and take a square root to obtain $v = \sqrt{3/4} c = 0.866c$.

RE 38-12: The light flash will move with speed c in our frame; this is a basic assumption of special relativity (Section 38-3). Verify this result by substituting the values $u' = c$ and $v^{\text{rel}} = 0.9c$ into Eq. 38-31.

$$u = \frac{c + v^{\text{rel}}}{1 + cv^{\text{rel}}/c^2} = \frac{c + 0.9c}{1 + 0.9c^2/c^2} = \frac{1.9c}{1.9} = c \text{ as we predicted.}$$

RE 38-13: Square both sides of Eq. 38-33 and multiply through by the resulting denominator: $(f/f_0)^2(1 + v^{\text{rel}}/c) = (1 - v^{\text{rel}}/c)$. Solve for v^{rel}

$$v^{\text{rel}} = \frac{1 - (f/f_0)^2}{1 + (f/f_0)^2} c = \frac{1 - 0.81}{1 + 0.81} c = 0.1c.$$

Problems

1. (a) $v/c = 3.16 \times 10^{-18}$ (b) $v/c = 9.26 \times 10^{-8}$ (c) $v/c = 2.87 \times 10^{-6}$ (d) $v/c = 10^{-4}$ **3.** EACH of the identical experiments should give the same result in the uniformly moving train as in the closed freight container. **5.** $v/c = 0.990$ or $v = 2.97 \times 10^8 \text{ m/s}$ **7.** You set your clock to the time $2 \times 10^{-4} \text{ s}$. **9.** $\Delta\tau = 4.7 \times 10^{-8} \text{ s}$ and $\Delta t = 17 \times 10^{-8} \text{ s}$. Therefore $\Delta t/\Delta\tau = 3.6$ **11.** (a) 26.3 y (b) 52.3 y (c) 3.71 y **13.** (a) $v/c = 0.995$ (b) $4.8 \times 10^3 \text{ m}$ (c) 480 m (d) 48 km (e) 9.8×10^4 particles will survive. **15.** (a) $v/c = 0.9999995$ (b) one year (c) It does not matter as long as the acceleration is small. **17.** (1, 2) timelike, yes; (1, 3) spacelike, no; (2,3) lightlike, yes **21.** $3.51 \times 10^{-8} \text{ kg/y}$ or about 35 micrograms/year **23.** $1.4467 \times 10^{-29} \text{ kg}$, or 8.127 MeV **25.** (a) $1.04 \times 10^{10} \text{ J}$ (b) 0.116 mg **27.** (a) $v/c = [N(N+2)]^{1/2}/(N+1)$ (b) $p = [N(N+2)]^{1/2} mc$ **29.** (a) $m[p^2/(2K)] - [K/(2c^2)]$. For slow particle speed this reduces to the first term, which becomes m , as expected. (b) $m/m_e = 206$ **31.** (a) The lowest total energy after the collision (equal to the total energy before the collision) leaves the products at rest. (b) Kinetic energy of each incident proton is equal to the rest energy (the mass) of one proton. (c) This incident kinetic energy is equal to 1 GeV, which is reasonable since in the zero-total-momentum frame all the incident kinetic energy goes into the creation of mass, provided that the products remain at rest. **33.** $v_x = v^{\text{rel}}$ and $v_y = v_y'[1 - (v^{\text{rel}})^2/c^2]^{1/2}$ **35.** (a) $\cos\phi = [\cos\phi' + v^{\text{rel}}/c]/[1 +$

Ans-20 Answers to Reading Exercises and Odd-Numbered Problems

$(v^{\text{rel}}/c) \cos \phi']$ (b) $\cos \phi_o = v^{\text{rel}}/c$ (c) $\phi_o = 8.1^\circ$ **37.** (a) $v = 2.6 \times 10^8$ m/s (b) $L = 50$ m. **39.** (a) Yes, at an appropriate speed, proper time between two timelike events can be made as small as desired. (b) $v = 0.999\,999\,15c$ **41.** velocity with respect to the rocket = $-0.82c$ **43.** Minimum and maximum values occur when daughter particles move along direction of relative motion. $u_+ = 0.990c$ and $u_- = 0.282c$ **45.** $f = 22.9$ MHz **47.** $v^{\text{rel}} = 0.96c$ **49.** (a) She does not age at all. (b) Both earth and Zircon age 100 y. (c) 350 y (d) 1200 y on earth **51.** 31.6 s **55.** (a) 0.511 MeV (b) $M_{\text{sys}} = m + 2m_e$ (c) Mass of the system is $2m_e$ both before and after the collision. **57.** $E_M = (M^2 + m^2)c^2/(2m)$ **61.** Partial answer: Let T be the time lapse between the instant we see the sun explode and the instant we see Venus change color. Then we have time $T/3$ to escape earth after we see Venus change color. This assumes that the alien ship moves faster than the pulse emitted by the sun.

Mathematical Formulas*

Quadratic Formula

$$\text{If } ax^2 + bx + c = 0, \text{ then } x = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a}$$

Binomial Theorem

$$(1 + x)^n = 1 + \frac{nx}{1!} + \frac{n(n-1)x^2}{2!} + \dots \quad (x^2 < 1)$$

Products of Vectors

Let θ be the smaller of the two angles between \vec{a} and \vec{b} . Then

$$\vec{a} \cdot \vec{b} = \vec{b} \cdot \vec{a} = a_x b_x + a_y b_y + a_z b_z = |\vec{a}| |\vec{b}| \cos \theta$$

$$\vec{a} \times \vec{b} = -\vec{b} \times \vec{a} = \begin{vmatrix} \hat{i} & \hat{j} & \hat{k} \\ a_x & a_y & a_z \\ b_x & b_y & b_z \end{vmatrix}$$

$$= \hat{i} \begin{vmatrix} a_y & a_z \\ b_y & b_z \end{vmatrix} - \hat{j} \begin{vmatrix} a_x & a_z \\ b_x & b_z \end{vmatrix} + \hat{k} \begin{vmatrix} a_x & a_y \\ b_x & b_y \end{vmatrix}$$

$$= (a_y b_z - b_y a_z) \hat{i} + (a_z b_x - b_z a_x) \hat{j} + (a_x b_y - b_x a_y) \hat{k}$$

$$|\vec{a} \times \vec{b}| = |\vec{a}| |\vec{b}| \sin \theta$$

Trigonometric Identities

$$\sin \alpha \pm \sin \beta = 2 \sin \frac{1}{2}(\alpha \pm \beta) \cos \frac{1}{2}(\alpha \mp \beta)$$

$$\cos \alpha + \cos \beta = 2 \cos \frac{1}{2}(\alpha + \beta) \cos \frac{1}{2}(\alpha - \beta)$$

Derivatives and Integrals

$$\frac{d}{dx} \sin x = \cos x \quad \int \sin x \, dx = -\cos x$$

$$\frac{d}{dx} \cos x = -\sin x \quad \int \cos x \, dx = \sin x$$

$$\frac{d}{dx} e^x = e^x \quad \int e^x \, dx = e^x$$

$$\int \frac{dx}{\sqrt{x^2 + a^2}} = \ln(x + \sqrt{x^2 + a^2})$$

$$\int \frac{x \, dx}{(x^2 + a^2)^{3/2}} = -\frac{1}{(x^2 + a^2)^{1/2}}$$

$$\int \frac{dx}{(x^2 + a^2)^{3/2}} = \frac{x}{a^2(x^2 + a^2)^{1/2}}$$

Cramer's Rule

Two simultaneous equations in unknowns x and y ,

$$a_1 x + b_1 y = c_1 \quad \text{and} \quad a_2 x + b_2 y = c_2,$$

have the solutions

$$x = \frac{\begin{vmatrix} c_1 & b_1 \\ c_2 & b_2 \end{vmatrix}}{\begin{vmatrix} a_1 & b_1 \\ a_2 & b_2 \end{vmatrix}} = \frac{c_1 b_2 - c_2 b_1}{a_1 b_2 - a_2 b_1}$$

and

$$y = \frac{\begin{vmatrix} a_1 & c_1 \\ a_2 & c_2 \end{vmatrix}}{\begin{vmatrix} a_1 & b_1 \\ a_2 & b_2 \end{vmatrix}} = \frac{a_1 c_2 - a_2 c_1}{a_1 b_2 - a_2 b_1}.$$

* See Appendix E for a more complete list.

The Greek Alphabet

Alpha	A	α	Iota	I	ι	Rho	P	ρ
Beta	B	β	Kappa	K	κ	Sigma	Σ	σ

Some Physical Constants*

Speed of light	c	3.00×10^8 m/s
Gravitational constant	G	6.67×10^{-11} N·m ² /kg ²
Avogadro constant	N_A	6.02×10^{23} mol ⁻¹
Universal gas constant	R	8.31 J/mol·K
Mass-energy relation	c^2	8.99×10^{16} J/kg 931.5 MeV/u
Electric constant (permittivity)	ϵ_0	8.85×10^{-12} C ² /N·m ²
Coulomb constant	$k = 1/4\pi\epsilon_0$	8.99×10^9 N·m ² /C ²
Magnetic constant (permeability)	μ_0	1.26×10^{-6} N/A ²
Planck constant	h	6.63×10^{-34} J·s 4.14×10^{-15} eV·s
Stefan-Boltzmann	σ	5.67×10^{-8} W/m ² ·K ⁴
Boltzmann constant	k_B	1.38×10^{-23} J/K 8.62×10^{-5} eV/K
Elementary charge	e	1.60×10^{-19} C
Electron mass	m_e	9.11×10^{-31} kg
Proton mass	m_p	1.67×10^{-27} kg
Neutron mass	m_n	1.68×10^{-27} kg
Deuteron mass	m_d	3.34×10^{-27} kg
Bohr radius	r_B	5.29×10^{-11} m
Bohr magneton	μ_B	9.27×10^{-24} J/T 5.79×10^{-5} eV/T
Rydberg constant	R	0.01097 nm ⁻¹

* For a more complete list, showing also the best experimental values, see Appendix B.

Some Conversion Factors*

Mass and Density

$$1 \text{ kg} = 1000 \text{ g} = 6.02 \times 10^{26} \text{ u}$$

$$1 \text{ slug} = 14.6 \text{ kg}$$

$$1 \text{ u} = 1.66 \times 10^{-27} \text{ kg}$$

$$1 \text{ kg/m}^3 = 10^{-3} \text{ g/cm}^3$$

Length and Volume

$$1 \text{ m} = 100 \text{ cm} = 39.4 \text{ in.} = 3.28 \text{ ft}$$

$$1 \text{ mi} = 1.61 \text{ km} = 5280 \text{ ft}$$

$$1 \text{ in.} = 2.54 \text{ cm}$$

$$1 \text{ nm} = 10^{-9} \text{ m} = 10 \text{ \AA}$$

$$1 \text{ pm} = 10^{-12} \text{ m} = 1000 \text{ fm}$$

$$1 \text{ light-year} = 9.46 \times 10^{15} \text{ m}$$

$$1 \text{ m}^3 = 1000 \text{ L} = 35.3 \text{ ft}^3 = 264 \text{ gal}$$

Time

$$1 \text{ d} = 86,400 \text{ s}$$

$$1 \text{ y} = 365\frac{1}{4} \text{ d} = 3.16 \times 10^7 \text{ s}$$

Angular Measure

$$1 \text{ rad} = 57.3^\circ = 0.159 \text{ rev}$$

$$\pi \text{ rad} = 180^\circ = \frac{1}{2} \text{ rev}$$

Speed

$$1 \text{ m/s} = 3.28 \text{ ft/s} = 2.24 \text{ mi/h}$$

$$1 \text{ km/h} = 0.621 \text{ mi/h} = 0.278 \text{ m/s}$$

Force and Pressure

$$1 \text{ N} = 10^6 \text{ dyne} = 0.225 \text{ lb}$$

$$1 \text{ lb} = 4.45 \text{ N}$$

$$1 \text{ ton} = 2000 \text{ lb}$$

$$1 \text{ Pa} = 1 \text{ N/m}^2 = 10 \text{ dyne/cm}^2$$

$$= 1.45 \times 10^{-4} \text{ lb/in.}^2$$

$$1 \text{ atm} = 1.01 \times 10^5 \text{ Pa} = 14.7 \text{ lb/in.}^2$$

$$= 76 \text{ cm-Hg}$$

Energy and Power

$$1 \text{ J} = 10^7 \text{ erg} = 0.239 \text{ cal} = 0.738 \text{ ft} \cdot \text{lb}$$

$$1 \text{ kW} \cdot \text{h} = 3.6 \times 10^6 \text{ J}$$

$$1 \text{ cal} = 4.19 \text{ J}$$

$$1 \text{ eV} = 1.60 \times 10^{-19} \text{ J}$$

$$1 \text{ horsepower} = 746 \text{ W} = 550 \text{ ft} \cdot \text{lb/s}$$

Magnetism

$$1 \text{ T} = 1 \text{ Wb/m}^2 = 10^4 \text{ gauss}$$

* See Appendix D for a more complete list.

Some Physical Properties

Air (dry, at 20°C and 1 atm)

Density	1.21 kg/m ³
Specific heat at constant pressure	1010 J/kg · K
Ratio of specific heats	1.40
Speed of sound	343 m/s
Electrical breakdown strength	3×10^6 V/m
Effective molar mass	0.0289 kg/mol

Water

Density	1000 kg/m ³
Speed of sound	1460 m/s
Specific heat at constant pressure	4190 J/kg · K
Heat of fusion (0°C)	333 kJ/kg
Heat of vaporization (100°C)	2260 kJ/kg
Index of refraction ($\lambda = 589$ nm)	1.33
Molar mass	0.0180 kg/mol

Earth

Mass	5.98×10^{24} kg
Mean radius	6.37×10^6 m
Free-fall acceleration at Earth's surface	9.8 m/s ²
Standard atmosphere	1.01×10^5 Pa
Period of satellite at 100 km altitude	86.3 min
Radius of the geosynchronous orbit	42,200 km
Escape speed	11.2 km/s
Magnetic dipole moment	8.0×10^{22} A · m ²
Mean electric field at surface	150 V/m, down

Distance to

Moon	3.82×10^8 m
Sun	1.50×10^{11} m
Nearest star	4.04×10^{16} m
Galactic center	2.2×10^{20} m
Andromeda galaxy	2.1×10^{22} m
Edge of the observable universe	$\sim 10^{26}$ m

SI Prefixes*

Factor	Prefix	Symbol	Factor	Prefix	Symbol
10^{24}	yotta	Y	10^{-1}	deci	d
10^{21}	zetta	Z	10^{-2}	centi	c
10^{18}	exa	E	10^{-3}	milli	m
10^{15}	peta	P	10^{-6}	micro	μ
10^{12}	tera	T	10^{-9}	nano	n
10^9	giga	G	10^{-12}	pico	p
10^6	mega	M	10^{-15}	femto	f
10^3	kilo	k	10^{-18}	atto	a
10^2	hecto	h	10^{-21}	zepto	z
10^1	deka	da	10^{-24}	yocto	y

*In all cases, the first syllable is accented, as in ná-no-mé-ter.
